Automotive Elevation Mapping with Interferometric Synthetic Aperture Radar

Leyla A. Kabuli, Griffin Foster

Abstract—Radar is a low-cost and ubiquitous automotive sensor, but is limited by array resolution and sensitivity when performing direction of arrival analysis. Synthetic Aperture Radar (SAR) is a class of techniques to improve azimuth resolution and sensitivity for radar. Interferometric SAR (InSAR) can be used to extract elevation from the variations in phase measurements in SAR images. Utilizing InSAR we show that a typical, low-resolution radar array mounted on a vehicle can be used to accurately localize detections in 3D space for both urban and agricultural environments. We generate point clouds in each environment by combining InSAR with a signal processing scheme tailored to automotive driving. This lowcompute approach allows radar to be used as a primary sensor to map fine details in complex driving environments, and be used to make autonomous perception decisions.

Index Terms—Automotive radar, synthetic aperture radar (SAR), interferometric SAR (InSAR), automotive SAR

I. INTRODUCTION

UTONOMOUS driving requires detailed mapping of the A surroundings of a vehicle to infer drivable paths. Radar, lidar, camera, and ultrasonics are common sensors used for mapping. Radar arrays are low-cost sensors that provide high accuracy in range and Doppler of targets within the field of interest. However, lidar and camera typically provide higher angular resolution and accuracy. In radar, the target directionof-arrival (DoA), the angle estimation in azimuth and elevation of the target, is typically limited due to the physical array size and number of available elements. This limitation is a significant barrier to the utilization of radar for automotive use cases, and an active area of research [1]. Automotive applications require measuring information in the plane of vehicle motion. As a result, most automotive radar sensors prioritize azimuth over elevation in array design. However, for safe driving, elevation information is necessary. In any driving environment, there are overhanging structures (e.g. bridges, lights, trees, tunnels) and passable on-ground objects (e.g. lane markers, rocks, sewer covers, soil). Without elevation, the DoA does not have sufficient information to determine if it is possible to safely drive under, through, or over a detected object.

We present a new application of Interferometric Synthetic Aperture Radar (InSAR) combined with a real-time processing scheme that handles the intricacies of automotive driving. This approach provides enhanced sensitivity and angular accuracy in both azimuth and elevation of the environment. Building on our prior work [2], we study system accuracy and show results for general urban and agricultural environments, mapping a 3D world with human-scale features for use in safe autonomous driving. To our knowledge, this is the first work to do automotive InSAR for elevation mapping of automotive environments.

The development of low-cost millimeter wave (mmWave) radar sensors has enabled innovations in automotive radar approaches [3]. One such approach is Synthetic Aperture Radar (SAR), which forms high dynamic range images with sub-degree resolution across much of the azimuthal field of view (FOV). With a single virtual antenna (VX), formed from a transmit antenna (TX) and receive antenna (RX), azimuthal resolution is improved by utilizing the direction of travel to form a large, synthetic aperture [4]. As the direction of travel is primarily on a plane, SAR does not provide any additional elevation resolution.

Interferometry is a technique that localizes a source by comparing the phase of signals received at two sensors. This pair of sensors, or baseline, measures a phase delay that depends on the source's location and the sensors' relative position and orientation. This phase delay can be used to determine the source's elevation. This method is commonly used in fields including optical imaging and radio astronomy [5], [6]. Interferometry is often performed using an array of sensors.

InSAR combines SAR and interferometry [7] to form a 3D map of an environment. Interferometry can be performed using the VX pairs on a radar array, forming baselines that further resolve a scene and provide elevation information. The choice of array layout with respect to the motion of travel is an important consideration when performing InSAR. At typical driving speeds for automotive radar, the azimuth resolution is dominated by the SAR point response rather than the array point response in all directions except the extreme cone centered on the direction of travel [4]. Additional baselines in the azimuth direction do not provide much in terms of resolution, but do provide additional sensitivity which is correlated with DoA accuracy. There is a significant advantage to using interferometry with elevation baselines as SAR alone does not provide enhanced resolution in that direction in the automotive case.

