ABSTRACT

High-resolution transmission spectroscopy of the warm gas-giant WASP-69b has revealed the presence of H_2O , CO, CH₄, NH₃, and C₂H₂ in its atmosphere. This study investigates the impact of vertical diffusion and photochemistry on its atmospheric composition, with a focus on the detected species plus HCN and $CO₂$, to constrain the atmospheric C/O ratio. We utilize non-equilibrium gas-phase simulations to conduct a parameter study for vertical diffusion strength, local gas temperature, and C/O ratio. Our results indicate that a carbon-rich atmosphere enhances CH₄ and C₂H₂ concentrations, while NH³ undergoes chemical conversion into HCN in carbon-rich, high-temperature environments. Consequently, HCN is abundantly produced in such atmospheres, though its strong spectral features remain undetected in WASP-69b. Photochemical production of HCN and C_2H_2 is highly sensitive to vertical diffusion strength, with weaker diffusion resulting in higher concentrations. Cross-correlation of synthetic spectra with observed data shows that models with $C/O=2$ best match observations, but models with $C/O=0.55$ and 0.9 lead to statistically equivalent fits, leaving the C/O ratio unconstrained. We highlight the importance of accurately modeling NH₃ quenching at pressures greater than 100 bars. Models for WASP-69b capped at 100 bars bias cross-correlation fits towards carbon-rich values. We suggest that if the atmosphere of WASP-69b is indeed carbon-rich with a solar metallicity, future observations should reveal the presence of HCN.

1. INTRODUCTION

The atmospheric composition of exoplanets can offer valuable insights on planet formation processes. Previous studies suggest that atmospheric elemental ratios, such as the carbon-to-oxygen ratio (C/O) , can help identifying the location of gas giant exoplanets' formation and their accretion history within a protoplanetary disk (e.g. [Oberg et al.](#page-18-0) [2011;](#page-18-0) [Helling et al.](#page-17-0) [2014;](#page-17-0) [Oberg & Bergin](#page-18-1) [2016;](#page-18-1) Mollière et al. [2022;](#page-18-2) [Tabone et al.](#page-18-3) [2023\)](#page-18-3). Whether the planetary C/O coincides with that of its host star could depend on the method of planet formation, with two possible scenarios: the "inheritance" scenario, where the planet inherits its chemical makeup from the parent molecular cloud, or the "chemical reset" scenario, where the accreted material is reset to its atomic state due to the ionising irradiation from the protostar [\(Eistrup et al.](#page-17-1) [2016,](#page-17-1) [2018\)](#page-17-2).

Previously, there have been a few observations that indicate super-solar C/O in exoplanet atmospheres (e.g. [Mad](#page-18-4)[husudhan et al.](#page-18-4) [2011;](#page-18-4) [Oppenheimer et al.](#page-18-5) [2013;](#page-18-5) [Tsiaras et al.](#page-18-6) [2016\)](#page-18-6). One example is WASP-69b, a transiting warm-giant exoplanet with an equilibrium temperature of T_{eq} ∼ 950K[\(Anderson et al.](#page-16-0) [2014;](#page-16-0) [Bonomo et al.](#page-17-3) [2017\)](#page-17-3). In their study, [Guilluy et al.](#page-17-4) [\(2022\)](#page-17-4) utilized high-resolution transmission spectroscopy to observe the atmosphere of WASP-69b, detecting H_2O , CH₄, NH₃, CO, and C₂H₂. [Guilluy et al.](#page-17-4) [\(2022\)](#page-17-4) employed radiative and thermochemical equilibrium models, incorporating disequilibrium-chemistry effects in a post-processing step, to explore different C/O ratios and atmospheric metallicity scenarios consistent with their observations. Their findings suggest that atmospheric scenarios

$2 \text{ BANGERA ET AL}.$

with super-solar metallicities are unlikely for this planet. Additionally, they propose that the observed presence of C_2H_2 and the stronger detection of CH₄ compared to H₂O could be better explained by an atmospheric C/O ratio greater than 1. Among the models tested, the most favorable match to observations was achieved by a model with solar metallicity, $C/O = 2.0$, and artificially increased concentrations for NH₃ and C_2H_2 at $10^{-7}-10^{-6}$. However, the high concentrations of NH_3 and C_2H_2 may also be explained by chemical disequilibrium processes in the atmosphere. Therefore, disequilibrium chemistry calculations are needed to confirm or disprove the conclusions of [Guilluy et al.](#page-17-4) (2022) on the presence of disequilibrium chemistry and on the inferred C/O. In this work, we build upon the findings of [Guilluy et al.](#page-17-4) [\(2022\)](#page-17-4) by employing a novel approach that couples kinetic modeling, which provides physically supported abundance profiles accounting for disequilibrium chemistry, and high-resolution transmission spectroscopy to constrain the chemical properties of the atmosphere.

At atmospheric pressures that can be probed by infrared observations $(10^{-6} - 1$ bar), vertical diffusion-induced quenching and photochemistry are the two key physical processes that may drive the atmospheric composition of an exoplanet out of thermochemical equilibrium. In the deep atmosphere, where gas temperatures and pressures are high, the chemistry can be assumed to be in thermochemical equilibrium. However, at lower atmospheric gas temperatures, when chemical timescales are larger than dynamical timescales, vertical diffusion can push the chemistry out of equilibrium (e.g. [Moses](#page-18-7) [2014;](#page-18-7) [Baxter et al.](#page-17-5) [2021;](#page-17-5) [Kawashima & Min](#page-17-6) [2021\)](#page-17-6). Molecules may thus be present in the upper atmospheric layers with concentrations higher than in equilibrium, suggesting that their concentrations are "quenched" in the deep atmosphere at thermochemical equilibrium concentrations and then transported upwards in the atmosphere faster than they can be chemically converted to the expected equilibrium species higher up in the atmosphere. These processes are expected to be particularly significant for planets with $T_{eq} \leq 1300 \text{ K}$ (e.g. [Madhusudhan et al.](#page-18-8) [2014;](#page-18-8) [Moses](#page-18-7) [2014\)](#page-18-7) such as WASP-69b. At these temperatures, where the carbon chemistry shifts between being $CH₄$ - and CO-dominated, while the nitrogen chemistry shifts between being NH₃- and N₂-dominated [\(Lodders & Fegley](#page-18-9) [2002;](#page-18-9) [Woitke et al.](#page-18-10) [2018\)](#page-18-10), vertical diffusion induced quenching can significantly impact both the diversity of the observed species and the strength of the observed spectral features. [Zamyatina et al.](#page-18-11) [\(2023\)](#page-18-11) find that while this diffusion-induced quenching is predicted to occur in the atmospheres of HAT-P-11b, HD 189733b, HD 209458b, and WASP-17b, the extent to which it affects spectra and phase curves varies from planet to planet.

Additionally, photochemistry, i.e. the impact of the stellar radiation on the gas composition, can influence atmospheric composition (e.g. [Madhusudhan](#page-18-12) [2012;](#page-18-12) [Moses et al.](#page-18-13) [2013;](#page-18-13) [Moses](#page-18-7) [2014;](#page-18-7) [Barth et al.](#page-17-7) [2021;](#page-17-7) [Baeyens et al.](#page-17-8) [2022b\)](#page-17-8). The parent molecules transported from deep atmospheric regions are photodissociated in upper layers producing radicals that react to form new species. The shape of the stellar spectra, as well as the atmospheric temperature profile and initial atmospheric elemental composition, influence the diversity of chemical products in the atmosphere. Lower atmospheric temperatures produce abundant CH_4 and NH_3 that is beneficial for photochemistry, since these species are more active photochemical precursors than CO and N_2 [\(Moses](#page-18-7) [2014\)](#page-18-7). High atmospheric temperatures serve to counter balance the effect of photochemistry, maintaining the atmospheric composition closer to what is expected in the presence of thermochemical equilibrium. Recently, direct evidence of photochemistry in hot gas-giant atmospheres was obtained from the JWST observations of SO_2 in the atmospheres of WASP-39b [\(Tsai et al.](#page-18-14) [2023\)](#page-18-14) and WASP-107b [\(Dyrek et al.](#page-17-9) [2023\)](#page-17-9). On WASP-69b, it is the detection of C_2H_2 that suggests that a photochemical model is preferable to chemical equilibrium models for interpreting the observations (e.g. [Moses et al.](#page-18-15) [2011;](#page-18-15) [Venot et al.](#page-18-16) [2012;](#page-18-16) [Moses](#page-18-7) [2014\)](#page-18-7).

