arXiv:2501.13092v1 [cs.IT] 22 Jan 2025 [arXiv:2501.13092v1 \[cs.IT\] 22 Jan 2025](http://arxiv.org/abs/2501.13092v1)

*Abstract*— The min-sum approximation is widely used in the decoding of polar codes. Although it is a numerical approximation, hardly any penalties are incurred in practice. We give a theoretical justification for this. We consider the common case of a binary-input, memoryless, and symmetric channel, decoded using successive cancellation and the min-sum approximation. Under mild assumptions, we show the following. For the finite length case, we show how to exactly calculate the error probabilities of all synthetic (bit) channels in time  $\mathcal{O}(N^{1.585})$ , where N is the codeword length. This implies a code construction algorithm with the above complexity. For the asymptotic case, we develop two rate thresholds, denoted  $R_{\text{L}} = R_{\text{L}}(\lambda)$  and  $R_{\text{U}} = R_{\text{U}}(\lambda)$ , where  $\lambda(\cdot)$  is the labeler of the channel outputs (essentially, a quantizer). For any  $0 < \beta < \frac{1}{2}$  and any code rate  $R < R_{\text{L}}$ , there exists a family of polar codes with growing lengths such that their rates are at least  $R$  and their error probabilities are at most  $2^{-N^{\beta}}$ . That is, strong polarization continues to hold under the min-sum approximation. Conversely, for code rates exceeding  $R_U$ , the error probability approaches 1 as the codelength increases, irrespective of which bits are frozen. We show that  $0 < R_{\text{L}} \le R_{\text{U}} \le C$ , where C is the channel capacity. The last inequality is often strict, in which case the ramification of using the min-sum approximation is that we can no longer achieve capacity.

## I. INTRODUCTION

Polar codes are a family of capacity-achieving error correcting codes with efficient encoding and decoding algorithms, introduced by Arıkan [\[1\]](#page-7-0). In this paper, we study the setting of a binary-input, memoryless and symmetric channel. Although many generalizations to this case exist  $[2]$ – $[16]$ , it is arguably the most basic and common one. Moreover, it affords a very efficient hardware implementation using the numerical minsum approximation (MSA) in the decoder.

The seminal decoding algorithm of polar codes is called successive-cancellation (SC) decoding. It is a recursive algorithm that makes repeated use of the following two functions:

$$
f(L_a, L_b) = 2 \tanh^{-1} \left( \tanh \left( \frac{L_a}{2} \right) \cdot \tanh \left( \frac{L_b}{2} \right) \right) , (1)
$$

$$
g_u(L_a, L_b) = (-1)^u \cdot L_a + L_b . \tag{2}
$$

The functions  $g_0$  and  $g_1$  are simple to implement, since addition and subtraction are hardware-friendly operations. However, the  $f$  function is somewhat complicated, since hyperbolic functions are expensive in terms of calculation time and power consumption. Therefore, in many practical implementations the MSA is used [\[17\]](#page-8-1). That is, similar to what is done in LDPC

<span id="page-0-0"></span>Fig. 1. The capacity C and the thresholds  $R_U$  and  $R_L$  of a BI-AWGN with 3-bit quantized output. For reference, the capacities of the corresponding nonquantized BI-AWGN and AWGN are also given.

decoder implementation  $[18]$ , the f function is replaced with a simpler function  $f$  given by

$$
\tilde{f}(L_a, L_b) = \text{sgn}(L_a) \cdot \text{sgn}(L_b) \cdot \min\{|L_a|, |L_b|\}, \quad (3)
$$

where  $sgn(\cdot)$  is the sign function defined as

<span id="page-0-1"></span>
$$
sgn(x) \triangleq \begin{cases} 1 & \text{if } x > 0, \\ -1 & \text{if } x < 0, \\ 0 & \text{if } x = 0. \end{cases}
$$