InSAR is typically used to build digital elevation models (DEMs) of large regions and surfaces to measure the gradual evolution of geological features [8]–[10]. As these imaging targets involve large physical and temporal scales, InSAR

is predominantly conducted at low frequency using airborne systems.

InSAR is also incorporated in ground-based automotive radar systems, which offer more flexibility than rail-based systems [9]. A ground-based SAR system was mounted on a vehicle to map natural environments [11]. A car-borne SAR system was used to determine the slope of hills [12]. In contrast with these works, which focus on extracting elevation information for large, geological features, we map dense and detailed environments at close range, including agricultural and urban scenes. Additionally, we extract small, human-scale features for use in safe autonomous driving. Beamforming techniques have been used for 3D SAR imaging with elevation resolution enhancement using a vertical radar array [13]. Our elevation mapping approach is interferometric and utilizes an off-the-shelf radar array with minimal elevation components. While these works capture the environment on one side of the vehicle in an acquisition, our SAR system images the full frontal FOV of the vehicle in a single drive path. We use a robust and compact automotive SAR setup that is integrated with the vehicle.

In Section II we describe our signal model. In Section III we describe our experimental setup and processing pipeline. In Section IV we analyze the results of our driving scenarios and in Section V discuss improvements and further work.

II. SIGNAL MODEL

In order to extract elevation, we start by forming SAR images from raw data. A separate SAR image is formed for each VX on the real array, with a common phase center defined at the origin in order to maintain relative phase between VXs at each coordinate position. Interferometric techniques are then used to extract phase delays from baselines on the real array, utilizing the complex-valued pixels in the SAR images. Source information, including elevation, is encoded in the phase delay for a baseline because the path length and resulting relative phase between a source and each VX is different.

For our signal model, we assume a narrow fractional bandwidth of a few percent centered in the standard automotive radar band of 78 – 81 GHz ($\lambda \approx 3.75$ mm). The chirp used for imaging has a small fractional bandwidth such that we make the approximation that phase delays have no frequency dependence. We model sources as plane waves with a farfield approximation, as typical sources imaged are sufficiently far from the radar array when compared to the length of a baseline.

We assume that each range-azimuth bin in the SAR image contains at most one source. We can verify this assumption by considering the azimuth resolution of a SAR image, $\Psi_{SAR} = \frac{\lambda}{L \sin \theta}$ where λ is the operational wavelength, *L* is the aperture in meters, and $\sin \theta$ is the target azimuth angle. For a 1 m aperture (reasonable for typical driving velocities) the azimuth resolution over much of the FOV is $< 0.25^{\circ}$ [4]. When combined with the typical range resolution on automotive radar (10–30 cm), the resulting SAR image bins are sufficiently small for most sources in automotive scenes. In the case of multiple sources within one bin, we fit the geometric

Fig. 1. Vertical Baseline Geometry: Illustration of the signal receive path from the source to the vertical baseline on the left. Dashed lines indicate the wavefront at regular intervals along the plane wave trajectory. The plane wave arrives at VX₁ with time delay τ_{ϕ} relative to VX₀.

mean of these sources. This fit will still be valid as long as there is one dominant source. In Section IV, our experimental results demonstrate that the fully sampled SAR image bins are sufficiently small for a one-source approximation to hold in many dense scenes. Future work could extend our approach to a multi-source model.

Under the signal model assumptions described above, the signal at each pixel in the SAR image is represented as a single complex-valued plane wave. For the SAR image formed for VX_i, the signal can be represented in terms of magnitude and phase as $S_i = |S_i|e^{j\psi_i}$. Given signals S_0 and S_1 from the baseline formed with VX₀ and VX₁, the phase delay at a pixel can be extracted from the complex correlation of the two signals

$$\Delta \psi = \angle (S_0 \cdot S_1^*) = \psi_0 - \psi_1. \tag{1}$$

A. Vertical Baseline Model

The interferometric model used to extract elevation information depends on the orientation of the baseline. The vertical baseline model is formed from two VXs at the same horizontal offset and different elevation offsets in the real array. As shown in Figure 1, the elevation offset between VXs results in a time delay τ_{ϕ} , which depends on the baseline geometry and target elevation angle ϕ . Using the vertical antenna spacing D_v and the speed of light *c*, time delay and elevation angle are related by

$$\tau_{\phi} = \frac{D_v}{c} \sin \phi. \tag{2}$$

As the signal received from a source is a phase delay, converting time delay to phase delay in Eq. (2) gives

$$\Delta \psi = 2\pi \frac{c}{\lambda} \tau_{\phi} = 4\pi \frac{D_v}{\lambda} \sin \phi.$$
(3)

