Summary. Occupational data play a vital role in research, official statistics, and policymaking, yet their collection and accurate classification remain a persistent challenge. This study investigates the effects of occupational question wording on data variability and the performance of automatic coding tools. Through a series of survey experiments conducted and replicated in Germany, we tested two widely-used occupational question formats: one focusing on "job title" (Berufsbezeichnung) and another on "occupational tasks" (berufliche Tätigkeit). Our analysis reveals that automatic coding tools, such as CASCOT and Occu-CoDe, exhibit significant sensitivity to the form and origin of the data. Specifically, these tools performed more efficiently when coding responses to the job title question format compared to the occupational task format. Additionally, we found that including examples of main tasks and duties in the questions led respondents to provide more detailed but less linguistically diverse responses. This reduced diversity may negatively affect the precision of automatic coding. These findings highlight the importance of tailoring automatic coding tools to the specific structure and origin of the data they are applied to. We emphasize the need for further research to optimize question design and coding tools for greater accuracy and applicability in occupational data collection.

1. Introduction

Work is a fundamental aspect of human life and a key driver of the global economy. In 2023, the average employed person in Germany worked 1,343 hours, contributing sig-†Corresponding author. Mailing Address: Social Data Science and AI Lab (SODA), Ludwigstr. 33, 80539 München, Germany Email: olga.kononykhina@lmu.de

nificantly to the country's economic output (OECD, 2023; World Bank, 2023). Despite its centrality, the collection and aggregation of occupational information for use in official statistics, research, and policymaking remains a complex and persistent challenge. While asking someone, "What do you do?" might seem straightforward in everyday conversations, responses such as "I am a teacher" lack the precision needed for statistical analysis. To inform employment trends, occupational health studies, migration patterns, and analyses of social status, occupational data must be collected in a way that ensures both clarity and consistency. Moreover, this information needs to be accurately coded into nationally or internationally recognized classification systems, such as the International Standard Classification of Occupations (ISCO).

In survey methodology, the clarity and specificity of responses to occupational questions are largely determined by the way these questions are phrased. This is especially critical in occupational research, where respondents must translate their familiarity with their jobs into responses that provide sufficient detail for accurate coding. Occupational questions have been a staple of population censuses since the 19th century and remain central to many national and international surveys (Tijdens, 2014). Typically, these questions follow a two-part structure: an initial open-ended question that gathers a summary of the respondent's job, followed by a second question seeking details about the individual's primary tasks or duties. Research has shown that the phrasing of these questions significantly influences the length and specificity of the responses (Martínez et al., 2017), which in turn affects the accuracy and reliability of occupational coding (Conrad et al., 2016).

Traditionally, occupational responses have been manually coded by trained professionals. While this method is accurate, it is labor-intensive, time-consuming, and prone to reliability issues due to human error and variability between coders (Massing et al., 2019). Recent advances have aimed to address these challenges through the development of automatic coding methods (Schierholz and Schonlau, 2021), ranging from basic textmatching algorithms to machine learning techniques, and more recently, large language models. These technologies have shown promise in improving coding efficiency, but they still face difficulties when dealing with noisy, ambiguous, or overly concise responses.

In response, more sophisticated models are being tested, larger datasets are being used for training, and in some cases, respondents are directly involved in the coding process. However, much of the focus remains on technical solutions, often overlooking the fact that the quality of occupational data—whether for input or training—originates from survey questions that are framed in specific ways.

As noted by the US Census, the wording of the occupational questions impacts the quality of answers and can hinder the quality of manual coding (Martínez et al., 2017). It is reasonable to assume that the same influence applies to automatic coding processes. However, the literature on automatic occupational coding has largely neglected the role of question wording and data origin, despite its potential to affect the performance of coding algorithms. Understanding how the framing of occupational questions influences both the richness of the data and its suitability for automatic classification is critical to improving the accuracy of these methods.

This study aims to fill this gap by examining the effect of occupational question framing on automatic coding. Given that question wording can vary widely and may be influenced by cultural or linguistic factors, we conducted an experiment using two question formats commonly employed in German surveys. Specifically, we aim to address the following research questions: Firstly, how does the framing of occupational questions affect the variability and richness of the responses? Secondly, do different question wordings produce information that is equally conducive to automatic coding? Our findings offer practical insights for practitioners and researchers involved in automatic coding, emphasizing the importance of considering the original question formulations when assessing the performance and accuracy of coding algorithms.

2. Background

This section is structured as follows. First, we provide an overview of the historical development and evolution of occupational questions. Next, we review empirical findings that highlight how the framing of these questions affects the quality of responses and their suitability for manual coding. In the third section, we discuss the advancements in, and challenges of, automatic coding techniques. Finally, we identify the research gap,

and present our research questions and hypotheses.

