The Role of Recurrency in Image Segmentation for Noisy and Limited Sample Settings

David Calhas¹, João Marques¹, and Arlindo L. Oliveira¹

¹INESC-ID, Instituto Superior Tecnico

Abstract

The biological brain has inspired multiple advances in machine learning. However, most state-of-the-art models in computer vision do not operate like the human brain, simply because they are not capable of changing or improving their decisions/outputs based on a deeper analysis. The brain is recurrent, while these models are not. It is therefore relevant to explore what would be the impact of adding recurrent mechanisms to existing state-of-the-art architectures and to answer the question of whether recurrency can improve existing architectures. To this end, we build on a feed-forward segmentation model and explore multiple types of recurrency for image segmentation. We explore self-organizing, relational, and memory retrieval types of recurrency that minimize a specific energy function. In our experiments, we tested these models on artificial and medical imaging data, while analyzing the impact of high levels of noise and few-shot learning settings. Our results do not validate our initial hypothesis that recurrent models should perform better in these settings, suggesting that these recurrent architectures, by themselves, are not sufficient to surpass state-of-the-art feed-forward versions and that additional work needs to be done on the topic.

1 Introduction

In semantic segmentation, given an input, the corresponding segmentation mask associates a class to each pixel of the image. The U-Net architecture is widely used in image segmentation [1, 2, 3] and can obtain good predictions in many different settings. Although the U-Net architecture has some similarities to the known structure of the visual cortex [4], it is critically different in that it is unable to use feedback from higher levels to improve its prediction. This is also the case for many state-of-the-art models that do not have a *feedback cycle* in their computational graph [5]. It is believed that the brain can be best described as a dynamical system, containing an internal state that represents its belief about the world [6]. When the stimuli are different from what is expected given its internal state, it processes the input and corrects its expectation [7]. In this work, we study the hypothesis that there is a fundamental limitation on current machine learning models because they are not able to process their decisions and use intermediate decisions to move towards a more correct/certain one. To this end, we apply recurrency to a state-of-the-art segmentation model and explore its application on artificial and medical images. Our contributions are the following:

• we describe how three recurrent types of paradigms used in this work (self-organizing maps, conditional random fields, and modern Hopfield networks, described in section 3) can be added

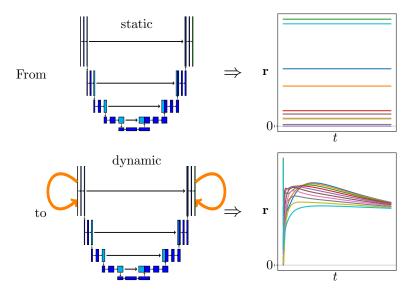

Figure 1: This figure illustrates the fact that a system with feedback connections is able to change its decision with time. For that, at least one cycle is needed in the computational graph.

or appended at any level of the U-Net. Specifically, we use the EfficientUnet++ [8] backbone as the base model, which is based on the U-Net++ architecture, with an EfficientNet [9] backend;

- we propose and make available a new dataset with irregular polygon shapes (see section 4.1.1) and define two experimental settings, the noisy and limited sample size cases, to analyze feed-forward and recurrent models (see sections 4.2 and 4.3);
- using artificially generated data, we show that self-organizing recurrency is the best type of model for noisy settings (see section 5) and recurrency is preferred to feed forward in limited sample size settings (see sections 5 and 6);
- we present experimental results showing that none of the models used has significant success in a real world medical imaging dataset (see sections 4.1.2, 5, and 6).

2 Problem description

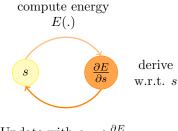

Let $\mathbf{X} = {\mathbf{x}_1, \ldots, \mathbf{x}_N}$ be a set of images (two-dimensional representations) and $\mathbf{Y} = {\mathbf{y}_1, \ldots, \mathbf{y}_N}$ the corresponding set of pixelwise labels, with $\mathbf{x}_i \in \mathbb{R}^{H \times W \times C} \land \mathbf{y}_i \in \mathbb{R}^{H \times W \times L}, \forall i \in {1, \ldots, N}$, where H and W define the dimension of the image, C the number of channels of the original representation (C = 3 for RGB), and L the number of classes. Our goal is to compute the parameters θ of a function f, such that

$$\theta = \operatorname{argmin}_{\theta} \frac{1}{N} \sum_{i}^{N} \mathcal{L}\left(f(\mathbf{x}_{i}; \theta), \mathbf{y}_{i}\right),$$
(1)

where \mathcal{L} is an objective function, e.g. cross-entropy.

3 Recurrent Models

Gradient descent is a form of recurrency, where we updates are performed recurrently as illustrated in figure 2.

Update with $s - \alpha \frac{\partial E}{\partial s}$

Figure 2: An illustration of recurrency, where the dynamics are governed by gradient descent, which implies the minimization of an energy function E w.r.t. a state s.

Consider a state s that evolves in time according to the dynamics

$$\tau \frac{ds}{dt} = -\frac{\partial E}{\partial s(t)},\tag{2}$$

where the evolution is governed by an energy function E that is being minimized. Then we can update a state s with gradient descent as

$$s(t+1) = s(t) - \alpha \frac{\partial E}{\partial s(t)},\tag{3}$$

where α is the learning rate. The goal of this study is to explore multiple forms of energy-based recurrency and bridge its dynamics with human neuronal processing, such as self-organizing maps [10], conditional random fields [11], and Hopfield networks [12].