To investigate the impact of disequilibrium chemistry on the atmospheric composition of WASP-69b, we performed a series of 1D calculations using the ARGO code [\(Rimmer & Helling](#page-18-17) [2016\)](#page-18-17), which incorporates thermochemical and photochemical kinetics along with vertical transport processes to model vertical atmospheric profiles. The code currently utilizes the STAND2020 network, which includes neutral and ion chemistry for molecules containing H, C, O, and N, with a limited neutral chemistry for S-bearing molecules. Our study focuses on three key parameters: atmospheric C/O ratio, thermal structure, and the strength of eddy diffusion. The atmospheric C/O ratio is of particular interest, as equilibrium modeling has suggested a carbon-rich atmosphere for WASP-69b, which contrasts with the C/O ratio of its host star [\(Anderson et al.](#page-16-0) [2014\)](#page-16-0). Additionally, we accounted for the temperature difference of up to ∼400 K between the two terminator regions, as expected for a planet with an equilibrium temperature of ∼1000 K orbiting a K-type star like WASP-69b [\(Helling et al.](#page-17-10) [2023\)](#page-17-10). The eddy diffusion coefficient was also examined, given its role as a poorly constrained parameter that can significantly influence atmospheric concentration predictions, potentially varying by orders of magnitude (e.g. [Moses et al.](#page-18-15) [2011;](#page-18-15) [Arfaux & Lavvas](#page-16-1) [2023\)](#page-16-1). Finally, synthetic spectra generated from our models were compared to the observations of [Guilluy et al.](#page-17-4) [\(2022\)](#page-17-4) to evaluate the consistency of our findings.

Quantity	Value	Source

Table 1. WASP-69b system parameters for the host star and the planet as used by [Guilluy et al.](#page-17-4) [\(2022\)](#page-17-4).

Note—The number in parentheses are the standard uncertainty corresponding to the last digits of the quoted values.

This paper is structured as follows. Section [2](#page-2-0) describes the modeling approach used to derive the atmospheric composition and synthetic spectra. Section [3](#page-5-0) presents how the disequilibrium results differ from the chemical equilibrium solution for our base model, and the results of the parameter space study for each of the detected species (H_2O, H_3O) CO, CH_4 CH_4 , C_2H_2 , NH₃), plus HCN and CO₂ that were not detected in the GIANO-B near-infrared data. Section 4 presents the synthetic transmission spectra in comparison to the observations of [Guilluy et al.](#page-17-4) [\(2022\)](#page-17-4), together with the implications for WASP-69b's atmospheric C/O. Section [5](#page-13-0) presents a discussion of the degeneracy in the models as well as the model sensitivities to boundary conditions. Section [6](#page-15-0) concludes the paper.

2. MODELLING APPROACH

We employ STAND2020 [\(Hobbs et al.](#page-17-11) [2021;](#page-17-11) [Rimmer et al.](#page-18-18) [2021\)](#page-18-18), an ion-neutral photochemical C/N/O/H+S ratenetwork with >4000 reaction paths to determine the local gas-phase composition in the observable terminator regions of WASP-69b. Leaving the required input radiation field constant, we explore the effect of local temperature, mixing efficiency, and C/O on the atmospheric chemistry leading to 14 independent models described in Table [2.](#page-4-0) The chemical models are used as input to calculate transmission spectra, which are then cross-correlated with the near-IR observations to test the conclusions of [Guilluy et al.](#page-17-4) [\(2022\)](#page-17-4) employing a physically motivated model.

2.1. Chemical Kinetics Modelling

We employed the 1D photochemical diffusion code ARGO [\(Rimmer & Helling](#page-18-17) [2016;](#page-18-17) [Rimmer & Helling](#page-18-19) [2019\)](#page-18-19) to model the atmospheric chemistry of WASP-69b in thermochemical disequilibrium. The model consists of two parts: a transport model that considers ion-neutral and neutral-neutral reactions, and a model calculating the chemical rate constants for photochemistry and cosmic rays. It solves the 1D continuity equation for each gas species i ,

$$
\frac{\partial n_i}{\partial t} = P_i - L_i - \frac{\partial \phi_i}{\partial z},\tag{1}
$$

where n_i , in cm⁻³, is the number density of species i, P_i and L_i are the production and loss rates of species i, respectively $\lbrack cm^{-3}s^{-1}\rbrack$, and $\frac{\partial \phi_i}{\partial z}$ is the vertical change in flux ϕ_i $\lbrack cm^{-2}s^{-1}\rbrack$. The production and loss terms P_i and L_i describe two-body neutral-neutral and ion-neutral reactions, three-body neutral reactions, dissociation reactions, radiative-association reactions, thermal ionization and recombination reactions. Vertical transport is assumed to occur via both eddy $(K_{zz} \text{ [cm}^2 \text{s}^{-1}])$ and molecular $(D_{zz} \text{ [cm}^2 \text{s}^{-1}])$ diffusion,

$$
\phi_i = -K_{\rm zz} \left[\frac{\partial n_i}{\partial z} + n_i \left(\frac{1}{H_0} + \frac{1}{T} \frac{dT}{dz} \right) \right] - D_{\rm zz} \left[\frac{\partial n_i}{\partial z} + n_i \left(\frac{1}{H_i} + \frac{1 + \alpha_T}{T} \frac{dT}{dz} \right) \right],\tag{2}
$$

where H_0 is the atmospheric pressure scale height at vertical height z , H_i is the atmospheric scale height for species i , T is the temperature, and α_T the thermal diffusion coefficient [\(Banks & Kockarts](#page-17-12) [1973;](#page-17-12) [Zahnle et al.](#page-18-20) [2006\)](#page-18-20). The molecular diffusion coefficients in ARGO are adopted from Chapman-Enskog theory [\(Enskog](#page-17-13) [1917;](#page-17-13) [Chapman & Cowling](#page-17-14) [1991\)](#page-17-14). The eddy diffusion coefficients are used as a free parameter.

2.2. Radiative Transfer with C-DISORT

In order to calculate photochemical rates, the stellar high-energy flux received at the top of the planet's atmosphere and its variation throughout the atmosphere is required. For the corresponding radiative transfer calculations, we added the discrete ordinate radiative transfer code C-DISORT [\(Hamre et al.](#page-17-15) [2013\)](#page-17-15) to ARGO. C-DISORT is an improved C version of the well-known DISORT code originally written in FORTRAN [\(Stamnes et al.](#page-18-21) [1988\)](#page-18-21).

C-DISORT provides the exact solution of the plane-parallel radiative transfer equation for a given set of polar angles. In the framework of a discrete ordinate radiative transfer schemes, these are referred to as streams and their number determines the numerical accuracy of the solution. For this work we employ four streams, which is usually sufficient for calculating angular-averaged quantities in scenarios without strongly asymmetric scattering. The C-DISORT radiative transfer yields the mean intensity as a function of atmospheric height which is subsequently converted into the actinic flux that is used to calculate the corresponding photodissociation rates.