The additional factor of 2 accounts for the two directions in the transmit-receive path of the signals. The elevation angle is recovered from phase delay by solving for ϕ in Eq. (3)

$$\phi = \sin^{-1} \frac{\lambda}{4\pi D_v} \Delta \psi. \tag{4}$$

For an array that is dense in elevation, such that baselines are of $D_v \leq \frac{\lambda}{4}$, Eq. (4) is sufficient to compute the unambiguous elevation angle of a source from a single baseline. For arrays with larger baselines, common interferometric techniques can be used to solve fringe pattern ambiguity using multiple baselines, temporal, or band information [5].

Inevitably, there is noise in $\Delta \psi$, which affects the computed elevation angle ϕ . As measurement noise increases, elevation accuracy decreases. The accuracy of ϕ is therefore dependent on the signal-to-noise ratio (S/N) of the signal measurement, which is determined by factors including the brightness of the source, the integration length used in the image formation process, and noise in the imaging system hardware. Source properties cannot be controlled and system properties are fixed, so their effects on S/N cannot be mitigated. S/N is improved with long integration lengths in SAR measurements, which then improves elevation accuracy. S/N is further improved by incorporating signal information from multiple VXs, using the average phase delay across multiple vertical baselines for $\Delta \psi$ in Eq. (4). When N vertical baselines are used, S/N is improved by a factor of \sqrt{N} .

B. 3D Mapping

In SAR processing, there is rotational invariance about the synthetic aperture [4]. This projects elevation along the range dimension. Each 3D source is projected into the SAR image space, which is a 2D range-azimuth projection space represented by the horizontal (u, v) plane. The source's projected position in range-azimuth space is different from its position in 2D Cartesian space (x, y) as visualized in Figure 2. As elevation angle increases, the difference in position is more prominent, with the projected position of a 3D source further from its 2D Cartesian position. Each source must be de-projected from range-azimuth space in order to correctly combine elevation with range and azimuth.

Combining the range-azimuth signal information from the SAR image with the elevation information from the interferometric measurement forms a 3D view of the surroundings of a vehicle. This corresponds to a spherical 3D coordinate representation, with range r, azimuth θ , and elevation ϕ . We transform this spherical coordinate representation to SARspecific Cartesian coordinates (s_x, s_y, s_z) in order to visualize the scene with a 3D point cloud

$$s_x = r\cos\theta, s_y = r\sin\theta\cos\phi, s_z = r\sin\theta\sin\phi.$$
(5)

This process takes advantage of SAR imaging to increase azimuth resolution. Furthermore, and most importantly, the improved S/N and source isolation in the SAR image produces a high-fidelity elevation fit with the elevation extracted with the real array.

Fig. 2. Projection Effect: A 3D source at Cartesian coordinates (s_x, s_y, s_z) with range r, azimuth θ and elevation ϕ is projected to position (s_u, s_v) in range-azimuth (u, v) space. As elevation increases, the projected position is further out than its 2D Cartesian position (s_x, s_y) .

III. EXPERIMENTAL SETUP AND PROCESSING

We apply this approach to agricultural and urban driving scenes, which are primary environments for automotive radar sensors. Two radar sensor arrays were mounted on a compact car. Each radar was positioned near the front edge of the vehicle and oriented at 45 degrees from the front. This configuration provided 180 degree azimuth coverage across the front of the vehicle. SAR images were generated independently for both the left and right radar sensors and merged to form images covering the full FOV. An interferometric processing scheme based on the signal model described in Section II was used to extract the elevation map and 3D point cloud. Processing time for each image is under one second, with minimal computational cost, making this approach well-suited for future use in real-time automotive InSAR.