<span id="page-0-2"></span>For the non-approximated setting,  $L_a$ ,  $L_b$ , and the outputs of  $f$  and  $g$  are log-likelihood ratios (LLRs) corresponding to certain channel outputs. For the approximated setting, we use the generalized term 'labels' for the corresponding quantities. At the base of the recursion the labels  $L_a$  and  $L_b$  are obtained by applying a labeling function  $\lambda(\cdot)$  on the channel outputs. The full definition of  $\lambda(\cdot)$  is given in Section [II.](#page-1-0) Informally,  $\lambda(y)$  is a quantized version of the LLR corresponding to the channel output y, up to a positive scaling constant.

The MSA is also used in decoders that are derivatives of the SC decoder, such as the SC list decoder [\[19\]](#page-8-3) and the SC stack decoder [\[20\]](#page-8-4). Often, the MSA incurs only a small penalty in

<span id="page-1-1"></span>Fig. 2. The capacity C and the thresholds  $R_U$  and  $R_L$  for the BSC(p).

error rate [\[21,](#page-8-5) Figure 7], [\[22,](#page-8-6) Figures 7-8], and [\[23,](#page-8-7) Figure 4]. In this paper, we analyze this phenomenon.

The following theorem is our main result for the asymptotic case. The theorem promises two rate thresholds,  $R_L$  and  $R_{\rm U}$ , when employing the MSA in SC decoding. Below  $R_{\rm L}$ , strong polarization is guaranteed, while above  $R_U$  the error probability approaches 1. Figures [1](#page-0-0) and [2](#page-1-1) plot these thresholds and the channel capacity  $C$  for the binary-input additive white Gaussian noise (BI-AWGN) channel with quantized output, and for the binary symmetric channel (BSC), respectively. As can be seen in these figures,  $R_L$ ,  $R_U$ , and C are all rather close. However, note that  $R_U$  is strictly smaller than C. That is, in these cases using the MSA means that we can no longer achieve capacity. The theorem assumes that a "fair labeler" is used, as defined in Definition [2](#page-2-0) below.

<span id="page-1-5"></span>Theorem 1. *Let* W *be a binary-input, memoryless and symmetric channel. Fix*  $0 < \beta < \frac{1}{2}$ . Let  $\lambda(\cdot)$  *be a fair labeler. Then, there exist thresholds*  $R_{\text{L}} = R_{\text{L}}(\lambda)$  *and*  $R_{\text{U}} = R_{\text{U}}(\lambda)$ *, such that*  $0 < R_L \leq R_U$ *. When using SC decoding and the MSA, the following holds. For any code rate* R < R<sup>L</sup> *there exists a family of polar codes with growing length* N *such that their rates are at least* R *and their word error probabilities* are at most  $2^{-N^{\beta}}$ . Conversely, for code rates exceeding  $R_{\text{U}}$ , *the word error probability approaches* 1 *as the code-length increases, irrespective of which bits are frozen.*

If we only assume a fair labeler,  $R_L$  is weak but still positive, and  $R_U$  is trivial. For a significant subset of fair labelers, "good labelers" (see Definition [1\)](#page-2-1), both bounds can be significantly strengthened. The good labeler case is often the case in practice.

For the finite-length case and the good labeler setting, we develop an algorithm for calculating the exact error probability of each min-sum synthetic channel, defined in [\(9\)](#page-2-2). The running time of our algorithm is  $\mathcal{O}(N^{1.585})$ . Note that in the nonapproximated setting, no such algorithm exists, only a method

<span id="page-1-0"></span>to calculate bounds on the error probabilities [\[24\]](#page-8-8).