2.3. Model Setup

For the incident stellar radiation, we constructed the stellar spectral energy distribution for WASP-69b (Figure [9\)](#page-19-0) by mixing a PHOENIX model in the UV, optical, and infrared [\(Husser et al.](#page-17-16) [2013\)](#page-17-16) with a scaled solar flux in the EUV and X-ray regimes [\(Claire et al.](#page-17-17) [2012\)](#page-17-17). The solar XUV emission has been scaled to best match the observed stellar X-ray luminosity [\(Nortmann et al.](#page-18-22) [2018\)](#page-18-22) and expected EUV flux [\(Fossati et al.](#page-17-18) [2023\)](#page-17-18). To model the terminator regions, we set the stellar zenith angle of the incident stellar beam in C-DISORT to 85°. In addition to stellar radiation, we include the effect of low-energy cosmic rays in our simulations based on [Rimmer & Helling](#page-18-17) [\(2016\)](#page-18-17). For atmospheric composition and synthetic transmission spectra calculations, we considered the same stellar parameters and planetary $log(g)$ used by [Guilluy et al.](#page-17-4) [\(2022\)](#page-17-4) (Table [1\)](#page-2-1).

We treated the local thermodynamic properties, element abundances, and mixing efficiency as free parameters in our models as described below:

[1](#page-4-1)) **Temperature profile:** Figure 1 illustrates the (T_{gas}, p_{gas}) profiles used as input to model WASP-69b's atmosphere chemistry. The base profile (orange curve) was obtained from 1D radiative-thermochemical-equilibrium calculations assuming solar composition [\(Guilluy et al.](#page-17-4) [2022,](#page-17-4) Cubillos et al. 2024, in prep). These radiative-equilibrium calculation considered an atmospheric model ranging from 100 to 10^{-9} bar, and a spectral window ranging from 0.3 to 30μ m to cover the bulk of the stellar and planetary radiation. The radiative transfer was computed with the PYRAT Bay code [\(Cubillos & Blecic](#page-17-19) [2021\)](#page-17-19), using the line-by-line sampling approach over a cross-section grid with a resolving power of 15000. The radiative-transfer routine in Pyrat Bay uses the line-sampling approach, considering the major sources of opacity expected in H₂-dominated atmospheres: CO , CO_2 , SO_2 , and CH_4 from HITEMP [\(Rothman et al.](#page-18-23) [2010;](#page-18-23) [Li et al.](#page-18-24) [2015;](#page-18-24) [Hargreaves et al.](#page-17-20) [2020\)](#page-17-20); H_2O , HCN, N H_3 , and C_2H_2 from ExoMol [\(Azzam et al.](#page-17-21) [2016;](#page-17-21) [Polyansky](#page-18-25) [et al.](#page-18-25) [2018;](#page-18-25) [Chubb et al.](#page-17-22) [2020;](#page-17-22) [Yurchenko et al.](#page-18-26) [2011;](#page-18-26) [Harris et al.](#page-17-23) [2006,](#page-17-23) [2008;](#page-17-24) [Underwood et al.](#page-18-27) [2016;](#page-18-27) [Coles et al.](#page-17-25) [2019\)](#page-17-25); Na and K [\(Burrows et al.](#page-17-26) [2000\)](#page-17-26); and collision-induced absorption (CIA) due to H_2-H_2 and H_2 –He [\(Borysow](#page-17-27) [et al.](#page-17-27) [1988,](#page-17-27) [1989,](#page-17-28) [2001;](#page-17-29) [Borysow & Frommhold](#page-17-30) [1989;](#page-17-30) [Borysow](#page-17-31) [2002\)](#page-17-31). The large molecular line-list databases were pre-processed with the repack algorithm [\(Cubillos](#page-17-32) [2017\)](#page-17-32) before sampling into the opacity data. An intrinsic heat flux of 100 K was adopted, as it is typically assumed for Jupiter-sized planets.

To extend the pressure profile to 1000 bar, capturing deeper regions where NH₃ quenching may occur [\(Moses et al.](#page-18-15) [2011\)](#page-18-15), we applied the hot adiabatic temperature profile from [Sainsbury-Martinez et al.](#page-18-28) [\(2019\)](#page-18-28) as detailed in equation 21 of [Schneider et al.](#page-18-29) [\(2022\)](#page-18-29),

$$
T(p > 100 \text{bar}) = \Theta_{\text{ad}} \cdot \left(\frac{\text{p}_{\text{gas}}}{100 \text{bar}}\right)^{\eta},\tag{3}
$$

where Θ_{ad} is the local gas temperature of the adiabat at 100 bars and $\eta = 1/3.56$. This extended profile serves as our base model "TP", while additional profiles are obtained by shifting TP by ± 100 K throughout the atmosphere.

2) Eddy diffusion coefficient (K_{zz}) : While several studies using 3D general circulation models (GCMs) have provided numerical and theoretical estimates of the eddy diffusion coefficient K_{zz} (e.g. [Parmentier et al.](#page-18-30) [2013;](#page-18-30) [Komacek](#page-18-31) [et al.](#page-18-31) [2019;](#page-18-31) [Arfaux & Lavvas](#page-16-1) [2023\)](#page-16-1), the parameter remains difficult to constrain. Three different K_{zz} profiles are investigated here (Figure [1\)](#page-4-1). The first is a constant $K_{zz,1} = 10^{10} \text{ cm}^2 \text{s}^{-1}$, throughout the atmosphere. The second depends on the local gas pressure derived by [Parmentier et al.](#page-18-30) [\(2013\)](#page-18-30) for HD 209458b, $K_{zz,2} = \frac{5 \times 10^8}{\sqrt{p_{gas}}} [\text{cm}^2 \text{s}^{-1}]$. [Parmentier et al.](#page-18-30) [\(2013\)](#page-18-30) find this to be a valid parametrization for $p_{gas}=10^2...10^{-6}$ bar. We extend the K_{zz,2} profile to 10^{-9} bar, resulting in high $K_{zz}(10^{13} - 10^{14} \text{ cm}^2 \text{s}^{-1})$ in the upper atmosphere. The $K_{zz,3}$ profile is $10\times K_{zz,2}$, across the same pressure range. For pressures greater than 100 bar in all 3 profiles, we set Kzz to a constant value of

Figure 1. Gas temperature-pressure (left) and eddy diffusion K_{zz} (right) profiles used in this work. The orange (T_{gas} , p_{gas}) profile , upto 100 bars, is adapted from [Guilluy et al.](#page-17-4) [\(2022\)](#page-17-4) for their analysis of WASP-69b and extended to 1000 bars assuming a hot adiabatic temperature profile.

All other (Tgas, pgas) profiles are obtained by shifting the orange profile in steps of 100 K.

 10^{10} cm²s⁻¹, as suggested by [Moses et al.](#page-18-32) [\(2022\)](#page-18-32). The various K_{zz} profiles investigate here allow to study a range of efficiencies in eddy mixing for both the top and bottom of the atmosphere.

3) $C/O:$ The elemental abundances are set to solar [\(Asplund et al.](#page-17-33) [2009\)](#page-17-33). For the composition of the atmosphere we consider $C/O = 0.55$ (solar), 0.9, 2 and 5, altering the C abundance each time. These values range from oxygen-rich to carbon-rich and are used to probe how high a value for C/O is required for C_2H_2 to be observable.