A. Radar Array

The radar sensor front ends use a TI AWR1243BOOST evaluation board. The AWR1243 operates in the 76–81 GHz band and supports 3 TXs and 4 RXs to generate up to 12 VXs in single-sensor mode. The array configuration of the TXs and RXs on the evaluation board forms a dense virtual array as shown in Figure 3. The virtual array has two elevation layers spaced $\lambda/4$ apart. Each three-patch microstrip antenna element provides a wide FOV in azimuth (78 degrees at half power) and elevation (40 degrees at half power).

Time-division multiplexing MIMO (TDM MIMO) coding scheme was used to cycle through the 3 TXs. TDM MIMO simplifies processing and maximizes dynamic range but limits the maximum velocity. To use TDM MIMO, we limit our driving velocity to 20 mph (9 m/s). Extensions to higher driving speeds will be discussed in Section V.

We used a modulation scheme optimized for SAR imaging in urban and agricultural environments. Each chirp was sampled with 512 samples at a rate of 18.75 Msps. The total chirp bandwidth was 820 MHz (27.3 μ s pulse length with a 30 MHz/ μ s ramp slope). The maximum range was 93.7 m with a

Fig. 3. Radar Array: TI AWR1243BOOST array consists of 4 RX (blue squares) and 3 TX (orange diamonds) antenna elements. Antenna elements form a dense, 2-elevation layer virtual array of VXs (green circles).

range resolution of 18.3 cm. The pulse repetition interval (PRI) was 63.9 µs from chirp to chirp, thus for 3 TX TDM coding the effective PRI was 191.7 µs. Chirp frames were structured to produce 256 chirps per TX with minimal idle time between frames to approximate regular sampling between frames. The modulation center frequency was $f_c = 77.4$ GHz resulting in a mean wavelength of $\nu_c = 3.87$ mm, the value used in determining the elevation baseline D_{ν} .

For accurate SAR processing, we use an off-the-shelf GPS IMU sensor to localize the relative ego-vehicle position to sub-wavelength accuracy [14]. Our acquisition system utilizes a common timestamp using the GPS signal to assign position information to each chirp. Our acquisition system offers two acquisition modes, a raw data recorder and a real-time SAR imaging system. For this experimental setup we used the raw data recorder, which captures the unprocessed ADC samples, timestamps, and GPS IMU information to file to be processed offline. We will discuss performing this approach in real time in Section V, which would be possible with little additional computational cost.

B. SAR Imaging

SAR images are formed per VX on the real array using the Fast Back-Projection (FBP) algorithm [4]. We use standard approximations in SAR imaging, and make the start-stop approximation across the complete TDM cycle. We image over a 1 m aperture, empirically chosen to balance maximizing the aperture length while minimizing the GPS IMU errors. For each VX, a 30 m x 30 m image is formed with a pixel resolution of 4 cm to oversample the range resolution. Each pixel is complex-valued, maintaining crucial phase information for the interferometric measurement.

S/N is improved by incorporating signal information from multiple VXs simultaneously in FBP. Furthermore, interferometric measurements from multiple vertical baselines are averaged to increase S/N. This utilizes the maximum number of VXs possible in our radar array (Figure 3).

C. Elevation Mapping and Processing

After SAR image formation, elevation is extracted from the interferometric measurement by applying Equation (4). Elevation is then combined with the range and azimuth information at each SAR image pixel to form a 3D representation of the scene. This initial cluster of points has no distinction between signal from real sources or noise. Noise and spurious effects are inevitable since data is acquired in real automotive environments. To extract scene structure, we use a custom series of signal processing operations, highlighting high-S/N information from strong sources, corresponding to real features, while suppressing low-S/N information from noise.

An S/N threshold of 15 dB separates real sources from noise. We compute S/N by comparing per-pixel signal magnitude to the median signal across the scene, as the median is more robust to outliers than the mean for large data. Since multiple baselines were averaged to improve S/N, points are further filtered based on phase variations across the VXs in these baselines. Removing these high variation points suppressed false arcing structures from strong point responses.