3.1 Self-organizing map

Originally proposed by Kohonen [10], a self-organizing map is a neural network architecture that learns the topology of a space and is inspired in the way some neuronal cells respond to orientation [13]. A self-organizing map is defined by a set of nodes, $\mathcal{V} \in \mathbb{R}^{M \times M \times L}$, that define a square lattice. The lattice can be rectangular if we define $\mathcal{V} \in \mathbb{R}^{H \times W \times L}$ with $H \neq W$. Each node $\mathbf{v} \in \mathbb{R}^L$ is a feature vector to be optimized according to the algorithm. Given a point \mathbf{x} , we first compute the distance to all nodes and select the closest node, $\mathbf{v}^* = argmin_{\mathbf{v} \in \mathcal{V}} ||\mathbf{x} - \mathbf{v}||_2^2$. The algorithm proceeds to update the closest node as

$$\mathbf{v}^* = \mathbf{v}^* + \alpha \left(\mathbf{x} - \mathbf{v}^* \right),\tag{4}$$

where α is the learning rate. The same update, $\mathbf{v}' = \mathbf{v}' + \alpha (\mathbf{x} - \mathbf{v}')$, is done for any node \mathbf{v}' that is a neighbour of \mathbf{v}^* . For a more compact notation, let $\mathcal{N} : \mathbb{R}^2 \to \mathbb{R}^{5 \times L}$ be the neighbor function

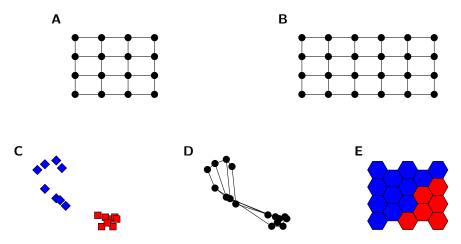

Figure 3: A self-organizing map square lattice.

of a node \mathbf{v} , that given its lattice coordinates i, returns the 4 direct neighbors and \mathbf{v} itself. For the sake of simplicity, we interchange between coordinates giving i and the representation of the node \mathbf{v} as input to \mathcal{N} , such that the neighbors \mathbf{v} are $\mathcal{N}(i) = \mathcal{N}(\mathbf{v})$. Then the update rule for the set of neighbors is

$$\mathcal{N}(\mathbf{v}^*) = \mathcal{N}(\mathbf{v}^*) + \alpha \left(\mathbf{x} - \mathcal{N}(\mathbf{v}^*) \right).$$
(5)

Note that this imposes a competitive dynamic for the nodes when iterating through the points of the space we are learning from. Space regions with more density are going to have more nodes nearby, while regions with less density are going to have fewer nodes. Regions with no density will not have nodes.

Self-organizing map energy. The energy of a map $\mathcal{V} \in \mathbb{R}^{M \times M \times C}$ given a set of instances Y is defined as

$$E^{\text{SOM}} = \frac{1}{M \times M} \sum_{j}^{M \times M} \frac{1}{5} \left(\sum \left(\mathcal{N} \left(\operatorname{argmin}_{\mathbf{v}} \sum (\mathbf{v} - \mathbf{y})^2 \right) - \mathbf{y}_j^{\mathsf{T}} \right)^2 \right), \tag{6}$$

where $\operatorname{argmin}_{\mathbf{v}} \sum (\mathbf{v} - \mathbf{y})^2$ determines \mathbf{y} , the best matching node and $\mathcal{N}(\operatorname{argmin}_{\mathbf{v}} \sum (\mathbf{v} - \mathbf{y})^2) - \mathbf{y}_j^\top$ computes the distance matrix of \mathbf{y} with the best matching node and its neighbors. The division by 5 refers to the normalization of the 5 nodes taken into account.

3.1.1 Self organizing segmentation

In the segmentation task, we can apply a type of self organizing recurrency given the belief segmentation map of an instance. We will introduce a different notation where a representation of node *i* is denoted as \mathbf{v}_i . Consider that the nodes are initialized using $\mathbf{v}_i = f(\mathbf{x}; \theta)_i \in \mathbb{R}^{H \times W \times L}, \forall i \in \{1, \ldots, H \times W\}$, which corresponds to a segmentation belief map. If we run the algorithm on the set of nodes itself, we will be updating the map representation recurrently to reduce energy.

Self-organizing segmentation. The energy of a segmentation belief map is computed from

neighbor nodes as

$$E^{\text{SOM}} = \sum_{i}^{H \times W} \frac{1}{5} \left(\sum \frac{1}{2} \left(\mathcal{N}(i) - \mathcal{N}(i)^{\top} \right)^{2} \right), \tag{7}$$

with $\mathcal{N}(i) - \mathcal{N}(i)^{\top}$ representing the distance matrix of the set of neighbors of node \mathbf{v}_i .