The base model utilizes the (T_{gas}, p_{gas}) profile "TP" (orange in Figure [1\)](#page-4-1), the pressure-dependent eddy diffusion profile $K_{zz,2} \sim 1/\sqrt{p_{gas}}$, solar element abundances with an oxygen-rich C/O = 0.55. Thirteen additional models are built by independently varying these parameters. A summary of the different model parameters is presented in Table [2.](#page-4-0)

Model Number	C/O	Temperature-Pressure profile (As in Fig. 1)	K_{zz} (As in Fig. 1)
1	0.55	TP	$K_{zz,1}$
$\overline{2}$	0.55	TP	$K_{zz,2}$
3	0.55	TP	$K_{zz,3}$
$\overline{4}$	0.55	$TP-100$	$K_{zz,2}$
$\overline{5}$	0.55	$TP+100$	$K_{zz,2}$
$\,6$	0.55	$TP+200$	$\mathrm{K}_{\mathrm{zz},2}$
$\overline{7}$	$\overline{2}$	TP	$K_{zz,1}$
8	$\overline{2}$	TP	$K_{zz,2}$
$\overline{9}$	$\overline{2}$	TP	$K_{zz,3}$
10	$\overline{2}$	$TP-100$	$K_{zz,2}$
11	$\overline{2}$	$TP+100$	$K_{zz,2}$
12	$\overline{2}$	$TP+200$	$K_{zz,2}$
13	0.9	TP	$K_{zz,2}$
14	$\overline{5}$	TP	$K_{zz,2}$

2.4. Cross-correlation to Observations

The 14 non-equilibrium chemistry models computed in this work are compared to the "full model" used in [Guilluy](#page-17-4) [et al.](#page-17-4) [\(2022\)](#page-17-4), where the authors conducted high-resolution transmission spectroscopy of WASP-69b. They analyzed data from three nights gathered with the near-infrared spectrograph GIANO-B of the Telescopio Nazionale Galileo.

To compute the transmission spectra of WASP-69b based on our photochemical kinetics result, we used the Pyrat Bay package, this time sampling the cross sections at a resolution of $R=80000$ over a wavelength range of 0.9–2.5 µm, to be able to compare the results at a high spectral resolution.

To maintain consistency, we employed the same data processing methodology described in [Guilluy et al.](#page-17-4) [\(2022\)](#page-17-4) starting from the residual GIANO-B spectra resulting from the Principal Component Analysis (PCA) for telluric correction. The real data are cross-correlated with our models by following the same approach described in Section 3 of [Guilluy et al.](#page-17-4) [\(2022\)](#page-17-4). Firstly, we convolved each model to the GIANO-B instrument profile (a Gaussian profile with full width at half maximum FWHM of $\sim 5.4 \text{ km s}^{-1}$). For each night, we used the GIANO-B orders selected in [Guilluy et al.](#page-17-4) [\(2022\)](#page-17-4), and performed cross-correlation (CC) for every phase over a lag vector corresponding to planet radial velocities (RVs) in the range -252 \leq RV \leq 252 km s⁻¹, in steps of 3 km s⁻¹ (to cover all possible RVs of the planet). Subsequently, we co-added the CC functions over the selected orders, nights, and orbital phase after shifting them in the planet rest frame by assuming a circular orbit (i.e. zero eccentricity). We scanned a range of planet RV semi-amplitudes $0 \le K_P \le 200 \text{ km s}^{-1}$, in steps of 1.5 km s⁻¹ (which includes the expected K_P, K_{P,theo} = 127.11^{+1.49} km/s, see Table 1 in [Guilluy et al.](#page-17-4) [2022\)](#page-17-4). To quantify the confidence level of our detections, we converted the total CC signal into signal-to-noise (S/N) , by dividing the total CC matrix by its standard deviation (calculated by excluding the CC peak, e.g., [Brogi et al.](#page-17-34) [2018;](#page-17-34) [Giacobbe et al.](#page-17-35) [2021\)](#page-17-35).

3. RESULTS

3.1. Equilibrium vs Quenching vs Photochemistry

The chemical species investigated in this work are H_2O , CO, CH₄, C₂H₂, NH₃, HCN, and CO₂. Of these, H₂O, CO, CH_4 , C_2H_2 and NH₃ have been detected in the terminator regions of WASP-69b based on high-resolution transmission spectra collected with the GIANO-B near-infrared spectrograph. Ion-neutral chemistry has been included in our modeling with STAND, but its impact on the aforementioned molecules is found to be negligible. We test the hypothesis by [Guilluy et al.](#page-17-4) [\(2022\)](#page-17-4) that these species can only be present simultaneously if chemical disequilibrium processes affect their formation and/or destruction. Since each of these molecules may be affected to a different extent by photochemistry and vertical diffusion in the atmosphere, three different cases are studied and compared: i) chemical equilibrium, ii) disequilibrium chemistry resulting from eddy diffusion, and iii) disequilibrium chemistry resulting from eddy diffusion and photochemistry. The equilibrium concentrations (case i) are calculated using the GGchem code [\(Woitke et al.](#page-18-10) [2018\)](#page-18-10) using solar element abundances and $C/O=0.55$. We use the respective (T_{gas} , p_{gas}) profile as our base model as outlined in Sect. [2.1](#page-2-2) for cases ii) and iii) with $K_{zz,2}$. The results are shown in Figure [2.](#page-6-0)

In both cases with ii) only diffusion and iii) diffusion with photochemistry, the concentrations of H_2O and CO remain close to their equilibrium values, except for $p_{\text{gas}} < 10^{-7}$ bar, where they are depleted by photodissociation. This agreement with equilibrium concentrations is because both species are already the most abundant species at their quench points and throughout the atmosphere, and thus not significantly affected by quenching. This is consistent with the results presented in [Moses et al.](#page-18-15) (2011) , [Drummond et al.](#page-17-36) (2020) , and [Baeyens et al.](#page-17-8) $(2022b)$. CH₄, being less abundant in WASP-69b's atmosphere than CO at these gas temperatures, is more significantly affected by diffusion. It is quenched at ~ 0.4 bar and photodissociated at $p_{gas} < 10^{-6}$, resulting in concentrations up to 4 dex larger than its equilibrium concentrations in the upper atmosphere.

 $NH₃$ concentrations depart from equilibrium and are quenched at \sim 100 bar. Similar high-pressure quenching for NH_3 has been reported by [Moses et al.](#page-18-15) [\(2011\)](#page-18-15) in the atmosphere of HD189733b, due to ammonia reaching the N₂-NH₃ interconversion quench point at high pressures and temperatures. We find that the quenching of NH³ results in it having comparable concentrations to N_2 on WASP-69b. In our model, NH₃ is produced through the following scheme

$$
N_2 + H \longrightarrow N_2H
$$

\n
$$
N_2H + H_2 \longrightarrow N_2H_2 + H
$$

\n
$$
N_2H_2 + H \longrightarrow NH_2 + NH
$$

\n
$$
NH + H_2 \longrightarrow NH_2 + H
$$

\n
$$
2(NH_2 + H_2 \longrightarrow NH_3 + H)
$$

\n
$$
2H + M \longrightarrow H_2 + M
$$

\n
$$

$$
 (4)

Figure 2. Local non-equilibrium gas-phase concentrations of H_2O , CO, CH₄, NH₃, C₂H₂, HCN, and CO₂ for i) thermochemical equilibrium (solid lines), ii) vertical diffusion but no photochemistry (dash-dot lines), and iii) vertical diffusion with photochemistry (dashed lines). The input (T_{gas}, p_{gas}) profile is the base model "TP" with the eddy diffusion profile $K_{zz,2}$, and $C/O=0.55$. NH³ and CH⁴ concentrations are increased by diffusion, which then contributes to increased concentrations of C2H² and HCN. Note that the x-axis range differs in each subfigure.