2.1. Occupational Question Framing

The collection and classification of occupational data can be traced back to the late 18th and early 19th centuries, depending on the country (Whitby, 2020). For instance, the early U.S. Census asked a straightforward question: "Profession, occupation, or trade of each person." However, this was supplemented by detailed instructions for enumerators, which expanded significantly over time—from 154 words in 1850 to 3,092 words in 1900 (Ruggles et al., 2024).

Fifty years later, in 1949, the International Conference of Labour Statisticians (ICLS) adopted a resolution that stated: "The basis of any classification of occupations should be the trade, profession, or type of work performed by the individual. Since many of the problems encountered in classifying individuals according to their occupation are due to the vagueness or insufficiency of the information furnished, particular attention should be paid to the formulation of the questions referring to the occupation" (ILO, 1949, p. 91).

Forty years after that, in 1987, the International Labour Organisation (ILO) reiterated the importance of well-designed and tested occupational questions, recommending the use of two questions—one focused on the job title and the other on main duties (ILO, 1987). However, it wasn't until 2012 that the ILO published formal guidelines on how these two occupational questions should be asked, and even then, without accompanying methodological research to support the recommendations (ILO, 2012). In the absence of such guidance, countries have historically adopted varying approaches to occupational question design.

For instance, from the 1950s until 2024, the U.S. Census and the American Community Survey (ACS) asked between one and three occupational questions, with the wording of the first question changing only once in 2018, from "What kind of work was he doing?" to "What was this person's main occupation?" (Ruggles et al., 2024). In contrast, over the same period in Germany, sixteen different question formulations were employed across the Census and Mikrozensus, typically involving one or two questions (see Table 1A in the Appendix) (Forschungsdatenzentrum, a; Zensus 2022, 2022; Zensus 2011, 2011; Volkszählung 1987, 1987; Forschungsdatenzentrum, b).

There is similar diversity in other surveys. Tijdens (2014) systematically compared occupational questions across 33 surveys in the USA and Europe, finding that 25 surveys asked at least one open-ended question, while 14 used two questions. The precise wording of the first question varied widely among the 25 surveys using open questions, although most surveys asked directly for "occupation/job title." In contrast, Schneider et al. (2022) compared the occupational questions in eight major German panel surveys, revealing that seven of them asked about "occupational tasks" rather than job titles, with some providing instructions or examples specifying that job titles should be included in the response. Meanwhile, the Swiss Household Panel (Tillmann et al., 2021), conducted in four languages—French, German, Italian, and English—changed the wording of the occupational question in 2014, but only for German-speaking respondents.

Even within a single survey, occupational questions can differ. The EU Labour Force Survey (LFS), conducted across 34 European countries by national statistical agencies, ultimately codes all responses into the international ISCO classification system, aiming for comparability. However, the framing of the occupational questions differs by country. For example, in 2024, LFS Sweden asked, "Into which occupation would you classify your work? If the respondent has difficulty in answering: What do you call yourself when other people ask what your job is?" In contrast, LFS Luxembourg in 2021 asked, "Which occupational task did you perform during the reporting week? Please state the exact title," while LFS Portugal in 2021 posed the question, "What is your occupation? Please be as comprehensive and detailed as possible and describe the functions or tasks you perform" (GESIS - Leibniz Institute for the Social Sciences, 2024).

In summary, despite nearly 200 years of inclusion in major national data collection initiatives, occupational questions continue to exhibit significant diversity in formulation, both internationally and within individual countries. As early as 1949, the ILO emphasized the need for better-worded questions due to concerns over data quality. Yet current recommendations, while endorsing the use of two questions, leave the precise formulation to the discretion of individual users. In the next section, we examine the

consequences of these varied approaches.

2.2. Question framing and data quality

A study by Velkoff et al. (2014) showed that people generally find it easy to understand a question about their "main occupation or title." However, this formulation poses challenges for individuals with no official title, multiple jobs, or titles that are specific to their industry but do not accurately reflect the nature of their work. Early ISCO developments (ILO, 1949) highlighted common issues where respondents provide non-occupational answers, such as "worker," "employee," or "owner," or exaggerate their job roles (e.g., a "cashier" describing themselves as an "accountant" or a "shop assistant" as a "branch manager").

If these kinds of responses are not captured and clarified during the interview, they reach the coding stage with significant ambiguity. Geis and Hoffmeyer-Zlotnik (2000) estimated that up to 25% of occupational answers could not be coded with maximum precision. Similarly, Ganzeboom (2010) noted that approximately 10% of occupational answers are so vague that coders have to make educated guesses when assigning codes. A more recent study by Massing et al. (2019) found that coders from different agencies agreed on only half of the codes, due to both systematic and random errors.