Component-based graph. To help the correct belief propagation through the square lattice, the edges that connect two pixels with a gradient are dropped. Let $F(\mathbf{x}) \in \mathbb{R}^{H \times W}$ be a filter, for instance, the Laplacian operator, Hessian filter [14], or even a neural-based filter. We drop edges from the square lattice (figure 3 A) with a message passing of the form

$$\phi_{i \to j}(\mathbf{x}) = \left(|F(\mathbf{x})_i - \mathcal{N} \left(F(\mathbf{x})_i \right)_j | \le \epsilon \right), \tag{8}$$

where $i \to j$ specifies a message from node *i* to node *j*. If $\phi_{i\to j}(\mathbf{x})$ holds true, then there is an edge connecting node *j* to the respective neighbor node *i*. Do this for all nodes and we should end up with an image with well-defined components around the semantic representations of interest, see figure 4.

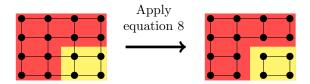

Figure 4: Given a filter, we can produce a grid-like graph with more than one connected component, where each component will have pixels from only one class.

Connected component equilibrium. To propagate the beliefs of each node throughout the lattice, we are going to take advantage of message passing. The update of a node j is influenced by a neighbour i with a message defined as $\phi_{i\to j}(\mathbf{x}) \times (\mathbf{v}_i - \mathbf{v}_j)$, which is the gradient to approximate \mathbf{v}_j to \mathbf{v}_i . The use of $\phi_{i\to j}$ cuts the communication between nodes that belong to different components. This type of propagation cuts off the mixing of different beliefs. The update of a node is given by

$$\mathbf{v}_{j} = \mathbf{v}_{j} + \alpha \left(\frac{1}{\sum_{i \in \mathcal{N}(j)} \phi_{i \to j}(\mathbf{x})} \sum_{i \in \mathcal{N}(j)} \phi_{i \to j}(\mathbf{x}) \times (\mathbf{v}_{i} - \mathbf{v}_{j}) \right), \tag{9}$$

which corresponds to the gradient descent update of node \mathbf{v}_j according to the energy defined in function 7.

Propagate high responses. Although the self-organizing algorithm has a competitive nature, in the segmentation task we want the network to make its prediction based on the neurons that have a high response and propagate sparse beliefs. It has been shown that using sparse activations that respond strongly to stimuli improves the performance of models [15]. To do this, we define the response of a neuron i as $\mathbf{r}_i = \sum \frac{1}{2} (\mathbf{v}_i - \mathbf{v}_i^{\top})^2$. The update rule becomes

$$\mathbf{v}_{j} = \mathbf{v}_{j} + \alpha \left(\sum_{i \in \mathcal{N}(j)} \frac{\exp\left(\mathbf{r}_{i} \times \phi_{i \to j}(\mathbf{x})\right)}{\exp(\mathbf{r}_{j}) + \sum_{k \in \mathcal{N}(j)} \exp\left(\mathbf{r}_{i} \times \phi_{i \to j}(\mathbf{x})\right)} \times (\mathbf{v}_{i} - \mathbf{v}_{j}) \right),$$
(10)

where the main difference from the update of equation 9 is the softmax normalization based on neuron response. This allows a neuron with low response, i.e. low norm, to approximate a neuron from the same component that has a high norm. In addition, a neuron with a high response will not be nudged by neighbors with a lower response because we are adding $\exp(\mathbf{r}_j)$ to the denominator of the softmax. This type of update is particularly interesting because it propagates high responses, such that when an attractor state is reached, neurons from the same component will have equal (likely high) responses.

3.2 Conditional random field for segmentation

This method is parametrized by \mathbf{w} which encodes the compatibility between two labels. We define the energy as

$$E^{\text{CRF}} = -\sum_{i} \sum_{j \neq i} \mathbf{w} \cdot \left(k_G(\mathbf{x}_i, \mathbf{x}_j) \cdot (\mathbf{v}_j^\top \cdot \mathbf{v}_i) \right), \tag{11}$$

where k_G computes a probability mass function that encodes the similarity between the features of pixels *i* and *j* as

$$k_G(\mathbf{a}, \mathbf{b}) = \frac{\exp\left(-(\mathbf{a} - \mathbf{b})^2\right)}{\sum_l \exp\left(-(\mathbf{a}_l - \mathbf{b}_l)^2\right)}.$$
(12)

By deriving this energy w.r.t. \mathbf{v}_i , we get

$$\frac{\partial E^{\text{CRF}}}{\partial \mathbf{v}_i} = -\sum_i \sum_{j \in \mathcal{N}(i)} \mathbf{w} \cdot \left(k_G(\mathbf{x}_i, \mathbf{x}_j) \cdot (\mathbf{v}_j)\right),\tag{13}$$

which results in the following update rule

$$\mathbf{v}_{i} = \mathbf{v}_{i} + \alpha \left(\sum_{j \in \mathcal{N}(i)} \mathbf{w} \cdot \left(k_{G}(\mathbf{x}_{i}, \mathbf{x}_{j}) \cdot (\mathbf{v}_{j}) \right) \right).$$
(14)

3.3 Associative memories

Hopfield [16] first introduced the notion of associative memories. It consists of a network, whose weights connect features. Given a set of memories ξ and a state pattern \mathbf{v} , the dynamical system evolves according to an energy function

$$E = -G(\boldsymbol{\xi} \cdot \mathbf{v}) + \mathbf{v}^{\top} \cdot \mathbf{v}.$$
⁽¹⁵⁾

This type of energy results in the dynamics

$$\tau \frac{d\mathbf{v}}{dt} = \xi^{\top} \cdot g(\xi \cdot \mathbf{v}) - \mathbf{v}, \tag{16}$$

where g = G' is the derivative of function G.