Here, M is any third body. The final quench point for NH₃ is at the intermediate gas pressures of ~ 1 bar. This arises because the gas temperature profile remains relatively constant in the pressure range between 1-100 bar, allowing the effective interconversion reactions between NH₃ and N₂ to persist [\(Moses et al.](#page-18-15) [2011\)](#page-18-15). At $p_{gas} < 1$ bar the temperature gradients become significant again (Fig [1\)](#page-4-1), causing the rates of the interconversion reactions to drop off, resulting in the final quenching of NH3, beyond which it maintains a uniform concentration, until photochemical destruction in the upper atmospheric layers. The impact of this quench point is more pronounced when comparing models with different K_{zz} values, as shown in Fig. [5.](#page-11-0)

 C_2H_2 follows its equilibrium profile up to ~ 1 bar. At 0.01 bar < p_{gas} < 1 bar, the disequilibrium concentrations are up to 1 dex higher than the equilibrium concentrations, caused by the increased concentrations of parent molecule CH_4 due to quenching. C_2H_2 production occurs through the following scheme at these pressure levels

$$
H + CH_4 \longrightarrow CH_3 + H_2
$$

\n
$$
CH_3 + CH_4 \longrightarrow C_2H_5 + H_2
$$

\n
$$
C_2H_5 + M \longrightarrow C_2H_4 + H + M
$$

\n
$$
C_2H_4 + H \longrightarrow C_2H_3 + H_2
$$

\n
$$
\frac{C_2H_3 + M \longrightarrow C_2H_2 + H + M}{\text{Net}: 2 \text{CH}_4 \longrightarrow C_2H_2 + 3H_2}
$$
\n(5)

At $p_{\text{gas}} \sim 0.01$ bar, C_2H_2 is quenched. Its concentration is further enhanced by up to 7 dex in the upper atmosphere due to the abundance of photochemically released atomic H, along with high levels of quenched CH₄. The following chemical scheme is responsible for the production of C_2H_2 in the upper atmosphere

$$
2\left(\text{CH}_4 + \text{H} \longrightarrow \text{CH}_3 + \text{H}_2\right)
$$

\n
$$
2\text{CH}_3 \longrightarrow \text{C}_2\text{H}_6
$$

\n
$$
\text{C}_2\text{H}_6 + \text{H} \longrightarrow \text{C}_2\text{H}_5 + \text{H}_2
$$

\n
$$
\text{C}_2\text{H}_5 + \text{H} \longrightarrow \text{C}_2\text{H}_4 + \text{H}_2
$$

\n
$$
\text{C}_2\text{H}_4 + \text{H} \longrightarrow \text{C}_2\text{H}_3 + \text{H}_2
$$

\n
$$
\text{C}_2\text{H}_3 + \text{H} \longrightarrow \text{C}_2\text{H}_2 + \text{H}_2
$$

\n
$$
3\text{H}_2 + \text{M} \longrightarrow 6\text{H} + \text{M}
$$

\nNet:
$$
2\text{CH}_4 \longrightarrow \text{C}_2\text{H}_2 + 3\text{H}_2
$$

This scheme also results in the release of molecular hydrogen in the upper (photochemically active) atmosphere. It is similar to [Moses et al.](#page-18-13) [\(2013\)](#page-18-13) for the production of C_2H_2 in the atmosphere of XO-1b, with the exception of the step that produces C_2H_4 . In their scheme, the production of C_2H_4 is accomplished through collision with a third body: $C_2H_5 + M \longrightarrow H + C_2H_4 + M$, resulting in the use of 2 fewer H and the production of 1 fewer H₂ in this reaction.

Similar to C_2H_2 , the concentration of HCN is influenced by chemical disequilibrium in three ways. First, in the deep atmosphere, the increased presence of parent molecules CH⁴ and NH³ leads to a higher chemical production of HCN. The production scheme is then as follows

$$
NH_3 + H \longrightarrow NH_2 + H_2
$$

\n
$$
NH_2 + H \longrightarrow NH + H_2
$$

\n
$$
NH + H \longrightarrow N + H_2
$$

\n
$$
CH_4 + H \longrightarrow CH_3 + H_2
$$

\n
$$
N + CH_3 \longrightarrow H_2CN + H
$$

\n
$$
H_2CN + M \longrightarrow HCN + H
$$

\n
$$
H_2 + M \longrightarrow 2H + M
$$

\n
$$
Net: NH_3 + CH_4 \longrightarrow HCN + 3H_2
$$

\n(7)

Figure 3. H₂O and CO concentrations for the terminator region of WASP-69b. Top: varying eddy diffusion, for TP, C/O=0.55 and 2. Middle: varying C/O ratios, for TP and $K_{zz,2}$. Bottom: varying (T_{gas}, p_{gas}), for $K_{zz,2}$ and C/O=0.55 and 2.

Second, HCN concentrations are quenched at $p_{gas} \sim 1$ bar. Third, XUV radiation boosts HCN at $p_{gas} = 10^{-3.5} - 10^{-8}$ bar and photodissociates it at higher altitudes. At these gas pressures, the production scheme is similar to scheme [7,](#page-7-0) except for the formation of NH, which happens through the photodissociation of NH₃ through: NH₃ \rightarrow NH + 2H. In agreement with [Drummond et al.](#page-17-36) [\(2020\)](#page-17-36), CO₂ is found to be depleted by a factor \sim 4 at p_{gas} < 10⁻¹bar through quenching as carbon is quenched into CH₄. CO₂ is depleted by photodissociation at $p_{gas} < 10^{-7}$ bar.

3.2. The parameter study for individual molecules 3.2.1. H2O

As shown in Figure [3,](#page-8-0) at solar C/O the strength of the eddy diffusion parameter does not significantly affect H_2O concentrations in the deep atmosphere. However, in the upper atmosphere, the stronger eddy diffusion can support concentrations against photodissociation, whereas for the weakest eddy diffusion probed, H_2O concentrations are depleted by > 4 dex. At higher C/O, for e.g. C/O=2, H₂O is no longer the dominant species at its quench point and hence the strength of mixing significantly affects the concentrations. Here, the model with the most efficient mixing in the deep atmosphere $(K_{zz,1})$ quenches at higher pressures and thus at higher concentrations. For "TP" and $K_{zz,2}$, an increase in C/O results in decreased concentrations for $H₂O$ as there is less oxygen available to form water once carbon sequesters the amount needed to form CO. This change in concentrations is less notable when $C/O < 1$, i.e. in an oxygen dominated atmosphere. For $C/O = 0.55$, a change in temperature does not significantly affect H₂O concentrations. At colder temperatures there is a slight increase in concentration as CO depletes in the atmosphere in

favour of CH₄. In contrast, for $C/O = 2$, an increase in gas temperature causes H₂O concentrations to deplete rapidly as more oxygen is preferentially trapped in CO.

3.2.2. CO

At a planetary equilibrium temperature of \sim 950 K, the CO–CH₄ interconversion becomes crucial in WASP-69b's atmosphere, with CO being the preferred species at higher temperatures. Thus, the strength of eddy diffusion does substantially affect the concentrations of CO, as seen in Figure [3.](#page-8-0) For a higher diffusion coefficient, CH_4 is quenched at higher concentrations, and consequentially CO is quenched at a lower concentration. This trend remains consistent for both C/O of 0.55 and 2. In the upper atmosphere, a higher diffusion strength serves to replenish concentrations against photodissociation, similarly to H_2O . As C/O increases, the concentration of CO increases until oxygen is entirely trapped in CO. Further increase in C/O only results in higher concentrations of $CH₄$ and other hydrocarbons. With regards to the dependence on the local gas temperature, high temperatures push the carbon chemistry towards CO instead of CH4. For WASP-69b this suggests that, at solar C/O, a gas temperature increase of ∼100K in the lower atmosphere can effectively turn the bulk of carbon from CH_4 into CO. The following chemical pathway converts CH_4 to CO in the upper atmosphere

$$
H_2O \xrightarrow{hv} H + H + O
$$

\n
$$
CH_4 + H \longrightarrow CH_3 + H_2
$$

\n
$$
CH_3 + O \longrightarrow CH_2O + H
$$

\n
$$
CH_2O + H \longrightarrow CHO + H_2
$$

\n
$$
CHO + H \longrightarrow CO + H_2
$$

\n
$$
Net: H_2O + CH_4 \longrightarrow CO + 3H_2
$$
\n(8)