### <span id="page-1-6"></span>II. NOTATION

Denote by  $W : \mathcal{X} \to \mathcal{Y}$  a general binary-input, memoryless, and symmetric channel with input alphabet  $\mathcal{X} = \{0, 1\}$  and output alphabet *Y*. For each pair  $x \in \mathcal{X}$  and  $y \in \mathcal{Y}$  the input probability is  $p(x)$ , and the transition probability is  $W(y|x)$ . Hence, the joint probability is given by  $W(y; x) = p(x)$ .  $W(y|x)$ . We will assume that  $p(x)$  is symmetric, i.e.  $p(0) =$  $p(1) = 1/2.$ 

For  $n \in \mathbb{N}$  denote  $N = 2^n$  and let  $(X_i, Y_i)_{i=0}^{N-1}$  be N i.i.d. pairs, each distributed according to  $W(y; x)$ . Denote by  $U_0^{N-1}$  the polar transform of  $X_0^{N-1}$ . For  $0 \le i < N$ , define the following synthetic joint distribution<sup>[1](#page-1-2)</sup>:

$$
W_N^{(i)}(y_0^{N-1}, u_0^{i-1}; u_i) =
$$
  
Pr(Y\_0^{N-1} = y\_0^{N-1}, U\_0^{i-1} = u\_0^{i-1}, U\_i = u\_i). (4)

By [\[1,](#page-7-0) Propostion 3],

$$
W_N^{(2j)}\left(y_0^{N-1}, u_0^{2j-1}; u_{2j}\right) = \n\sum_{u_{2j+1}} W_{N/2}^{(j)}\left(y_0^{\frac{N}{2}-1}, u_{0,e}^{2j-1} \oplus u_{0,o}^{2j-1}; u_{2j} \oplus u_{2j+1}\right) \n\cdot W_{N/2}^{(j)}\left(y_\frac{N}{2}^{N-1}, u_{0,o}^{2j-1}; u_{2j+1}\right),
$$
 (5)

and

$$
W_N^{(2j+1)}\left(y_0^{N-1}, u_0^{2j}; u_{2j+1}\right) =
$$
  
\n
$$
W_{N/2}^{(j)}\left(y_0^{\frac{N}{2}-1}, u_{0,e}^{2j-1} \oplus u_{0,o}^{2j-1}; u_{2j} \oplus u_{2j+1}\right)
$$
  
\n
$$
\cdot W_{N/2}^{(j)}\left(y_{\frac{N}{2}}^{N-1}, u_{0,o}^{2j-1}; u_{2j+1}\right), \quad (6)
$$

where  $W_1^{(0)}(y;x) = W(y;x)$  and "⊕" is addition over GF(2). In the above,  $u_{0,e}^{2j-1}$  and  $u_{0,o}^{2j-1}$  are the even and odd entries of  $u_0^{2j-1}$ , respectively. As shown in [\[1\]](#page-7-0),  $W_N^{(2j)}$  and  $W_N^{(2j+1)}$  are the result of applying the "−" and "+" transforms, respectively, on  $W_{N}^{(j)}$  $N/2$ , up to a relabeling of the output.

For each joint distribution  $W_N^{(i)}$  we define the LLR  $L_N^{(i)}$  as

<span id="page-1-4"></span><span id="page-1-3"></span>.

$$
L_N^{(i)}\left(y_0^{N-1}, u_0^{i-1}\right) \triangleq \log_2\left(\frac{W_N^{(i)}\left(y_0^{N-1}, u_0^{i-1}; u_i = 0\right)}{W_N^{(i)}\left(y_0^{N-1}, u_0^{i-1}; u_i = 1\right)}\right)
$$

Using the relations described in  $(5)$  and  $(6)$  we obtain recursive transforms for the LLRs. Namely, these are  $(7a)$  and  $(7b)$ below, once we remove all the tildes. The starting condition for this recursion is  $L_1^{(0)}(y) = \log_2(W(y; 0) / W(y; 1)).$ 

The SC decoder uses  $f$  and  $g$  to recursively calculate the LLRs of all synthetic joint distributions, yielding a decoding algorithm with running time  $\mathcal{O}(N \log N)$ .