There have been both theoretical and practical efforts to improve the quality of occupational data. For example, Geis and Hoffmeyer-Zlotnik (2000), a former leader in Germany's occupational classification efforts, argued against starting with the question "Please name your occupation/job title." They reason that job titles often provide little information about the actual tasks being performed, which is essential for successful coding into the international ISCO classification systems. Instead of the common two-question sequence, they recommend asking three questions: first, about the occupational task (the kind of work a person does), second, a follow-up to gather additional details, and only then asking whether the job has a specific title or name. German guidelines published by the Federal Statistical Office (Hoffmeyer-Zlotnik et al., 2024) recommend this three-question sequence. However, it has not been fully adopted in current German surveys, likely due to concerns about increasing respondent burden.

Practical strategies to improve the specificity of occupational answers have included modifying the wording of questions, adjusting the size of response boxes (Martínez et al., 2017), providing examples alongside questions (Massing et al., 2019), and offering additional training to interviewers (Cantor and Esposito, 1992).

Current research offers several insights into how occupational questions can be structured for better quality and successful manual coding. Occupational questions are typically asked as part of an open-ended, two-question sequence. However, according to Kim et al. (2020); Christoph et al. (2020) respondents may not always be aware of which aspects of their jobs are most crucial to mention, and would often answer with a job title (Massing et al., 2019; Tijdens, 2014). Martínez et al. (2017) found that asking "What is [Name's] occupation?" is expected to provide more specific answers than "What kind of work does [Name] do?". While offering guiding examples can encourage respondents to provide more detailed occupational descriptions (Massing et al., 2019; Martínez et al., 2017), several studies (Conrad et al., 2016; Massing et al., 2019; Kim et al., 2020) have shown that this can negatively impact the accuracy of classification. According to Cantor and Esposito (1992), coders find that longer occupational descriptions are more likely to include contradictory information, making manual coding less reliable. However, Martínez et al. (2017) and Massing et al. (2019) argue that the issue is more nuanced, as some respondents provide better answers that are easier to code when offered examples.

2.3. Automatic Coding

While much of the occupational data is still processed manually, automatic solutions have been gaining popularity due to their efficiency. Martínez et al. (2017) demonstrated that trained coders required between 52 and 126 minutes to code 100 occupations, whereas an automatic system can accomplish the same task in a matter of seconds. Manual coders typically rely on both occupational questions—short job descriptions and detailed job duties (and sometimes information about the industry)—to make accurate coding decisions (Martínez et al., 2017). In contrast, many popular automatic solutions attempt to classify occupations based solely on the responses to the first question (Wan and

et al., 2023). When evaluating automatic coding tools, their accuracy is often measured by comparing their output to that of human coders who have processed the same data. However, these comparisons frequently show considerable variability.

For instance, CASCOT, developed by Jones and Elias (2004), is one of the most well-known multi-language text-matching algorithms, relying on job title inputs. When Belloni and et al. (2016) tested CASCOT on a Dutch survey that asked for job titles, 86% of the answers received a code, but only 52% of those codes were confirmed by human coders. In a more recent study, Wan and et al. (2023) evaluated three algorithms (CASCOT, LabourR, AUTONOC) on Chinese occupational data translated into English, again using job title-based questions. CASCOT assigned codes to 97% of the responses, but only 22% were confirmed by manual coders. While direct comparisons are unavailable, these results suggest that the same tool can perform very differently depending on the survey and question design, even when both use variations of the "What is your job title?" question. Similar findings were observed by Schierholz et al. (2018), who tested a predecessor of OccuCoDe (a German-language machine learning tool) across different German surveys. These surveys varied in their first occupational question, with some asking about job titles and others about occupational tasks. The accuracy of automatic predictions varied dramatically between studies, suggesting that question wording may influence performance, though the direction of this effect remains unclear.

Not all algorithms are designed to rely solely on short job title responses. For example, Russ and et al. (2016) developed and tested an ensemble classifier (SOCcer) that incorporated job titles, detailed task descriptions, and industry information in its training data. Their results indicated that more detailed occupational information slightly improved coding accuracy. Specifically, predictions based on job titles alone had an accuracy of 43%, which increased to 45% when job titles, task descriptions, and industry information were included. Similarly, Nan Li and Bie (2023), lacking a suitable benchmark for occupational data, tested their large-language model-based tool (LLM4Jobs) on job posting texts. CASCOT struggled with long inputs in this context, whereas Large Language Model (LLM) based tools performed more effectively.

These findings highlight a potential paradox: while automatic coding seems to benefit from longer and more detailed inputs, such inputs are known to complicate manual coding. Moreover, it remains unclear whether encouraging respondents to provide longer answers—by including detailed examples, for instance—will result in not only longer but also richer information.