In this section, we treat \mathbf{v}_i as a patch of an image representation, instead of a single voxel (as in the previous sections). According to what was done by Hoover et al. [12], we focus on the associative memory component of their study and use patch representation as $\mathbf{v}_i \in \mathbb{R}^{P \times C}$ (see figure 5). P denotes the dimension of the patch, which is $\ll M$.

3.3.1 Hopfield networks for segmentation

Given a set of learnable memories $\xi \in \mathbb{R}^{I_1 \times I_0}$, where $I_0 = P \times C$, P is the size of a flattened image patch, and I_1 is the size of the memory dimension; we define the energy of Hopfield lattice network as

$$E^{HN} = -\sum_{i}^{I_{1}} log\left(\sum_{j}^{I_{0}} \exp(\xi \cdot \mathbf{v}_{i})\right) + \frac{1}{2} \mathbf{v}_{i}^{\top} \cdot \mathbf{v}_{i}.$$
(17)

In this setting we chose G = LogSumExp function, whose derivative is the softmax function. The update rule for a node *i* is

$$\mathbf{v}_{i} = \mathbf{v}_{i} + \alpha \left(\sum_{j} \xi^{\top} \cdot \operatorname{softmax} \left(\xi \cdot \mathbf{v}_{i} \right) - \mathbf{v}_{i} \right).$$
(18)

In addition to the softmax, one may have more functions to select the *memory* that won for the state **v**. For instance, choosing $G = x^2$ results in representing g = ReLU [17]. The ReLU function has the advantage of suppressing memories when x < 0, but it may result in a collection of too many memories for x > 0. Functions with sparser activations [18] may be a good choice. Typically, researchers work with G = LogSumExp and tweak the temperature parameter. However, one can manipulate the energy landscape to force states to reach fixed point attractors instead of metastable states [19].

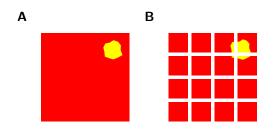

Figure 5: The original image, figure **A**, is split into equal sized patches, figure **A**. These patches are then used as tokens for the memory retrieval process of the modern Hopfield network.

4 Experimental setting

We proceed to describe the experimental setting for the results presented in this manuscript. The parameters used in the learning session were: Adam [20] optimizer with a learning rate set to 1e-2; batch size of 1; 10 epochs. All the results, shown in section 5, are averaged through 5 simulations with different seeds.

4.1 Datasets

In this section, two datasets are described: Shapes and Catheter Artery Segmentation (CAD) [8]. The first is an artificial dataset generated randomly and the second is a medical imaging dataset.

4.1.1 Artificial shapes data

We define a dataset to test the segmentation performance of the models under noisy and limited sample settings. For this, we take into consideration polygons and circles (a circle being a polygon with ∞ sides). Each instance contains two classes: a background and a shape class. Please refer to algorithm 1 for a detailed explanation of this dataset.

Algorithm 1: Artificial data generation algorithm

 $\begin{array}{ll} N \ ; & /* \ \text{Argument for size of dataset } */\\ L \leftarrow \{3,4,5,6,7,8,9,10,11,12,13,\infty\} \ ; & /* \ 15 \ \text{classes in total } */\\ \mathcal{D} = \{\}; & \\ \textbf{while} \ N > 0 \ \textbf{do} & \\ & l \sim \mathcal{U}(L) \ ; & /* \ \text{Chosse a class } */\\ \textbf{x} \leftarrow generate(l) \ ; & /* \ \textbf{function that generates a shape based on a class } */\\ & \textbf{y} \leftarrow one_hot(l); & \\ & \mathcal{D} = \mathcal{D} \cup (\textbf{x}, \textbf{y}); & \\ & N \leftarrow N-1; & \\ \textbf{end} \\ \mathcal{D}; & \end{array}$

4.1.2 Catheter artery segmentation data

This dataset contains X-ray images of arteries and their corresponding masks. This dataset has a total of 515 X-ray coronary angiography scan images, with a 512×512 resolution. Multiple cardiology experts manually labeled the associated segmentation masks. The classes considered for segmentation were: background, vessel, and catheter. Patients gave consent to have their X-ray data recorded and included in this *private dataset*. For this dataset, we perform the same types of data augmentation operations done in Lourenço-Silva et al. [8]: image rotation with a ± 20 degree angle; shifts of 10%; zoom of $\pm 10\%$; and brightness change of $\pm 10\%$.

4.2 Noise corrupted instances

We corrupt instances with Gaussian noise. This process takes the form

$$\tilde{\mathbf{x}} = \mathbf{x} + n : n \sim \mathcal{N}(0, \epsilon), \tag{19}$$

with the new dataset taking the form $\mathcal{D} = \bigcup(\tilde{\mathbf{x}}, \mathbf{y})$, such that only the inputs are corrupted.