The min-sum SC decoder is a simplified version of the original SC decoder, as it uses  $\tilde{f}$  (see [\(3\)](#page-0-1)) instead of the computationally heavier  $f$  during the recursion. Unlike  $f$ , both  $f$  and  $g$  are positive homogeneous (i.e. multiplying

<span id="page-1-2"></span><sup>&</sup>lt;sup>1</sup>We find it notationally easier to track joint distributions instead of channels. The latter is simply obtained from the former by multiplying by 2.

both inputs by a positive constant multiplies the output by the same constant). This implies that the min-sum decoder is not affected by scaling. Therefore, we further extend the approximation and allow the initial labels at the base of the recursion not to be LLRs, but some values obtained by applying a labeling function  $\lambda$  on the channel outputs. We now list 3 properties required of a labeler  $\lambda$  to be called a "good labeler".

**Definition 1** (Good labeler). A labeler  $\lambda : \mathcal{Y} \to \mathbb{R}$  is a good labeler with respect to a binary-input memoryless symmetric channel  $W : \mathcal{X} \to \mathcal{Y}$  if the following holds:

- 1) Symmetry preservation: since  $W$  is symmetric, there exists a permutation  $\pi : \mathcal{Y} \to \mathcal{Y}$  such that for all  $y \in \mathcal{Y}$ ,  $W(y|1) = W(\pi(y)|0)$  and  $\pi(\pi(y)) = y$ . We require that  $\lambda(\pi(y)) = -\lambda(y)$  for all  $y \in \mathcal{Y}$ .
- <span id="page-2-11"></span>2) Sign consistency: for all positive t we have  $\alpha_t \geq \alpha_{-t}$ , where  $\alpha_t = \sum_{y: \lambda(y)=t} W(y|0)$ , and the inequality is strict for at least one  $t$ .
- <span id="page-2-1"></span>3) Finite integer range: the range of  $\lambda$  is contained in  ${-\gamma, -\gamma + 1, \ldots, \gamma - 1, \gamma}$ , for some positive integer γ.

<span id="page-2-0"></span>We also define a "fair labeler" as follows.

**Definition 2** (Fair labeler). A labeler  $\lambda$  is a fair labeler if the first two requirements of a good labeler are met.

Note that if we were to take  $\lambda(y) = LLR(y)$ , we would have a fair labeler, for any channel with positive capacity. The last property of the good labeler is required only for computational reasons, and is often the case due to quantization. The justification for it is by the homogeneous property of  $f$  and  $g$ and its implications, as described above.

Under the MSA, labels are calculated recursively by

<span id="page-2-7"></span>
$$
\tilde{L}_{N}^{(2j)}\left(y_{0}^{N-1}, u_{0}^{2j-1}\right) = (7a)
$$
\n
$$
\tilde{f}\left(\tilde{L}_{N/2}^{(j)}\left(y_{0}^{N/2-1}, u_{0,e}^{2j-1} \oplus u_{0,o}^{2j-1}\right), \tilde{L}_{N/2}^{(j)}\left(y_{N/2}^{N-1}, u_{0,o}^{2j-1}\right)\right),
$$
\n
$$
\tilde{L}_{N}^{(2j+1)}\left(y_{0}^{N-1}, u_{0}^{2j}\right) = (7b)
$$
\n
$$
g_{u_{2j}}\left(\tilde{L}_{N/2}^{(j)}\left(y_{0}^{N/2-1}, u_{0,e}^{2j-1} \oplus u_{0,o}^{2j-1}\right), \tilde{L}_{N/2}^{(j)}\left(y_{N/2}^{N-1}, u_{0,o}^{2j-1}\right)\right),
$$

with starting condition  $\tilde{L}_1^{(0)}(y) = \lambda(y)$ .