3.2.3. CH4

Figure [4](#page-10-0) shows the effect of the different parameters on CH₄ concentrations. Conversely to CO, a stronger mixing serves to increase the concentrations of CH_4 in the upper observable atmosphere. In the upper atmosphere, CH_4 is photodissociated, resulting in higher order hydrocarbons, and is also chemically recycled into CO through scheme [8.](#page-9-0) CH_4 concentrations experience a significant gain when $C/O > 1$. As the equilibrium CH_4 concentration is larger at the quench point for the higher C/O models, the quenched methane concentration is larger for these models. This larger concentration then enhances the effectiveness of mechanisms that convert $\rm CH_4$ to hydrocarbons like $\rm C_2H_2$ (for e.g. through schemes [5](#page-7-1) and [6\)](#page-7-2). For a solar C/O , there is a rapid depletion of $CH₄$ concentrations as the gas temperature increases, as the carbon chemistry shifts towards CO. However, for higher C/O , CH₄ remains the preferred carrier of carbon due to the limited amount of oxygen available in the atmosphere, and hence there is no strong depletion of concentrations with increase in temperature.

3.2.4. CO2

The concentration of $CO₂$ in the atmosphere of WASP-69b varies in response to the disequilibrium abundances of $H₂O$ and CO via the following scheme

$$
H_2O + H \longrightarrow H_2 + OH
$$

\n
$$
CO + OH \longrightarrow CO_2 + H
$$

\n
$$
\overline{Net}: H_2O + CO \longrightarrow H_2 + CO_2
$$
\n(9)

Thus, as seen in Fig [4,](#page-10-0) for a low C/O the reaction rate is limited by the concentration of the less abundant CO, and thus CO² reflects the same dependence on the eddy diffusion strength and local gas temperature as CO. Conversely, for a high C/O , $H₂O$ concentrations are strongly depleted, and thus the dependence of $CO₂$ on K_{zz} and gas temperature are similar to that of $H_2O. CO_2$ is therefore also created more abundantly in an oxygen rich environment, as it needs to sequester the oxygen from H_2O .

$$
3.2.5. \quad C2H2
$$

Figure 4. Same as Figure [3](#page-8-0) but for CH_4 and CO_2 .

The relationship between K_{zz} and C_2H_2 concentrations is complex, with a behavior that is not uniform throughout the atmosphere and depends on the local abundances of other species, as illustrated in Figure [5.](#page-11-0) At higher pressures $(10^{-2}-10^{2}$ bars), C₂H₂ concentrations increase with stronger mixing (K_{zz,1}), as C₂H₂ is formed through scheme [5](#page-7-1) by the neutral-neutral reactions of CH_4 and CH_3 , and thus reflects methane's dependency on K_{zz} at these pressures. Conversely, in the upper atmosphere ($p_{\text{gas}} < 10^{-2}$ bar), C₂H₂ concentrations decrease for higher mixing strengths, because C_2H_2 formation here requires the interaction of photochemically released H with the quenched CH_4 . Stronger diffusion in the upper atmosphere works against photochemistry, leading to a lower production of C_2H_2 . In the lower atmosphere ($p_{\text{gas}} > 10$ mbar), the dependence on K_{zz} is more prominent for the solar C/O model, as CH₄ concentrations depend strongly on the K_{zz}. In the upper atmosphere, the dependence on K_{zz} is stronger for $C/O=2$, as C_2H_2 concentrations are impacted by the strong depletion of H_2O against the XUV flux for small K_{zz} values. When the C/O ratio exceeds 1, the concentration of C_2H_2 increases significantly due to the increased efficiency of the formation pathway through schemes [5](#page-7-1) and [6.](#page-7-2) This is in agreement to the results of [Helling et al.](#page-17-37) [\(2017\)](#page-17-37), where the effect of increasing thermal stability of more complex hydrocarbon molecules with increasing C/O ratios was demonstrated for brown dwarfs. Similarly to $CO₂$, there is an inversion in the dependence on temperature for low and high C/O . At low C/O , an increase in temperature leads to more CO production rather than CH_4 , which in turn makes the production pathway of C_2H_2 through CH₄ less efficient. However, at high C/O , the concentration of CH_4 increases and the production pathway to form C_2H_2 becomes more efficient at higher temperatures, resulting in higher concentrations of C_2H_2 . In all models, C_2H_2 is primarily lost into larger hydrocarbons such as C_2H_4 and C_2H_6 , which have similar concentrations to C_2H_2 . [Gasman et al.](#page-17-38) [\(2022\)](#page-17-38) suggest that a concentration above 1×10^{-7} – 1×10^{-6} is needed to observe hydrocarbon species through the atmosphere. This is also the requirement placed in [Guilluy](#page-17-4)

Figure 5. Same as Figure [3](#page-8-0) but for C_2H_2 and NH₃.

[et al.](#page-17-4) [\(2022\)](#page-17-4) for their best fit model. Our models show that these concentrations are achieved at high C/O, high temperatures, and low K_{zz} .

3.2.6. NH3

Figure [5](#page-11-0) presents the effect of the different parameters on NH₃ concentrations. A more efficient atmospheric gas diffusion helps to maintain the quenched $NH₃$ concentration up to higher altitudes, as the fast eddy diffusion offsets the NH₃ loss caused by photodissociation (see also [Ohno & Fortney](#page-18-33) [2023\)](#page-18-33). NH₃ quenching occurs deep in the atmosphere at $p_{\text{gas}} \sim 100$ bar, and since the K_{zz} values at the model lower boundary are identical across the profiles, no difference in NH₃ concentrations are observed at these depths. At pressures of \sim 1 bar the second quench point emerges. Here the differences in K_{zz} between the profiles - approximately 1 dex - impacts NH_3 concentrations by a factor of 2. Molecules such as NH_3 and N_2 , that do not contain carbon or oxygen, are relatively unaffected by the C/O ratio. However, as the quenched concentration of CH_4 increases with higher C/O ratios, processes that kinetically convert CH_4 and NH₃ into HCN (scheme [7\)](#page-7-0) become more effective for high C/O. This leads to a lower NH₃ concentration in the middle atmosphere above the quench point for the $C/O = 2.0$ model as compared to the $C/O = 0.5$ model. At these temperatures, nitrogen is preferentially stored in NH_3 . For both a solar and $C/O=2$ model, NH_3 concentrations are depleted as temperatures increase and $NH₃$ is converted to HCN and $N₂$.

3.2.7. HCN

In these models, HCN is generated in the deep atmosphere through scheme [7.](#page-7-0) Figure [6](#page-12-1) illustrates that for stronger diffusion HCN is quenched at lower concentrations in the deeper regions of the atmosphere. Conversely, less efficient

Figure 6. Same as Figure [3](#page-8-0) but for HCN.

diffusion results in higher quenched HCN concentrations since it is quenched at higher altitudes, where $NH₃$ and CH_4 concentrations are also quenched, allowing for local chemical production. In the upper atmosphere, a lower K_{zz} supports the concentrations (until it is photochemically destroyed), because NH₃ photodissociation is not offset by diffusion. The higher concentrations of CH_4 at larger C/O results in more NH_3 chemically converted to HCN for high C/O ratios. In addition, the higher C/O also smooths out the HCN profile throughout the atmosphere as the quenched HCN concentrations approach those produced by photochemistry. HCN concentrations initially rise with temperature up until the (T_{gas}, p_{gas}) profile "TP+200", at which profile the concentration decreases. This is because the reaction rate coefficient of HCN formation from CH_4 and NH_3 increases as temperatures rise, while the concentrations of NH_3 and CH_4 themselves decrease. HCN is primarily destroyed in these models by being recycled back into NH_3 as follows

4. COMPARISON TO OBSERVATIONAL DATA: MID-IR TRANSIT SPECTROSCOPY

Table 3. Cross-correlation and Likelihood test results

NOTE—From left to right: the model name, the CC result with theoretical models in the S/N framework, and the LH findings. The planet orbital semi-amplitude (K_{P0}) as well as the velocity in the planet rest frame (v_{rest_0}) of the CC and LH peak are reported. The S/N, the maximum of the likelihood matrix LH_{max} , and the goodness of fit obtained with the Wilk's theorem on the LH-ratio test are also present. The goodness of fit of the models is shown with respect to the best model in units of standard deviations σ (the higher σ , the more disfavored the model).