The radar has high sensitivity to close-range objects. Elevation angles exceeding 45 degrees were removed, based on the largest angles for typical scene objects and the radar FOV. The close-range sensitivity resulted in a constant cluster of points appearing in front of the car. This cluster was removed with a minimum radius cutoff of 2 meters and an azimuth cutoff of \pm 15 degrees from the front. Due to multiple path effects and reflections from the ground, some points accumulated phase corresponding to points underground, which cannot be detected in our environment and with our experimental setup. A minimum elevation threshold was used to remove points that appeared underground.

After signal post-processing, the spherical coordinate representation is transformed to Cartesian coordinates using Equation (5). The resulting points in the scene are stored in a point cloud [15]. Point clouds are visualized using PCL Tools [16].

D. Accuracy Test

To validate our elevation mapping approach in a controlled environment, we set up a simple scene in a test chamber to study the accuracy. We placed one radar array on a tabletop rail system, mounted perpendicular to the direction of travel and formed a 1 m aperture. All other acquisition parameters are as described in Section III-A.

This simple scene contained two high Radar Cross Section (RCS) corner reflectors. One reflector was placed on the ground and the other reflector was placed behind it on a tripod mount with an extended arm and adjustable height. We tested two height positions for the reflector mounted on the tripod: 33 cm and 63 cm. The SAR image corresponding to this scene with the mounted reflector at 63 cm is shown in Figure 4a. An absorber structure surrounds the two reflectors. The scene also contains overhead tube lights, a desk chair, a computer monitor, and a window.

Figure 4b shows the 2D Cartesian projection of the scene, where points are colored by elevation in meters. 0 m corresponds to ground elevation. We can see the objects in the room are well localized in elevation. Each object in the room is outlined with a colored box and a corresponding label. The mounted reflector is outlined with a gray box. When the mounted reflector was placed at 33 cm, the measured elevation with our elevation mapping approach was 33.9 cm. When the mounted reflector was placed at 63 cm, the measured elevation with our elevation mapping approach was 62.8 cm.

Fig. 4. Reflector Accuracy: a) SAR log magnitude image of test scene with two reflectors. b) 2D projection map with points colored by elevation in meters. One reflector is placed on the ground and the other is placed on a mount at either 33 cm or 63 cm. This projection map corresponds to the 63 cm case. Other objects in the scene include an absorber structure around the reflectors, tube lights, a desk chair, a window, and a computer monitor, each labeled with a colored box.

The reflector on the ground is outlined with a black box. The center of this reflector is 5 cm off of the ground, and the measured elevation with our elevation mapping approach was 6.4 cm. The extended objects in the room also have sensible elevations. The tube lights are above 2 m, the desk chair is up to 1 m, the computer monitor on the ground is below 0.5 m, the window edge is at around 1 m, and the absorber structure is at maximum brightness at the table height as that is the antenna boresight.

IV. RESULTS AND ANALYSIS

We apply this approach to agricultural and urban driving scenes. For the agricultural use case, we demonstrate driving through a vineyard on a poorly-paved road. For the urban use case, we show a typical driving scene: an intersection in a dense environment with other vehicles, buildings, and trees. For each use case, we display a camera view of the scene and a high-resolution SAR image. We generate a 2D Cartesian projection of the 3D scene representation by using the elevation mapping procedure outlined in Section III and projecting across z. In the 2D Cartesian projection, an elevation of 0 m corresponds to the mounted position of the radar arrays on the vehicle, which is slightly above ground.

A. Agricultural Driving

The camera view of the agricultural scene is shown in Figure 5a. There are rows of grapevines on both sides of the road, a person crouching next to the road on the right, and clusters of taller trees among the grapevines on the left. Figure 5b shows the high-resolution log-magnitude SAR image. The rows of grapevines are bright vertical lines and trees are round clusters, both in green. Both trees and grapevines cause strong point response and projection effects, producing arcing structures.