## III. POSYNOMIAL REPRESENTATION

For a fair labeler, we now define the synthetic joint distributions (on the label t and input  $u_i$ ) at stage i of the SC decoder and min-sum SC decoder. These are, respectively,

$$
Q_N^{(i)}(t; u_i) \triangleq \sum_{\substack{y_0^{N-1}, u_0^{i-1}: \\ L_N^{(i)}(y_0^{N-1}, u_0^{i-1}) = t}} W_N^{(i)}(y_0^{N-1}, u_0^{i-1}; u_i), \quad (8)
$$
  

$$
\tilde{Q}_N^{(i)}(t; u_i) \triangleq \sum_{y_0^{N-1}, u_0^{i-1}:} W_N^{(i)}(y_0^{N-1}, u_0^{i-1}; u_i). \quad (9)
$$

 $\tilde{L}^{(i)}_N(y_0^{N-1},u_0^{i-1}){=}t$ 

Denote by  $\tilde{\mathcal{T}}_{N}^{(i)}$  the support of  $\tilde{Q}_{N}^{(i)}(t; u_i)$  with respect to t. In the setting of a good labeler, by definition,  $\tilde{\mathcal{T}}_1^{(0)} \triangleq$  ${-\gamma, \ldots, \gamma}$ . As will soon become apparent, under this setting,

<span id="page-2-9"></span><span id="page-2-5"></span>
$$
\tilde{\mathcal{T}}_N^{(i)} \triangleq \{-2^{\text{wt}(i)} \cdot \gamma, \dots, 2^{\text{wt}(i)} \cdot \gamma\},\tag{10}
$$

and  $wt(i)$  is the Hamming weight of the vector whose entries are the binary representation of i. Indeed, this follows by  $(11a)$ and [\(11b\)](#page-2-6) below, and the definitions of  $\hat{f}$  and  $g$  in [\(3\)](#page-0-1) and [\(2\)](#page-0-2).

Using the relations in  $(5)-(7)$  $(5)-(7)$  $(5)-(7)$ , we obtain the following minus and plus transforms of synthetic min-sum joint distributions.

Lemma 2 (Transforms of synthetic joint distributions).

$$
\tilde{Q}_{N}^{(2j)}(t; u_{2j}) = (11a)
$$
\n
$$
\tilde{Q}_{N}^{(2j)}(t; u_{2j+1}) = \tilde{Q}_{N/2}^{(j)}(t_{a}; u_{2j} \oplus u_{2j+1}) \cdot \tilde{Q}_{N/2}^{(j)}(t_{b}; u_{2j+1})
$$
\n
$$
\tilde{Q}_{N}^{(2j+1)}(t; u_{2j+1}) = \sum_{\substack{t_{a}, t_{b}, u_{2j}: \\ t_{a}, t_{b}, u_{2j}: \\ g_{u_{2j}}(t_{a}, t_{b}) = t}} \tilde{Q}_{N/2}^{(j)}(t_{a}; u_{2j} \oplus u_{2j+1}) \cdot \tilde{Q}_{N/2}^{(j)}(t_{b}; u_{2j+1})
$$
\n(11b)

The following lemma ensures that symmetry holds for the min-sum synthetic distributions.

Lemma 3 (Symmetry of synthetic joint distribution).

<span id="page-2-6"></span>
$$
\tilde{Q}_N^{(i)}(t; u_i) = \tilde{Q}_N^{(i)}(-t; u_i \oplus 1) . \tag{12}
$$

The above symmetry implies that the probability of error at the  $i$ -th stage of the min-sum SC decoder (when aided by a genie that reveals the correct values of  $u_0^{i-1}$ ) is given by

$$
P_{\mathbf{e}}\left(\tilde{Q}_{N}^{(i)}\right) = 2 \cdot \left(\frac{1}{2}\tilde{Q}_{N}^{(i)}(0;0) + \sum_{t<0} \tilde{Q}_{N}^{(i)}(t;0)\right) .
$$
 (13)