2.4. Research Gap, Research Questions, Hypotheses

There are several inconsistencies in the existing literature regarding the collection of occupational data. First, there is significant variation in how occupational information is gathered, with no standardized recommendation on the preferred wording of questions. Research has shown that the phrasing of occupational questions influences the specificity of the responses, which in turn affects the ease of manual coding. Additionally, while longer answers can be elicited by providing examples within the questions, these more detailed responses complicate manual coding.

However, the impact of question wording and data origin on automatic coding remains underexplored. Studies have demonstrated that automatic coding tools often perform very differently depending on the data source, but no direct experimental research has systematically investigated this issue. Furthermore, some automatic tools have shown improved accuracy when provided with more extensive textual input, but it is unclear whether encouraging respondents to provide longer answers will necessarily lead to richer, more codable data for these systems.

Our research addresses these gaps by investigating the following research questions: What is the variance in responses due to different occupational question framings? Do these different framings yield similarly rich information?

To answer these questions, we designed, conducted, and replicated a survey experiment in Germany using two versions of occupational questions commonly found in German surveys. We then tested the responses using two automatic coding tools available for the German language. Based on the collected data, we formulated and tested the following hypotheses:

H1: Both automatic tools (CASCOT and OccuCoDe) will show a higher codability

rate when coding responses to job titles compared to occupational task.

H2: The question about job titles will encourage job titles, leading to less linguistic diversity in the responses. In contrast, the question about occupational tasks will result in a broader range of linguistic expressions, with respondents providing both occupational titles and descriptive terms, thus increasing linguistic diversity.

H3a: Responses to the question about detailed tasks that include a guiding example will be longer than those to a question without an example.

H3b: Responses to the question about detailed tasks with a guiding example will exhibit greater linguistic diversity than those provided without an example.

3. Methodology

This section provides a detailed explanation of our survey experiment and its replication.

3.1. Data

We conducted an online experimental study, managed by Forsa, and simultaneously replicated it in the panel managed by Bilendi. Forsa operates a probability-based panel, recruiting respondents via telephone and subsequently inviting them to participate in specific studies. Bilendi, by contrast, is an entirely opt-in panel. Both companies compensated respondents with digital vouchers for their participation. The Forsa experiment was conducted in Germany between December 7 and 13, 2022. The replication study, conducted by Bilendi, took place over a shorter period, from December 7 to 9, 2022. Both surveys were administered via the Unipark platform, ensuring an identical user experience across both panels.

3.2. Experimental Design

Our split-ballot experiment, along with its replication, consisted of two sequential openended questions, as illustrated in Figure 1 (the original German version is shown in Figure 1A in the Appendix). Respondents were randomly assigned to see one of the two experimental conditions, ensuring a balanced distribution across versions of two questions.

Fig. 1: Overview of the survey experiment and replication study. Experimental design illustrating the split-ballot approach. Respondents were randomly assigned to one of two versions of Question 1 ("Title" or "Task") and, independently, to one of two versions of Question 2 ("Example" or "No Example"). This design tests the effects of each question version separately without examining interactions between the questions.

The first question involved two different versions of the occupational question commonly used in German surveys:

- Question 1"Title": "What is your current job title?" (German: "Welche Berufsbezeichnung hat Ihre gegenwärtige Tätigkeit?"), currently used in the Mikrozensus.
- Question 1"Task": "What is the occupational task that you mainly perform?" (German: "Welche berufliche Tätigkeit üben Sie derzeit hauptsächlich aus?"), currently used in German panel surveys.

Respondents were randomly assigned to one of these two versions. Since both questions were framed in the present tense (inquiring about the current job title or primary occupational activity), respondents who were retired or not employed were given the option to select a separate category: "I am retired" or "I am not working," rather than providing a text response. Approximately 40% of respondents in both surveys selected

12 O. Kononykhina et al. this option.

The follow-up question asked respondents to provide further details about the tasks and duties they performed in their occupation. Half of the respondents were shown a detailed example of a response: "I teach biology to 8th-grade students. Together with my colleague, I plan and prepare the lessons, grade homework, and exams. I give extra tuition to gifted pupils and pupils with learning difficulties. I do the necessary paperwork for the school and inform the parents about the students' progress." The other half received no example. Although the exact wording of the second question varied slightly depending on the phrasing of the first question, in this article we focus solely on the presence or absence of the example and treat these slight differences as insignificant.

3.3. Analysis

This section explains the measures and analytical tools we use to test the hypotheses. All tests are applied separately to the experimental and replication study.