Figure 5c contains the 2D Cartesian projection image, where points are colored by elevation in meters. The grapevines have consistent elevation of approximately 1.5 m, with clusters of trees represented by blue and green points at higher elevation than the grapevines. The point response and projection artifacts that appear in the SAR image are corrected. Points at higher elevation are more concentrated and arcing artifacts on points in the grapevines are reduced.

Figure 5d highlights insets from the 3D point cloud of this scene. The purple box on the left contains the cluster of trees from the left corner in the camera view in Figure 5a. The grapevines surrounding the trees are at consistent elevation, represented by red and orange points. The tree trunks appear as thin columns in the center, colored by red and orange, with branches outlined by yellow and green points that reach upwards. The blue box in the middle isolates the person crouching next to the grapevines. The dark red points clustered in the center correspond to the person, with yellow points for the grapevines on the right and the grapevine branch reaching out behind the person. The orange box on the right shows the rows of grapevines on the right side of the road. Each row of grapevines has consistent elevation, with yellow points at the top. At the ends of the rows there are scattered green points from stray grapevine branches, and the irrigation systems and weeds on the ground are represented with dark red clusters.

In this agricultural scene we demonstrate successful and consistent extraction of elevation. The long-range capabilities of SAR are highlighted by the many vineyard rows with consistent elevation, even though the number of high-S/N points decrease further from the sensors. The elevations of features in the scene, such as grapevines, are as expected. Trees are clearly separated from the vineyard rows below. Small details that are close together, such as the person in front of the grapevine, are distinguishable but push the limits of the single source per range-azimuth bin approximation.

B. Urban Driving

The camera view of the urban scene is shown in Figure 6a. There is a four-way intersection with parked cars, trees, poles, curbs, and a tall building with pillars and grids of windows. Figure 6b shows the high-resolution log-magnitude SAR image. The outlines of parked cars are visible. Thin lines denote sidewalks and curbs, sharp right-angled structures are building features, and diffuse clusters are trees.

Fig. 5. Vineyard Scene: a) Camera view containing features of interest including rows of grapevines, trees, and a person. b) SAR log magnitude image. c) 2D projection map with points colored by elevation in meters and boxes around regions of interest. d) Point cloud renderings of regions of interest. Points colored by elevation according to the color scale in c). The left purple box contains a cluster of trees with visible tree trunks, appearing above the rows of grapevines. The middle blue box contains a person kneeling down next to the grapevines. The right orange box contains rows of grapevines.

Figure 6c displays the 2D Cartesian projection image, in which points are colored by elevation in meters. Cars have consistent elevations around 1 m, tree branches appear starting at 2 m, and the two-story building is around 5 m, which are all reasonable elevations for the objects. With the S/N threshold, there are fewer points captured for fine features such as sidewalks and curbs, but those captured points are correctly located on the ground.

In Figure 6d, insets from the urban scene are highlighted. The purple box on the left displays the side of the two-story brown building visible on the left side of Figure 6a. The grid of pillars and windows are represented by the vertical columns that reach from the ground (in red) to the top of the building (in dark blue). The protrusion of each pillar in front of the windows is captured. In the front of this inset is a red and yellow cluster representing the end of the car and the telephone pole next to it. Red points on the side correspond to the ramp and bike next to the building. The blue box in the middle displays a zoom in on the white car and stop sign on the left side of the intersection, with a tree reaching above the car. These sources are not completely visible in the camera view in Figure 6a, but are clearly captured in the SAR image in Figure 6b. The car is the rounded red and yellow cluster. The yellow and green points are the large tree branch reaching over the car and out towards the road, with a branch bending down to the right of the car. The orange box on the right contains three cars, a curb, a pole, and a tree. This inset is rotated 90 degrees counterclockwise relative to the camera view for better point cloud visualization. The three red and yellow clusters corresponding to cars have consistent elevation. The detailed outline of each car is correctly captured, with the roof in yellow and the hood in red. Next to the first car, a right-angled structure of dark red points at ground level corresponds to a garden bed with weeds on the sidewalk. Next to the middle car, there is a tree in the garden bed, represented by the cluster of yellow and green points, at higher elevation than the cars. Sections of the curb next to the main road are captured in the bottom left of the inset, with a thin yellow line corresponding to the pole, and the yellow cluster corresponding to the corner of the tan-colored building.