<span id="page-2-3"></span>To derive a Bhattacharyya-like upper bound on  $P_e$ , and to aid in notation in general, we abuse notation and define the following posynomial, in the indeterminate  $\xi$ :

<span id="page-2-8"></span>
$$
\tilde{Q}_N^{(i)}(\xi) \triangleq \sum_t \tilde{Q}_N^{(i)}(t;0) \xi^t . \tag{14}
$$

<span id="page-2-4"></span>The above is indeed a posynomial: all the coefficients are nonnegative as they are probabilities, while  $t$  is not restricted to non-negative numbers. We further define the following:

$$
Z\left(\tilde{Q}_N^{(i)}, \xi\right) \triangleq 2 \cdot \tilde{Q}_N^{(i)}(\xi) \ . \tag{15}
$$

<span id="page-2-10"></span>Our upper bound on  $P_e$  is presented in the following lemma.

**Lemma 4** (Bhattacharyya-like bound). *For*  $0 < \xi_0 \leq 1$ ,

$$
P_{\mathbf{e}}\left(\tilde{Q}_{N}^{(i)}\right) \le Z\left(\tilde{Q}_{N}^{(i)}, \xi_{0}\right) \tag{16}
$$

<span id="page-2-2"></span>We remark that setting  $\xi_0 = 1/\sqrt{2}$  and removing the tildes yields the Bhattacharyya bound on the error probability at the i-th stage of the non-approximated genie-aided SC decoder. Also, we may optimize over  $\xi_0$  to yield the tightest upper bound, denoted

$$
Z^{\star}\left(\tilde{Q}_{N}^{(i)}\right) \triangleq \min_{0 \leq \xi_0 \leq 1} Z\left(\tilde{Q}_{N}^{(i)}, \xi_0\right) . \tag{17}
$$

The above optimization is an instance of geometric programming, and can thus be efficiently computed  $[25, Section 4.5]$ .

The following shows that the evolution of  $Z$  and  $Z^*$  is similar to the evolution of the Bhattacharyya parameter in the non-approximated setting.

**Lemma 5** (Bhattacharyya-like evolutions). *For*  $0 < \xi_0 \leq 1$ *and*  $0 \leq j \leq N/2$  *we have* 

$$
Z\left(\tilde{Q}_{N}^{(2j)},\xi_{0}\right) \leq 2 \cdot Z\left(\tilde{Q}_{N/2}^{(j)},\xi_{0}\right),\tag{18a}
$$

$$
Z\left(\tilde{Q}_{N}^{(2j+1)},\xi_{0}\right) = \left(Z\left(\tilde{Q}_{N/2}^{(j)},\xi_{0}\right)\right)^{2}.
$$
 (18b)

*Furthermore,*

<span id="page-3-4"></span>
$$
Z^{\star}\left(\tilde{Q}_{N}^{(2j)}\right) \leq 2 \cdot Z^{\star}\left(\tilde{Q}_{N/2}^{(j)}\right) ,\qquad (19a)
$$

$$
Z^{\star}\left(\tilde{Q}_{N}^{(2j+1)}\right) = \left(Z^{\star}\left(\tilde{Q}_{N/2}^{(j)}\right)\right)^{2} . \tag{19b}
$$

To prove the above, we state the following two lemmas.

Lemma 6 (Bound on posynomial minus transform). *For all*  $0 < \xi_0 \leq 1$  *we have* 

$$
\tilde{Q}_N^{(2j)}(\xi_0) \le 2 \cdot \tilde{Q}_{N/2}^{(j)}(\xi_0) \ . \tag{20}
$$

Lemma 7 (Posynomial plus transform).

$$
\tilde{Q}_N^{(2j+1)}(\xi) = 2 \cdot \left( \tilde{Q}_{N/2}^{(j)}(\xi) \right)^2 \,. \tag{21}
$$