H1. Job Titles/Occupational Tasks Automatic Codability: We use two readily available automatic coding tools for the German language, CASCOT and OccuCoDe, that can code answers into national German (KldB 2010) and international (ISCO-08) classifications. When either algorithm assigns a code to a job title or an occupational task, it produces a confidence score to indicate the level of certainty that a given occupation should receive a specific code. For example, OccuCoDe will assign an answer "surgeon" (Chirurg) to the German classification KldB 2010 code 81434 (Surgeon) with a confidence score of 0.8. The second most likely choice will be the code 81474 (Dentist) with a confidence score of 0.05 etc. CASCOT will assign the same job to the 81434 (Surgeon) with a confidence score of 70. The second most probable job code will be 81332 (Surgical technical assistant) with a confidence score 20, and so on. Both tools aim to offer high-quality suggestions and warn against relying on suggestions that have a low score. In practice, it means that if a person answers "Civil servant" (Beamter), OccuCoDe will suggest that the most likely job category is "Administrative assistant" (Verwaltungshelfer/in) with a confidence score of 0.46, CASCOT will offer "civil servant working at a stud farm" (Beamter/Beamtin Landgestüte) with the score 52. Both sug-

gestions lie below the tools' recommended minimum confidence score levels (0.535 for OccuCoDe (possible range: 0-1) (Simson et al., 2023) and 64 (possible range: 0-100) for CASCOT (Jones and Elias, 2004)). As a result, the job "civil servant" is considered not precise enough for automatic coding and will require a manual coder's effort. We will call occupations that can be confidently coded using automatic tools "easy-to-code"; the remaining jobs will be called "hard-to-code." We do not aim to compare the coding decisions of the two tools. Instead, we are only interested in whether more answers to the job title question (Question 1"Title") fall under the "easy-to-code" category than the ones asking about occupational task (Question 1"Task").

In order to evaluate if the origin of data affects automatic codability, we select the code with the highest confidence score for each answer and calculate two binary variables. Outcome 1 indicates that a given answer's highest confidence score is equal or above 0.535 (OccuCoDe) – easy-to-code; otherwise, 0 – hard-to-code. The second variable is coded as 1 (easy-to-code) when CASCOT gave a score above 64 to a response; otherwise 0. We apply χ^2 test (p= 0.05) to test Null-hypothesis that there is no difference in the rates of easy-to-code answers between "job title" and "occupational task" versions.

H2: Job Title/Occupational Task linguistic diversity To evaluate diversity in lexical structure, we first coded all answers to the job title/occupational task questions using Azure Open AI GPT-4 model. We created six partially overlapping binary categories: nouns, nouns that represent an occupational title (ones that end with -mann, -frau, -er, -erin, -in, -eur, -e, -ist, -wirt), verbs, adjectives, stop words (German stop words like und, ich, der, die, das, etc.), derived nouns (nouns that are derived from verbs and have endings like -ung, -heit, -keit, -nis, -schaft). For example, "Schulleitung" (school leadership/direction) was coded as noun - 1, verb - 0, adjectives - 0, stop words - 0, derived noun - 1. We evaluate the difference in answers using Exact Fisher's test (= 0.05) and tested the sets of Null Hypotheses that there is no difference in usage of different lexical groups between "job title" and "occupational task" versions.

Second, we preprocess the responses by tokenizing, removing stop words, and applying stemming. We then measure linguistic richness using the Type to Token Ratio (TTR), which evaluates the number of unique words relative to the total number of words. The

TTR ranges from 0 to 1, with higher values indicating a greater proportion of unique words (deBoer, 2014; Gavras, 2022). We calculate separate TTR for answers to job titles and professional activities, measure the difference TTRdif = TTRprofessional activity - TTRjob titles, and apply bootstrapping (N=1000) to estimate whether the difference is statistically significant (= 0.05).

In addition, following Martínez et al. (2017); Struminskaya (2015); Meitinger et al. (2021), we compare job title responses with professional activity using the length of answers (in words and characters). We apply a two-sided Mann–Whitney U (MWU) test test to measure the difference in length, as well as Levene's test to measure the variability in answer length.

H3: Detailed tasks that include a guiding example First, we compare the length of answers (in characters and words) to the detailed tasks question with the example and without the example (Martínez et al., 2017; Massing et al., 2019). We apply the one-sided MWU test and Levene's test to measure the difference in answer length variation. Second, we measure linguistic diversity by coding all answers using Azure Open AI with a full manual check of the results into six partially overlapping groups: nouns, nouns that represent an occupational title (nouns that end with -mann, -frau, -er, -erin, -in, -eur, -e, -ist, -wirt), verbs, adjectives, stop words (German stop words like und, ich, der, die, das, etc.), and derived nouns (nouns that are derived from verbs and have endings like -ung, -heit, -keit, -nis, -schaft). Since the answers to the tasks and duties questions are typically longer than one word, we count the number of words of each type and use a χ^2 test (= 0.05) for the H0 that there is no difference in the count of words between versions with example and without example. Third, as we did for Hypothesis 2, we also measured lexical diversity using TTR difference between respondents who answered the question with an example and without one.