The datasets described in section 4.1 have different distributions and, as a consequence, different levels of noise impact the performance differently. To assess the impact of noise, we want to choose a set of noise values where the performance decreases for at least one of the models. With that in mind, we ran preliminary experiments, and the chosen sets are:

- Artificial shapes dataset: $\epsilon \in \{10, 20, 30, 40, 50, 60, 70, 80, 90, 100\};$
- Catheter artery segmentation data: $\epsilon \in \{0, 1, 2, 3, 4, 5, 6, 7, 8, 9, 10\}$.

We include $\epsilon = 0$ in the CAD data experiments because we hypothesize that the complexity is much greater for this dataset. While we have irregular shapes present in the artificial shapes dataset, the nature of the data somehow follows a known distribution, whereas the CAD data is closer to a truly random, but unknown, distribution. The vessels of different individuals do not have the same shape and given the context of a vessel, one is not able to infer the true shape of a given location. We hypothesize memory retrieval recurrency will not have as good a performance as in the artificial shapes data.

4.3 Learning from limited examples

In the limited sample setting, we want to study the impact of the size of \mathcal{D} . For this, we limit the size of the training set and leave the test set size¹ the same.

Consider \mathcal{D} , the training set, defined by

$$\mathcal{D} = \bigcup_{i=1}^{N} \left(\mathbf{x}_{i}, \mathbf{y}_{i} \right), \tag{20}$$

where N is the size, also referred to as $|\mathcal{D}|$. The values for size are $N = \{10, 20, 40, 80, 160, 320\}$, for both datasets. We also test N = 2 for the CAD dataset.

4.4 Loss function and evaluation metrics

We use the same loss Lourenço-Silva et al. [8] used, for both feed-forward and recurrent versions. The loss function is defined by two components: *generalized dice loss* and a *focal loss*. The generalized dice loss is the conjugate of the score version of this metric, defined as

$$GDL = 1 - GDS = 1 - 2 \frac{\sum_{l=1}^{L} w_l \sum_{i=1}^{H \times W} g_{li} p_{li}}{\sum_{l=1}^{L} w_l \left(\sum_{i=1}^{H \times W} g_{li} + p_{li}\right)},$$
(21)

which is translated to the final form of this loss component as

$$\mathcal{L}_G = \frac{GDL}{1 + k(1 - GDL)},\tag{22}$$

where k is set to 0.75. The g_{li} is the ground truth and p_{li} is the probability given to pixel i for class l. Class weights, w_l , are set to

$$w_l = \frac{1}{\left(\sum_{i=1}^{H \times W} g_{li}\right)^2} \tag{23}$$

to address class imbalance. This is particularly useful for medical data, i.e. in the CAD dataset.

The second component is the focal loss that, as the name says, allows the model to focus more on a class that appears with a certain density. Let

$$p'_{li} = \begin{cases} p_{li} & \text{if } g_{li} = 1, \\ 1 - p_{li} & \text{if } g_{li} = 0. \end{cases}$$
(24)

Then the loss takes the form

$$\mathcal{L}_F = -\alpha' (1 - p'_{li})^{\gamma} log(p'_{li}), \qquad (25)$$

where α balances positive and negative samples and α' is derived similarly to p'_{li} , γ forces the model to learn classes that may appear with more or less density. We set the value of $\gamma = 2$ and $\alpha = 0.25$ [8].

¹**Test size**: we set the test size to 200 instances for the artificial shapes data and we consider 20% of the whole CAD dataset as the test set

The loss given to the optimization problem is

$$\mathcal{L} = \mathcal{L}_G + \mathcal{L}_F. \tag{26}$$

To evaluate the quality of the segmentation belief maps we use the intersection over union (IoU). We also look into the precision, the amount of hits for a class i divided by all of the misses it made predicting i when in fact it was another class j, and recall, i is the hits divided by the misses predicting a class j when it was i

$$IoU = \frac{\sum_{i} T_{i}}{\sum_{i} \sum_{j} T_{i} + F_{i|j} + F_{j|i}},$$
(27)

$$\operatorname{precision}_{i} = \frac{T_{i}}{\sum_{j} F_{i|j}},\tag{28}$$

$$\operatorname{recall}_{i} = \frac{T_{i}}{\sum_{j} F_{j|i}}.$$
(29)

5 Results

The results on the artificial dataset experiments are illustrated in figures 6. Regarding the impact of increasing noise, we observe that all models deteriorate their segmentation as the noise level increases. The model that performs best in high-noise settings is the self-organizing recurrency. showing a more stable segmentation quality as the number of iterations increases. Right after, the feed-forward version had the second-best performance, decreasing at the same rate as the SOM. The CRF recurrency seems to begin with a good segmentation, but as the number of iterations increases the segmentation quality decreases. The latter is a quality we do not want to see in recurrent models. This happens at all noise values tested. Though the Hopfield recurrency had the worst performance out of all the baselines studied, it showed an increase as the number of iterations increased. This shows that the initial segmentation belief was flawed, but the memory retrieval mechanism improves the quality and enables the system to reach an equilibrium quickly. In the limited sample setting, the results do not show as much as large a discrepancy as in the noise experiments. The feed-forward and the self-organizing recurrency are the best models in the limited sample test. They appear to have the same performance for all values, with the selforganizing recurrency having a slightly better performance in the smallest sample experiment for $|\mathcal{D}| = 10$ (the most interesting number of samples, since we want to assess which algorithm performs best in small sample dataset). The Hopfield recurrency performed third best overall. It showed the same performance for all the values tested and it decreased its segmentation quality after 20 iterations and stabilized after. The CRF was the worst of all baselines in this setting, with high variability with the number of iterations. Regarding the CRF dynamics, it was similar to the noise experiments, where it increased its segmentation quality after the first 20 iterations, peaking at 40 iterations, and stabilizing at 60 iterations in a worse segmentation quality. Nonetheless, the segmentation quality at 40 iterations is competitive with the other baselines.