The previous lemma implies that the coefficients of  $\tilde{Q}_{N}^{(2j+1)}(\xi)$  can be calculated efficiently from those of  $\tilde{Q}_N^{(j)}$  $\big(\begin{array}{c} \n\frac{1}{2} \\
N/2 \n\end{array}\big)(\xi)$ . We now show an analogous result for  $\tilde{Q}_N^{(2j)}(\xi)$ . In aid of this, we define the "above" and "below" posynomials:

$$
\tilde{A}_N^{(i)}(\xi) \triangleq \sum_{t \in \tilde{\mathcal{T}}_N^{(i)}} \left( \sum_{t' > t} \tilde{Q}_N^{(i)}(t'; 0) \right) \xi^t ,\qquad (22)
$$

$$
\tilde{B}_N^{(i)}(\xi) \triangleq \sum_{t \in \tilde{\mathcal{T}}_N^{(i)}} \left( \sum_{t' < t} \tilde{Q}_N^{(i)}(t'; 0) \right) \xi^t \,. \tag{23}
$$

Namely, if we write out  $\tilde{Q}_N^{(i)}(\xi)$  in ascending order of powers of  $\xi$ , then the coefficient of  $\xi^t$  in  $\tilde{A}_N^{(i)}(\xi)$  (resp.  $\tilde{B}_N^{(i)}(\xi)$ ) is the sum of the coefficients strictly above (resp. below) the monomial  $\tilde{Q}_N^{(i)}(t;0)\xi^t$ .

Let  $\Gamma(\xi)$  and  $\Lambda(\xi)$  be two posynomials. Denote by  $\left[\xi^t\right]\Gamma(\xi)$ the coefficient of  $\xi^t$  in  $\Gamma(\xi)$ . Define the "positive" and "negative" operators, and Hadamard (element-wise) product: these operators return posynomials, where for all  $t$ ,

$$
[\xi^t] \text{ pos} \langle \Gamma(\xi) \rangle = \begin{cases} [\xi^t] \Gamma(\xi) & t \ge 0, \\ [\xi^{-t}] \Gamma(\xi) & t < 0. \end{cases} \tag{24}
$$

$$
\left[\xi^t\right] \text{ neg}\left\langle \Gamma(\xi)\right\rangle = \begin{cases} \left[\xi^t\right] \Gamma(\xi) & t \le 0 \\ \left[\xi^{-t}\right] \Gamma(\xi) & t > 0 \end{cases} \tag{25}
$$

$$
[\xi^t] \left( \Gamma(\xi) \odot \Lambda(\xi) \right) = \left( [\xi^t] \Gamma(\xi) \right) \cdot \left( [\xi^t] \Lambda(\xi) \right) . \tag{26}
$$

Lemma 8 (Posynomial minus transform).

$$
\tilde{Q}_{N}^{(2j)}(\xi) = 2\left(\tilde{Q}_{N/2}^{(j)}(\xi) \odot \text{pos}\left\langle 2\tilde{A}_{N/2}^{(j)}(\xi) + \tilde{Q}_{N/2}^{(j)}(\xi)\right\rangle\right) \n+ 2\left(\tilde{Q}_{N/2}^{(j)}(1/\xi) \odot \text{neg}\left\langle 2\tilde{B}_{N/2}^{(j)}(\xi) + \tilde{Q}_{N/2}^{(j)}(\xi)\right\rangle\right) \n- 2\left([\xi^{0}] \tilde{Q}_{N/2}^{(j)}\right)^{2}.
$$
\n(27)

# <span id="page-3-2"></span>IV. FINITE-LENGTH CASE

In this section, we assume a good labeler. For the finite length case, our aim is to calculate  $P_e\left(\tilde{Q}_N^{(i)}\right)$  $\binom{i}{N}$  for all  $0 \leq i <$ N, where the codeword length is  $N = 2<sup>n</sup>$ . The expression for this is given in  $(13)$ , which we can recast using  $(25)$  as