4. Results

4.1. Descriptive Statistics

We received 840 responses from the two agencies after excluding everyone who explicitly selected the option "I am retired, or I am not working." As recorded in Table 1, only

one respondent did not answer a question (Hard non-response), and 66 respondents (8%) provided an answer that was classified as a Soft non-response (gibberish, irrelevant answer etc) and also excluded from further analysis. The final number of observations with valid responses is 773. Respondents, on average, used 1.3 (Bilendi) to 1.3 (Forsa) words or from 15 to 16.7 characters to describe their job title (Quesions 1"Title") and from 1.3 (Bilendi) to 1.4 (Forsa) words or from 14.8 to 16.7 characters to answer the question about the occupational task (Question 1"Task").

 Table 1: Descriptive Statistics of Response Patterns for Job Title (Title) and Occupational Task (Task) experimental conditions.

	Forsa		Bile	Bilendi	
Category	Task	Title	Task	Title	
Hard nonresponse (HNR)	1	0	1	0	
Soft nonresponse (SNR)	13	15	23	14	
Valid response	188	146	224	215	
Mean length of the answer (N characters)	16.7	16.7	14.8	15	
Median length of the answer (N characters)	14	16	13	14	
Mean length of the answer (N words)	1.4	1.3	1.3	1.3	
Median length of the answer (N words)	1	1	1	1	

Descriptive statistics in Table 2 provide a summary of answers to the detailed tasks question where an example was provided compared to the question where no example was provided. Answers to the question that included an example are longer: the average answer is between 65 and 104 characters long or between 8 (Bilendi) and 13 (Forsa) words long. Answers to the questions where the example was not provided are between 44 and 57 characters long or between 5 and 7 words long. Respondents to the Bilendi-administered survey provided shorter answers than did respondents to the Forsa-administered one.

Table 2: Descriptive Statistics of Response Patterns for questions with the example and questions with no example.

	Fors	Forsa Bilendi		endi
Category	Example	No Example	Example	No example
Hard nonresponse (HNR)	5	3	5	4
Soft nonresponse (SNR)	2	2	10	15

Continued on next page

Table 2: Descriptive Statistics of Response Patterns for questions with the example and questions with no example. (Continued)

	Forsa		Bilendi	
Valid response	163	159	195	216
Mean length of the answer (N characters)	104	57	65	44
Median length of the answer (N characters)	78	43	47	33
Mean length of the answer (N words)	13	7	8	5
Median length of the answer (N words)	9	5	6	3

4.2. Codability of answers

We tested the codability of answers to the questions about job titles and occupational task using the two automatic occupational coding tools introduced in the Methods section: OccuCoDe and CASCOT. The results show that over 50% of responses are hard-to-code for the automatic tools regardless the question respondents answered. For example, as seen in Table 3, 38% of responses received by Forsa study to the question about occupational task and 47% of answers to the question about job titles were easy-to-code when OccuCoDe was used. The rest are hard-to-code answers and need to be classified manually.

			5	5 1				
		Autom	atic				Required	
Tor	1/Study	Coding	Rate	$\chi^2 ext{-Test}$ for Codable	NT	Effect Size	Sample	\mathbf{Size}
100	n/ Study	Task	Title	Answers ($\alpha = 0.05$)	IN	ϕ	for a	80%
		Task	11010				Power	
Occ	uCoDe-Forsa	38%	47%	χ^2 (1) = 1.99, p = .16	334	0.08	1320	
Occ	uCoDe-Bilendi	38%	45%	χ^2 (1) = 1.52, p = .2	438	0.06	2264	
CAS	SCOT-Forsa	29%	31%	χ^2 (1) = 0.04, p = .85	334	0.01	72882	
CAS	SCOT-Bilendi	32%	34%	χ^2 (1) = 0.16, p = .69	438	0.02	21337	

Table 3: Summary of Automatically Codable Responses and Statistical Tests

Hard-to-code responses included terms such as clerk, employee, self-employed, worker, consultant, and salesperson, among others. These are generic and ambiguous answers for which multiple occupational categories could be equally appropriate, as indicated by their low confidence scores. Both CASCOT and OccuCoDe showed a higher proportion of easy-to-code responses when participants answered the job title question. However, according to a series of chi-square (X^2) tests, there was no statistically significant difference in the proportion of easy-to-code responses between Question 1"Title" and Question

1"Task".

Effect size analysis indicated a negligible effect size across all groups. A subsequent power analysis demonstrated that a sample size of over 2,000 respondents would be required to detect a statistically significant effect using OccuCoDe. For CASCOT, the required sample size is approximately 70,000 respondents. Although the calculated effect size is small, the power analysis suggests that with sufficiently large sample sizes (that is usually required for training ML models), these effects could still be statistically significant and potentially meaningful in improving the accuracy of automatic coding.