This scene shows isolation of sources in a detailed, largerange scene with lots of information. There are many objects and structures that result in complex interactions, reducing the number of high-S/N signal points extracted. With fewer points, some details such as small curbs are not fully outlined. However, there are more complicated features available in this urban scene than in the agricultural scene, and many objects and details are extracted clearly, such as the cars and tree in the right inset in orange in Figure 6d. Separation of objects that are close together, such as the car and tree above in the middle inset in blue in Figure 6d, is limited due to the single source per range-azimuth bin approximation. We successfully produced detailed elevation maps of a car's drivable region for multiple use cases.

V. CONCLUSION

We have shown that Interferometric SAR processing can be used to enhance the elevation accuracy and S/N of off-theshelf radar arrays used in common human-scale autonomous vehicle environments such as agricultural processing and urban driving. We demonstrated high-quality automotive elevation mapping with InSAR, forming 3D point cloud representations of urban and agricultural environments using a simple, interpretable, and low computational cost processing approach. This is a new application of InSAR, accounting for the complex trajectories and vehicle dynamics that are associated with driving in diverse automotive environments.

This approach can easily be incorporated in a real-time SAR imaging system [4]. In this work, we processed captured data offline. Applying our elevation mapping procedure took less than one second per SAR image frame. Optimizing the computation of each phase extraction and signal filtering operation will provide further improvements to computation speed. Using this approach in real time will provide a low-latency point cloud of static objects. Static object point clouds, combining elevation information with enhanced azimuth resolution from SAR, would be an excellent starting point to providing a drivable area occupancy grid for perception and inference in autonomous driving [17], [18]. The point cloud produced in our approach is primarily of stationary objects because moving objects are well-filtered in SAR images. Traditional range-Doppler processing [19] would complement our SAR processing approach by providing detection and localization of moving objects.

The low elevation resolution in our array is a dominant limiting factor for our elevation accuracy. In our controlled environment studies, we were able to localize nearby objects to centimeter-level accuracy even with the low elevation resolution. This is because the accuracy is related to the aperture size and the S/N of the object. In the on-vehicle tests, the range of objects was extended leading to lower S/N and lower accuracy. We used a manufacturer-supplied radar array optimized for simplicity and azimuth resolution. This is not the ideal array for our approach, as the azimuth resolution is dominated by the synthetic aperture response. A more optimal array design would primarily focus on elevation resolution. For the most flexibility in use, the ideal array would still maintain some azimuth resolution to enable moving object tracking with traditional range-Doppler processing.

With a higher elevation resolution array, we would expect vibrations of the array (e.g. due to rough roads) to become a limiting factor. Elevation accuracy would be improved by modeling vibration patterns and using an array geometry with a larger physical elevation aperture.

For our experimental set up we used TDM MIMO as a simple form of MIMO coding. This limits the maximum velocity of the vehicle before aliasing artifacts start appearing in the SAR image. A natural extension of this work is to use a coded MIMO scheme. This would have the benefit of extending the maximum velocity and potentially increasing sensitivity over a fixed aperture.

We used a simple phase difference model to determine the elevation angles for each SAR image pixel. This model used only the vertical baselines in an array. Using baselines with various orientations in a generalized approach could further enhance elevation resolution and sensitivity. Furthermore, our

Fig. 6. Urban Scene: a) Camera view containing features of interest including cars, trees, and buildings. b) SAR log magnitude image. c) 2D projection map with points colored by elevation in meters and boxes around regions of interest. d) Point cloud renderings of regions of interest. Points colored by elevation according to the color scale in c). The left purple box contains a car, electrical post, and a building section with regularly-spaced pillars. model made the approximation of a single source per rangeazimuth bin. This approximation held for most portions of the agricultural and urban environments, but had limitations for objects that were close together, such as the person next to the grapevine in Figure 5d and the car and tree in Figure 6d. A more advanced model, such as maximum likelihood estimation or iterative deconvolution [20], could be used in order to fit and resolve multiple sources per range-azimuth bin.