In order to better assess, for each setting, which baselines were the best, we ran statistical t-tests (illustrated in figure 7). These tests were performed with the average of the other dimensions. For instance, the statistical tests for the limited sample values, shown in figure 7 C, were done with

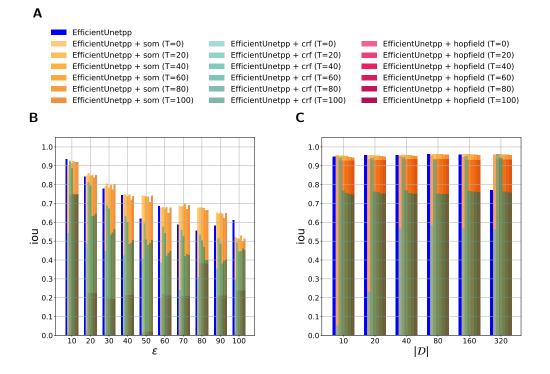

Figure 6: IoU performance, in the **artificial** setting, of the versions studied: EfficientUnetpp, SOM, CRF, and Hopfield. The color scheme is shown in plot \mathbf{A} , which was chosen taking into account how the colors blend. For visual support of this figure, the Hopfield barplot is behind the SOM barplot, which is in turn behind the CRF bars. In \mathbf{B} , the impact of noise is shown. And \mathbf{C} shows the impact of the number of examples.

the iterations, classes, and seed dimensions averaged. We decided to illustrate the superiority of a model with statistical significance with the same color scheme of the bar plot (figure 6), but with the difference that if there is no statistical significance of the best model, i.e. p > 0.05, we represent it with the color black. The color bar has four dimensions, one for each model, and it is illustrated in figure 7 A. We start by assessing which classes had the most impact on the performance of the models (figure 7 B). For instance, it is hard to distinguish a polygon with 40 sides from a circle. Overall there is no statistical significance in the precision, both for the noise and limited sample experiments. Regarding the recall of each class, the self-organizing recurrency had statistical significance for most classes in the noise setting, which is in accordance with previous observations. The Hopfield recurrency had statistical significance in most classes, for the number of examples tests, which shows that the superiority of the feed-forward and self-organizing recurrency in the IoU metric did not translate to the recall metric. When it comes to the number of limited samples (figure 7 C), we observe different phenomena: Hopfield had statistical significance in *precision* for all values, and the self-organizing recurrency had statistical significance in *recall* for all values. This shows the importance of looking from different perspectives/dimensions. Regarding the noise setting (figure 7 D), the self-organizing recurrency had statistical significance in precision for some

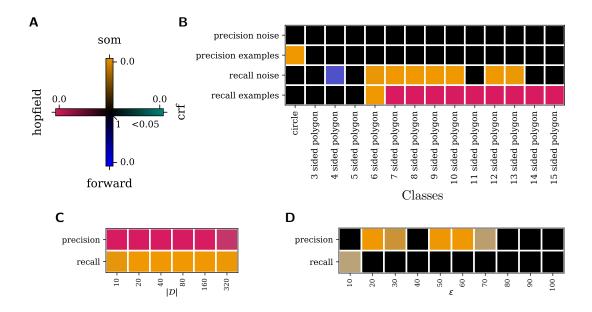

Figure 7: Experiments on artificial shapes data show a clear superiority for both SOM and Hopfield types of recurrency, across the considered metrics. **A** shows the color scheme used in this figure. In total, we compared four models and each is associated to a color. If one model has a better IoU/precision/recall with statistical significance (*p*-value< 0.05), then the respective color is associated to that square in the other figures (**B**, **C**, and **D**). **B** shows the best model that outperformed the others with statistical significance in precision and recall for the *noise* and *number of examples* settings. We do not see any statistical significance in precision, but SOM and Hopfield recurrency show statistical significance in recall.

values, which is in accordance with the bar plots (figure 6 B).

Figure 8 shows the performance of the models in a medical imaging setting (CAD dataset). Though the IoU plots show a reasonable performance for all the models, the precision for each class of interest (*catheter* and *artery*), was low. Regarding the noise setting, it seems that even small amounts of noise decrease the performance very fast. The feed-forward version had the best performance in low-noise settings. On the other hand, recurrency appeared to be better than feed-forward in high-noise settings. As the number of iterations increases, the precision for the *catheter* and *artery* classes deteriorates rapidly for the SOM and CRF models. The Hopfield recurrency showed again stability, meaning that it reached an equilibrium state. However, in low noise values, the Hopfield recurrency had the worst precision. In general, the low precision and high recall phenomena tell us that the models were mostly predicting background. Regarding the size of the training set, there is no clear consensus of the best model in terms of IoU. The feed-forward and self-organizing recurrency are the best models. The CRF and Hopfield recurrency have trouble handling limited sample settings, with the worst performance when $|\mathcal{D}| = 2$. The performance of all models increases of interest, recurrency seems to handle better $|\mathcal{D}| = \{2, 10\}$ settings.