4.3. Linguistic diversity of job title/occupational task answers

The evidence from Figure 2 indicates that most of the answers followed the same pattern: irrespective of the formulation of the question asked, almost all respondents answered with a job title. Fisher's Exact Test confirms that there is no statistical difference between the types of words used to answer the first occupational question, whether asking about job title or occupational task. The result is identical to the main experiment and its replication. (*Forsa*_{p-value} = 0.94, *Bilendi*_{p-value} = 0.65).

Fig. 2: Distribution of Word Types in Responses.

The figure shows the percentage of different types of words (e.g., nouns, adjectives) that respondents used in their answers to the Question 1 variations. Blue bars show the percentages for answers to Job Title question (Question 1"Title"), while yellow bars show the percentages for answers to Occupational Task question (Question 1"Task").

Next, we formally tested the linguistic diversity using TTR (type-to-token ratio). The results show that respondents used fewer unique words when answering the question about occupational task than job title $\text{TTR}_{\text{diff}} = -0.1$ for Forsa and $\text{TTR}_{\text{diff}} = -0.03$ for Bilendi. However there is no statistical evidence (bootstrapped results (N = 1000)) that the variety of words used to answer job title question is different from that of occupational task answers Forsa: t = -0.1, bias = 0.05, std.error = 0.05. Bilendi: t = -0.03, bias = 0.01, standard error = 0.04].

Lastly, Figure 3 displays the distribution of the answers' length (in characters) for the two question formulations. The results of the MWU test as well as Levene's test are consistent for experiment and replication and indicate that there is no statistical difference between the length of responses [Bilendi: F value = 0.05, df = 437, Pr[> F] = 0.8, α = 0.05; Forsa: F value = 1.14, df = 332, Pr[> F] = 0.29, α = 0.05.]

Fig. 3: Distribution and characteristics of answers based on length (in characters). The figure shows the length of answers (in characters) for two Question 1 versions: "Job Title" (blue) and "Occupational Task" (orange). Density curves represent the distribution of answer lengths, with boxplots below summarizing the central tendency and spread. Statistical tests (Levene's Test and MWU Test) suggest no evidence of differences in variability/median answer length between the two question versions.

Our results were consistent across both the experiment and its replication, and they partially contradicted the expectations outlined in Hypothesis 2. First, contrary to our expectations, we found that respondents tended to provide job titles regardless of the question wording. Second, we confirmed that the length of responses did not differ significantly between the two question formats. Third, contrary to our hypothesis, the wording of the questions had no measurable impact on the variety of words used in the responses.

4.4. Response Patterns to the detailed tasks Occupational Question: Example vs. No Example

As measured by the one-sided MWU-test in Figure 4, the responses to the question with examples are significantly longer. The variation of length is significantly different for both Forsa and Bilendi respondents [Forsa: F value = 17.1, df = 320, Pr[> F] = 0.00], [Bilendi: F value = 6.3, df = 409, Pr[> F] = 0.01].

Fig. 4: Distribution and characteristics of answers based on length (in characters). The figure shows the length of answers (in characters) for two Question 2 (Detailed job descriptions) versions: "Example" (green) and "No example" (purple). Density curves represent the distribution of answer lengths, with boxplots below summarizing the central tendency and spread. Results from statistical tests (Levene's Test and Mann-Whitney U Test) indicate evidence of differences in variability and/or median answer lengths between the two question versions.

As detailed job descriptions are longer, the pattern of word types also changes (Figure 5). Nouns are still the most frequently used type of word. However, tasks description nouns are no longer occupational titles. Moreover, on average, responses to the question with an example include at least one verb (2 Forsa / 1 Bilendi) and those with no example include 0.7 / 0.8 verbs. A χ^2 test confirms that the frequency of words used to answer

Fig. 5: Comparative Analysis of Word Types in Detailed Job Description (with example and without example).

The figure shows the average number of different types of words (e.g., nouns, adjectives) that respondents used in their answers to the Question 2 (Detailed Job descriptions) variations. Green bars show the average for answers to the question with example (Question 2"Example"), while purle bars show the averages for answers to the question without example (Question 2"No Example")

the question with an example is different from that corresponding to the question with no example (Forsa: $\chi^2(5) = 61.9$, p = .00, $\alpha = 0.05$; Bilendi: $\chi^2(5) = 47.3$, p = .00, $\alpha = 0.05$).

The most frequently mentioned words to the question with and without examples tend to differ (for details see Figure 2A in the Appendix). For instance, the verb "to lead" is used by the respondents who were offered the example but not by the other group. An expression like "I lead/I manage" helps to identify managerial occupations that are not always clear based on the initial answer about the job title. For example, in our data, we found upon manual examination that twelve respondents who gave a non-managerial professional activity/job title answer (kindergarten teacher, bank clerk, geriatric nurse, web developer) but used some form of the word "to lead" to describe management duties. Eight of these had received an example, and four had not. To illustrate it further, a respondent who answered "Geriatric nurse" as their job title further wrote, "I manage a residential area in a retirement home. I coordinate the assignments of my staff, write duty rosters, and liaise with relatives." A web developer wrote "Executive Management." On the other hand, respondents whose occupation was "project management" also used expressions like "I lead/I manage" but did not provide additional information that could help coders distinguish between people who manage tasks and people who staff as their main duties.