Of the fourteen models computed in this work, eight models (Table [3\)](#page-13-1) are found to have cross-correlation maps that peak at the expected location (v_{rest} ∼0 km/s and K_P∼K_{P,theo} = 127.11^{+1.49} km/s), where K_{P,theo} refers to the expected radial-velocity semi-amplitude of WASP-69b(see Table [3\)](#page-13-1). The S/N maps for all models computed in this work are shown in Figure [10.](#page-20-0)

The CC framework implicitly assumes that the signal amplitude and the S/N are uniform across the considered spectral range. Yet, this assumption is only valid at a first-order level. To delve deeper into this aspect, we transformed the CC values into likelihood (LH) mapping values for the eight models following the method proposed by [Brogi &](#page-17-39) [Line](#page-17-39) [\(2019\)](#page-17-39) and utilized by [Giacobbe et al.](#page-17-35) [\(2021\)](#page-17-35). In this approach, LH is determined by considering the model's line depth alongside the S/N order by order and spectrum by spectrum. Consequently, identifying a peak in the LH at the correct position within the (v_{rest}, K_P) space provides additional confirmation of the detection. Yet, the eight models are compatible within 2σ , suggesting that they are statistically equivalent.

This study represents one of the first applications of high-resolution data to derive atmospheric properties based on kinetic chemistry modeling. Among the eight models fitting the data in CC, the four exhibit C/O of 2.0, including model 9, which yields the best fit in the likelihood analysis. This aligns with [Guilluy et al.](#page-17-4) [\(2022\)](#page-17-4)'s findings of a carbon-rich atmosphere $(C/O = 2.0)$ on WASP-69b. Conversely, the remaining four models suggest C/O of 0.55 and 0.9, preventing a definitive conclusion of a carbon-rich atmosphere. Furthermore, seven of the eight models suggest an atmosphere with a temperature-pressure profile comparable to or cooler than equilibrium modeling predictions at the sub-stellar point, while only one indicates a hotter atmosphere. Finally, the observational data used here does not conclusively constrain the shape or value of the K_{zz} parameter.

Our results highlight the intrinsic degeneracy in the problem at hand, at least within the scope of our grid of models. One of the possible reasons for this degeneracy is that the physical and chemical properties of planetary atmospheres are not homogeneous across the terminator (see Section [5.1\)](#page-13-2). One possible additional explanation is that transmission spectra generated with different parameter combinations could appear similar. Finally, we acknowledge that there are data analysis steps yet to be fully understood, especially when high-resolution observations are used to derive atmospheric properties. One such aspect is the order selection used for the CC analysis [\(Guilluy et al.](#page-17-4) [2022,](#page-17-4) Giacobbe et al., in prep). To address these challenges in future works, retrievals could be applied, although this may lead to non-physical solutions. Nonetheless, the computation of physically motivated models is still too slow to be applied in a retrieval framework, and therefore it is crucial to compare the results of retrieval analyses to those obtained from physically motivated forward modeling.

5. DISCUSSION

5.1. Multi-dimensional nature of planetary atmospheres

If the atmosphere of WASP-69b is indeed carbon-rich, as indicated by four out of eight models that match the observations, the temperature variations among these models may reflect the contrasting conditions of the morning

Figure 7. Synthetic transmission spectra for model 12 with indications for the C_2H_2 , HCN and NH₃ signal strengths.

(cooler) and evening (warmer) terminators. These differences align with the expected temperature gradients for a planet of this type [\(Helling et al.](#page-17-10) [2023\)](#page-17-10). As the observation is time and space-averaged, contributions from both regions can be expected. Efforts to disentangle the components from the two terminators on exoplanets have been a focus of several recent studies, utilizing both low-resolution and high-resolution data to reveal differing atmospheric conditions across the two regions (e.g. [Ehrenreich et al.](#page-17-40) [2020;](#page-17-40) [Espinoza & Jones](#page-17-41) [2021;](#page-17-41) [Grant & Wakeford](#page-17-42) [2023\)](#page-17-42).

A notable observation is the detection of C_2H_2 in WASP-69b's atmosphere, accompanied by the lack of detection of HCN. Both molecules are commonly considered tracers of warm, carbon-rich atmospheres [\(Venot et al.](#page-18-34) [2015;](#page-18-34) [Ohno](#page-18-35) [& Fortney](#page-18-35) [2022\)](#page-18-35). Among our best fit models, only model 12 - which features the highest temperature within the carbon-rich models - shows a strong C_2H_2 signal. This model also predicts a substantial HCN concentration with a spectral signal comparable to that of C_2H_2 , and over ten times stronger than that of NH₃, particularly near 1.5 μ m (see Figure [7\)](#page-14-0). Therefore, if C_2H_2 is present on WASP-69b, we predict that HCN should also exist at detectable levels, suggesting that future observations might reveal its signature.

Our 1D modeling does not account for 3D mixing effects and wind jets. In tidally locked hot Jupiters, uneven heating may result in significant temperature contrasts between the day and night sides, leading to variations in atmospheric composition. Strong super-rotating equatorial jets may instead homogenize these differences in composition (e.g. [Madhusudhan et al.](#page-18-36) [2016;](#page-18-36) [Baeyens et al.](#page-17-43) [2022a\)](#page-17-43). In line with the results of [Baeyens et al.](#page-17-44) [\(2023\)](#page-17-44), it can be anticipated that the main effect of horizontal chemical transport in WASP-69b would be to quench molecular concentrations on the evening terminator to values typical of the hotter day-side regions and those on the morning terminator to levels resembling the colder night side. Given that the equilibrium temperature of WASP-69b ∼ 950 K puts it on the cusp of CH_4 -CO conversion and NH_3 -N₂ conversion, and that our models show that temperature differences of 100-200 K through the atmosphere significantly changes the concentrations of the observed molecules, this horizontal quenching may result in significantly different concentration profiles for the two terminator regions. An additional consequence of the horizontal mixing would be an increase in photochemical products HCN and C_2H_2 on the morning terminator due to mixing of the more photochemical active parent species CH_4 and NH_3 from the night-side, while there may be fewer of these photochemical products on the evening terminator, as demonstrated by [Tsai et al.](#page-18-37) [\(2024\)](#page-18-37).

5.2. Capturing NH³ Quenching

The (T_{gas}, p_{gas}) profile retrieved through equilibrium modeling in [Guilluy et al.](#page-17-4) [\(2022\)](#page-17-4) is constrained to a maximum pressure of 100 bars. To evaluate the implications of this constraint on non-equilibrium chemistry, we compare our models with lower boundary pressures of 1000 bars to those restricted to 100 bars.

Our models are initialized with atomic abundances at the lower boundary, as opposed to equilibrium values, and are then evolved until a steady state is achieved. This approach reveals significant deviations from equilibrium concentra-

Figure 8. Concentrations of key species for the terminator region of WASP-69b, for a model with lower boundary 100 bars vs lower boundary 1000 bars.

tions for NH_3 and HCN at 100 bars (Figure [8\)](#page-15-1), indicating that NH_3 quenching occurs at pressures deeper than 100 bars, in agreement with the findings of [Moses et al.](#page-18-15) [\(2011\)](#page-18-15) for HD189733b, where NH₃ concentrations at 100 bars are strongly influenced by the N_2 -NH₃ interconversion quench point at higher temperatures and pressures.