Statistical t-tests, see figure 9, do not have a general consensus on which is the best model for

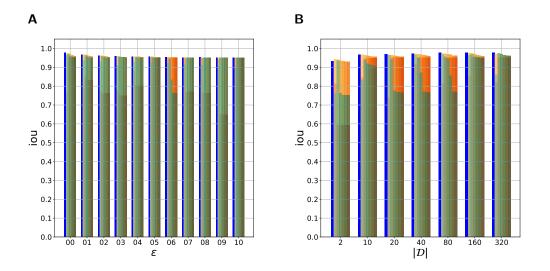

Figure 8: IoU performance, in the CAD dataset. Figure A shows the impact of different values in noise and figure B shows the impact of the training set size.

each class. In terms of noise, the feed-forward version is the best one with statistical significance for the recall metric. For the set size, Hopfield had statistical significance in the precision metric.

6 Discussion

In this study, we compare the feed forward version of the EfficientUnetpp [8] and the same network appended with energy based recurrency, explained in section 3. In general, models that outperformed the others with statistical significance have, in their majority, a type of recurrency (see figure 7).

Self-organizing maps benefit segmentation in noisy settings. Our results show a clear advantage for the self-organizing recurrency in noisy settings (see figures 6 B and 7 D). We hypothesize that this advantage is due to two special characteristics of our SOM implementation: *propagation of certainty* and *component separation using an image filter*. Propagation uncertainty seems to ease the work for the EfficientUnepp, because theoretically the segmentation belief map needs only a small set of pixels with high certainty on the correct class and the self-organization will propagate that certainty to neighbour pixels. The latter promotes sparse belief maps (few pixels with a high norm, according to equation 10). The other trait, separating image components using a filter, ensures that we do high-certainty beliefs do not contaminate sections of the image that belong to a different class. At the cost of under higher noise settings, we may stop beliefs from propagating at all, making the gain of self-organization smaller. Nonetheless, in preliminary experiments, we found this feature necessary for the whole algorithm to be stable and reach energy local minima that are close to the ground truth.

Noise and limited sample settings impact recall. Our results suggest that both noisy and limited sample settings impact the recall of all models. Some more than others. Whilst this is more noticeable in the IoU of the noisy analysis, it is also present when we assess the recall of each

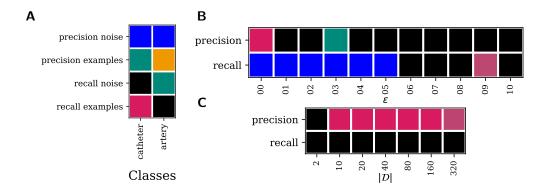

Figure 9: Experiments on CAD data show that all models did not handle well noise nor limited sample size. However, the statistical significance tests show a tendency for recurrent models to outperform the feed-forward version even though the difference was bigger in the artificial setting. Figure **A** reports the statistical significance for the classes, *catheter* and *artery*. Figure **B** reports the same for the values of noise tested. Figure **C** reports the same for different sample sizes.

class for the limited sample settings. Recurrency handles limited sample settings better than feed-forward. Though figure 6 C does not show much difference of IoU between the models compared, when assessing the recall of each class (see figures 7 B and C), we are able to observe an impact on recall. This tells us that models have trouble classifying the correct class in this setting.

Self-organizing maps are good for noise, while Hopfield networks are best suited for limited sample settings. Our results suggest that the feed-forward version of the EfficientUnetpp is not the best for the settings considered. However, there is not a consensus of what is the best type of recurrency. In noisy settings, self-organizing maps are superior. In limited sample settings, Hopfield networks had the best performance. For the noisy settings, we believe that the ability of the SOM recurrency to propagate beliefs that have high certainty benefits the model. While the filter cuts off the propagation of beliefs to parts of the image where those beliefs should not be propagated, the propagation inside each graph component improves the segmentation quality. And since images were corrupted using Gaussian noise, the memory retrieval mechanism deteriorates when the noise is too much. Which is validated by the very poor IoU metric of Hopfield recurrency. But one of the reasons self-organization benefits the EfficientUnetpp in noisy settings is because the feed-forward model was able to learn internal representation so that it outputs a good belief map. When the number of examples is low, self-organization is no longer advantageous. Instead, memory retrieval is more useful in this setting. When the model has stored memories that correspond to specific classes, the memory size compensates for the lack of size of the training set (although the first is built with the second). This explains how suitable the memory retrieval mechanism is for limited sample settings.