Finally, we evaluate the uniqueness of the answers measured by the difference in TTR. The results show that Forsa respondents used relatively less unique words when offered the example (TTR_{Forsa diff} = -0.06]). There was no difference for Bilendi respondents (TTR_{Bilendi diff} = -0.01). However, bootstrapped results show that those differences are not significant even for Forsa: [Forsa: t = -0.06, bias = 0.02, std.error = 0.04; Bilendi: t = -0.01, bias = -0.002, std.error = 0.04]

The results support Hypothesis 3a - responses to the questions with examples were significantly longer; and not support Hypothesis 3b. Overall, responses were highly diverse, with answers that included examples showing a higher frequency of nouns and verbs (e.g., I lead/manage), which may help in identifying managerial positions. However, the TTR analysis revealed that providing an example tends to guide respondents towards using specific words and phrases when describing their detailed tasks. As a result, despite the increased word count, the overall vocabulary diversity remained similar to that of responses without the example.

5. Conclusion

Our research focused on investigating the impact of occupational question wording on variability and automatic codability of answers. In order to test that, we conducted a split-ballot survey experiment and simultaneously replicated it. All our findings hold for both studies and show that question framing should be considered when designing or applying automatic coding tools. First, between 29% and 47% of occupational answers, depending on the question formulation, were confidently coded by the two automatic coding tools we tested. Second, both automatic tools performed better when coding answers to the "job title" than the "occupational task" question. That was especially visible for OccuCoDe, where responses to the job title question had 9% higher codability rate. Our sample was too small to detect an effect statistically, however, power analysis

showed that with the sample sizes common for panel studies the difference could be statistically significant.

Third, contrary to our expectations, we found that irrespective of the question formulation, over 80% of respondents named their job title. Fourth, in line with the findings of Massing et al. (2019); Martínez et al. (2017), the answers to the question with an example proved to be significantly longer. The variation of types of answers between versions also differed, with answers to the question using examples of using more nouns and verbs (for example, I manage, I lead). On the other hand, our TTR analysis showed that examples may steer respondents towards using certain words as overall vocabulary in the answers with examples was not different from the answers without examples.

Our findings have several practical implications. The wording of the occupational question impacts data quality for manual and automatic coding. As noted by Velkoff et al. (2014), asking to name the job title might not be the best option for those with multiple employments or industry-specific jobs, but, according to our findings, the job title is the answer that will be most likely given. Researchers should pay attention to the wording of the occupational question when given the data for training and testing automatic occupational tools. Working with "job title -Berufsbezeichnung" instead of "occupational task -berufliche Tätigkeit" in German context may increase the accuracy of the automatic coding tools without adjustments to the algorithm. The findings might be different for other cultural and linguistic contexts; however, together with Martínez et al. (2017), our study points out that the origin of the data matters. Future studies should examine causal mechanism that trigger difference in responses.

Next, our study showed that working with only short job title types of answers is limiting. Following Christoph et al. (2020) that respondents don't always know what is required of them to answer, we end up with many answers that are hard to code. Our results showed that detailed duties questions gave crucial information about some respondents' managerial duties that could not be foreseen from their initial answers and thus coded correctly. Therefore, researchers in the field of automatic coding could aim not to reach maximum precision with coding job titles but instead to expand allowed input to include detailed task descriptions or industry.

Lastly, our study showed that on the one hand, asking respondents to describe their detailed duties elicits longer and sometimes more detailed answers. Research shows that more input benefits the quality of automatic coding for advanced algorithms (Russ and et al., 2016; Nan Li and Bie, 2023). However, we also found that respondents might follow the answer pattern and provide longer but similar answers using the same pool of words. Thus, researchers should be cautious when training their models on such answers, since more words per answer does not necessarily mean more distinct words that can help to create more accurate models.

6. Acknowledgments

This paper is written with the support of the DFG grant 290773872. We thank Frederic Gerdon for his help in organizing data collection, Wiebke Weber and Regina List for their valuable comments and edits. We used Azure Open AI GPT-4 for R code suggestions and to format Overleaf tables; to translate and classify answers (as detailed in the Analysis Section). Elicit and ResearchRabbit were used to collect relevant papers for the literature review, Grammarly and EditGPT (mode "proofread" and "thesis") for spellcheck and proofreading. No text was automatically generated using AI-based tools, and authors take full responsibility for it.