At lower atmospheric temperatures, the kinetics pathways favour NH³ formation. For WASP-69b, the deeper atmospheric layers are cooler than that of HD189733b. As a result, the 100 bar models over-predict NH_3 concentrations relative to their equilibrium value, and produce higher $NH₃$ concentrations than expected for the deeper pressure models. This overestimation also impacts the formation of HCN, amplifying its abundance. In contrast, other key molecules such as CH4, CO, and H2O show minimal sensitivity to the pressure boundary, as their concentrations are largely dictated by equilibrium chemistry even at 100 bars, and they are quenched at lower pressures, minimizing their dependence on deeper atmospheric dynamics.

To evaluate the observational implications of these differences, we generated synthetic spectra for the 100-bar models. The spectra consistently show stronger HCN spectral features compared to NH3, reflecting the higher HCN concentrations across these models. Additionally, only three of the fourteen 100-bar models achieve robust CC fits and likelihoods, compared to the eight models in the 1000-bar atmosphere models. The three good fit models in this case correspond to the parameters of Model 7, 9, and 12 of table [2,](#page-4-0) thus biasing the conclusions to carbon-rich atmospheres $(C/O=2)$. This difference highlights the importance of accurately capturing the NH₃ quenching at high pressures.

Uncertainty in individual rate coefficients is another factor that may influence the quenched $NH₃$ concentrations in high pressure and temperature environments. The N_2 -NH₃ interconversion is particularly sensitive to non-equilibrium chemistry, and differences of over an order of magnitude in the relevant reaction rate coefficients are reported in literature (e.g. [Moses](#page-18-7) [2014;](#page-18-7) [Tsai et al.](#page-18-38) [2021;](#page-18-38) [Veillet et al.](#page-18-39) [2024\)](#page-18-39). For example, [Moses](#page-18-7) [\(2014\)](#page-18-7) demonstrates that NH³ predictions for HD189733b could differ by up to an order of magnitude depending on whether the [Moses et al.](#page-18-15) [\(2011\)](#page-18-15) or [Venot et al.](#page-18-16) [\(2012\)](#page-18-16) chemical network was employed. [Rimmer & Helling](#page-18-17) [\(2016\)](#page-18-17) provides a further discussion on the choice of reaction rate coefficients for NH³ adopted in STAND, and a comparison with the [Moses et al.](#page-18-15) [\(2011\)](#page-18-15) network.

6. SUMMARY

A parameter study of K_{zz} , (T_{gas}, p_{gas}) and C/O ratio was conducted with 1D photochemistry-diffusion modeling to analyse the effect of vertical mixing and photochemistry in producing the species detected in WASP-69b's atmosphere, and further constrain C/O. With this study, we confirm the hypothesis of Guilluy et al. (2022) that the near-IR WASP-69b transition spectrum is more likely shaped by chemical disequilibrium processes rather than equilibrium; however, our exploration of 1D disequilibrium chemistry prescriptions cannot replicate all of the spectral features observed on WASP-69b. Our results indicate that

- 1. CH_4 , NH_3 , C_2H_2 and HCN are the species most sensitive to vertical diffusion and photochemistry in WASP-69b. Of the three parameters tested in this work, the local gas temperature has the strongest impact on the concentrations of these species in the terminator regions. However, this dependency cannot be easily disentangled from that of atmospheric C/O.
- 2. A highly efficient mixing in the upper atmosphere competes with the effect of photodissociation, effectively retaining the photochemical parent species at their quenched concentrations and thereby reducing the production of species like C_2H_2 and HCN.
- 3. A combination of high gas temperatures and C/O \sim 2 is required to produce C₂H₂ concentrations at the 10⁻⁷– 10^{-6} level in the lower atmosphere. However, at gas pressures $\lt 10^{-6}$ bars, high concentrations of C₂H₂ are also photochemically produced for solar C/O.
- 4. The relation of C_2H_2 concentrations and K_{zz} is complex and dependent on the local gas temperature and composition (i.e. C/O).
- 5. The observational data is not sufficient to distinguish different mixing profiles.

Metallicity has not been examined in this study as a free parameter. However, if atmospheric metallicity were to increase, the resulting reduction in CH₄ concentrations would cause a corresponding decrease in HCN and C_2H_2 concentrations, due to the balance between CO and CH_4 production shifting towards CO [\(Soni & Acharyya](#page-18-40) [2023\)](#page-18-40). [\(Moses et al.](#page-18-13) [2013\)](#page-18-13) find that although the CH_4/H_2O fraction is more sensitive to C/O than to metallicity, the individual concentrations are very sensitive to metallicity. In terms of NH_3 , [Ohno & Fortney](#page-18-33) [\(2023\)](#page-18-33) found that although the quenched $NH₃$ concentration remains constant as atmospheric metallicity increases, the ratio of $NH₃$ to bulk atmospheric nitrogen abundance decreases significantly, as N becomes locked in N_2 . Therefore, higher metallicity can be expected to result in lower concentrations of CH_4 , HCN, C_2H_2 and NH₃. As outlined in [Guilluy et al.](#page-17-4) [\(2022\)](#page-17-4), this scenario is disfavored by the observations.

After performing cross-correlation of the simulated transmission spectra for the fourteen models with the observed high-resolution data, eight models were identified with the expected planetary rest-frame velocity $v_{rest_0} = 0$ km/s and planetary maximal radial-velocity K_P∼K_{P,theo}. These models all differ in C/O and K_{zz}, but suggest a temperaturepressure profile consistent with the predictions of equilibrium modeling, or cooler. The difficulty in distinguishing between models of varying (T_{gas}, p_{gas}) and K_{zz} might be related to the spatial and temporal averaging of the observations. Interestingly, despite the high C/O models suggesting high HCN concentrations, this molecule has not been detected in the atmosphere of WASP-69b. The transmission and emission spectroscopy observations of WASP-69b with JWST (GTO programs 1177 and 1185, and GO program 3712) can be expected to provide more insights on its atmospheric properties. By combining the low- and high-resolution observations, the atmospheric properties of this planet may be better constrained and a better understanding obtained of the kinetic processes in its deep and it upper atmosphere.

APPENDIX

A. ADDITIONAL FIGURES AND TABLES

Figure [9](#page-19-0) presents the input stellar flux at the top of the atmosphere of WASP-69b. Figure [10](#page-20-0) shows the posterior distribution for the S/N fitting of disequilibrium model spectra produced in this work to the high-res data obtained by [Guilluy et al.](#page-17-4) [\(2022\)](#page-17-4). In Figure [11,](#page-21-0) the LH maps for the eight models with $v_{rest_0} = 0$ km/s and K_P∼K_{P,theo} are shown.

Figure 9. Spectral energy distribution (SED) of the host star at top of the atmosphere of WASP-69b. The SED is constructed by mixing a PHOENIX model in the UV, optical and infrared [\(Husser et al.](#page-17-16) [2013\)](#page-17-16) and a scaled solar flux in the EUV and X-ray regimes [\(Claire et al.](#page-17-17) [2012\)](#page-17-17).

Figure 10. Cross correlation in S/N of all models produced in this work to the high-resolution transmission spectroscopy of WASP-69b conducted by [Guilluy et al.](#page-17-4) [\(2022\)](#page-17-4) as a function of the planet's maximum radial velocity (KP) and the planet's rest-frame velocity (Vrest). The numbers inset correspond to the models listed in Table [2.](#page-4-0) The CC peaks are indicated by a red cross.

Figure 11. LH confidence intervals maps for the models with $v_{rest_0} = 0$ km/s and K_P∼K_{P,theo} in CC. The plot titles correspond to the model descriptions in Table [2.](#page-4-0)