Medical imaging data has a high amount of noise. The medical imaging data, CAD data, contains high amounts of noise. It not only has noise in the input image, but it also has some inconsistencies on the masks that were manually labeled. This is natural in these types of datasets, where the amount of samples is limited and the association between input and output is hard to uncover. The performance of all models deteriorates when we add even more noise and for the SOM and CRF cases, as the number of iterations increases, the performance worsens. The

random nature of blood arteries makes the memory retrieval mechanism of the Hopfield network not suitable because in true random phenomena, nothing is the same. In other words, there are no common patterns. This shows that the task is difficult and the recurrency models employed are not suitable for this task. **Models struggle with small frequency classes, such as catheter and artery.** The focal loss, explained in section 4.4, emphasizes errors for classes that appear in a small area of the image. However, both forward and recurrent models struggle to identify these correctly when the noise increases. Specifically, SOM and CRF recurrencies appear to worsen their precision with the number of iterations, meaning that previously correct pixels (correctly labeled by the forward version of the network) change to a different class because of the recurrent process. This suggests that both competitive and relation types of recurrency are not fit for problems that have consistently small frequency classes.

7 Related work

Belief propagation recurrency. One very well-known type of recurrency is belief propagation. This type of model consists on a graph of factors and nodes. Jointly these define a joint probability distribution. This is exactly the formulation of a conditional random field [11]. One can define the model as a graph neural network that performs message passing and whose messages are themselves gradients of an energy function. Some call this technique belief propagation networks [21, 22]. Self-organizing recurrency can be a type of belief propagation recurrency, with the addition of a competitive component. The name of self-organization was introduced by Kohonen [10], but the update rule is also used in particle optimization [23]. Zheng et al. [11] made a breakthrough in image segmentation at the time, by introducing conditional random fields on the output of a neural network. A conditional random field can learn the relations between labels, i.e. how likely is to see this class next to the other one a.k.a. compatibility. This methodology also fits into belief propagation, since we are propagating beliefs based on the general compatibility of those beliefs.

Associative memories. Hopfield networks were introduced by Hopfield [16], at the time referred to as associative memory networks. These have recently attracted attention of researchers, with significative advances made by Krotov and Hopfield [17], Ramsauer et al. [24] and Hoover et al. [12]. Grushin [25] discusses the use of recurrency with internal states. The input is mapped to the hidden state as $W \cdot x$ and the hidden state is also mapped to the input with the same weights $W^{\top} \cdot x$. One can think of W as the memories of the model. The novelty of this study is that it evolves the internal states in time. Krotov and Hopfield [17] proposed an energy function that is capable of a much higher memory capacity than the original version [16], then Demircigil et al. [26] showed that representing the energy function with a LogSumExp has an even larger capacity. These findings later propelled the community to study the connection between the memory retrieval mechanism with attention [27]. Recently, Krotov [28] proposed a theory that uses multiple layers with internal states and each layer send information to the next and the previous one. However, it remains an open question on how we can train this type of model.

Non energy based recurrency. We refer to this type of recurrency as the techniques used in [29]. These networks have a hidden state, **h** and an input, **x**, and typically have the form $W \cdot \mathbf{x} + U \cdot \mathbf{h}$. However, this type of recurrency may not be stable nor reach an equilibrium. Nonetheless, studies have shown that using this recurrency allows us to better understand some human cognitive processes. For instance, Spoerer et al. [5] developed a recurrent neural network, inspired on the fact that the visual cortex contains feedback connections that are activated during the process of object recognition. The results suggest that as you let the system evolve in time (more recurrent/feedback iterations) the higher the accuracy of the neural network. This observation made the authors hypothesize a link between additional iterations and human reaction times. With an additional experiment involving recorded human reaction times to images of the same dataset that the models were trained on, the authors were able to support this hypothesis. Goetschalckx et al. [30] delves further into analyzing the human reaction time using a recurrent neural network. Their model is able to quantify uncertainty on a task where the goal is to detect if two points are in the same object. The model propagates flows from those points to the rest of image. The weights of the recurrent neural network detect when we are at the boundary of an object. Further, it appears that the model is stable due to being optimized with the contractor recurrent back propagation algorithm [31]. Unfortunately, the use of this algorithm remains limited to the community².

There is a general consensus that we need recurrency in models in order to emulate neuronal processes, such as memory retrieval and visual processing. There have been extraordinary findings that suggest recurrency is fundamental in uncertainty quantification and reaction time processes. However, these models do not follow an energy function. In this study, we applied multiple energy-based types of recurrency to assess how they perform in noise and limited sample settings. We plan to release the source code soon in a github repository.

8 Conclusion

Our results did not validate our original hypothesis that recurrent neural networks should outperform feed-forward networks in the settings we studied. Although we found that recurrency improves segmentation in our artificial dataset experiments, this improvement was not observed for the medical imaging data, and adding recurrency actually worsens the initial segmentation computed by the base model. In terms of noise, it seems that self-organizing recurrency is slightly better suited for this setting, while there was no consensus in limited sample settings.

Energy-based recurrency has the advantage of being stable and it is perfect if the energy function is well suited for the task. However, it is not always the case for the latter as designing a good energy function is very difficult. Nonetheless, we hypothesize that incorporating the focal loss in the energy function (such that it is unsupervised) might be advantageous. Another type of recurrency worth exploring is the one used in Spoerer et al. [5] and Goetschalckx et al. [30].

Future work. While self-organizing recurrency performed well in noisy settings, Hopfield networks were more effective with limited samples. However, neither model achieved consistent performance across both conditions. Future work could look at hybrid models that leverage both SOM and Hopfield properties or explore ensemble methods that dynamically apply the best-performing architecture based on data characteristics.