<span id="page-3-3"></span>
$$
P_{\mathbf{e}}\left(\tilde{Q}_{N}^{(i)}\right) = \text{neg}\left\langle \tilde{Q}_{N}^{(i)}(\xi)\right\rangle \Big|_{\xi=1} . \tag{28}
$$

We use [\(21\)](#page-3-1) and [\(27\)](#page-3-2) to calculate  $\tilde{Q}_N^{(i)}(\xi)$  for all i, and then apply [\(28\)](#page-3-3) to yield the error probability. The following two lemmas specify the complexity of calculating  $\tilde{Q}_N^{(2j)}(\xi)$ and  $\tilde{Q}_N^{(2j+1)}(\xi)$  from  $\tilde{Q}_{N/}^{(j)}$  $N/2(\xi)$ . Namely, the complexity of calculating all the coefficients of the former, given all the coefficients of the latter. Recall that  $\tilde{\mathcal{T}}_N^{(i)}$  is defined in [\(10\)](#page-2-9).

<span id="page-3-6"></span><span id="page-3-1"></span>**Lemma 9.** The complexity of calculating  $\tilde{Q}_N^{(2j)}(\xi)$  from  $\tilde{Q}_N^{(j)}$  $_{N/2}^{(j)}(\xi)$  is  $\mathcal{O}\left(|\mathcal{\tilde{T}}_{N/2}^{(j)}\right)$  $\binom{(j)}{N/2}$ *.*

<span id="page-3-7"></span>**Lemma 10.** *The complexity of calculating*  $\tilde{Q}_N^{(2j+1)}(\xi)$  *from*  $\tilde{Q}_N^{(j)}$  $_{N/2}^{(j)}(\xi)$  is  $\mathcal{O}\left(|\mathcal{\tilde{T}}_{N/2}^{(j)}\right)$  $\frac{N}{N/2}|\cdot {\rm log}(|\tilde{\cal T}^{(j)}_{N/2}|)$  $\binom{(j)}{N/2}$ .

The following theorem is our main result for this section. It shows that the complexity of calculating all the probabilities of error  $P_{\rm e}$   $\left(\tilde{Q}_N^{(i)}\right)$  $\begin{pmatrix} i \\ N \end{pmatrix}$  is polynomial in the codeword length N and in  $\gamma$  (recall Definition [1\)](#page-2-1).

Theorem 11 (Total complexity of evaluating  $P_e$ ). When using a good labeler  $\lambda$ , the complexity of calculating  $P_e\left(\tilde{Q}_N^{(i)}\right)$  $\binom{i}{N}$  for *all*  $0 \le i \le N$  *is*  $\mathcal{O}(N^{\log_2 3} \log N \cdot \gamma \log \gamma)$ *. We simplify this to*  $\mathcal{O}(N^{1.585} \cdot \gamma \log \gamma)$ *.* 

## V. ASYMPTOTIC CASE

<span id="page-3-8"></span>In this section we prove Theorem [1.](#page-1-5) We first do so assuming a fair labeler, and then show how to significantly improve the thresholds  $R_L$  and  $R_U$  for the case of a good labeler. The following three results are required for deriving  $R_{\rm L}$ .

<span id="page-3-5"></span>**Proposition 12.** Let  $B_1, B_2, \ldots$  be i.i.d. random variables *such that*  $Pr(B_i = 0) = Pr(B_i = 1) = 1/2$ *. Let*  $S_0, S_1, \ldots$ *be a* [0, 1]*-valued random process that satisfies*

$$
S_{n+1} \le \kappa \cdot \begin{cases} S_n, & B_{n+1} = 0 \\ S_n^2, & B_{n+1} = 1 \end{cases}, \quad n \ge 0. \tag{29}
$$

<span id="page-3-0"></span>*Then, for every*  $\epsilon' > 0$  *and*  $\delta' > 0$  *there exist*  $n' = n'(\epsilon', \delta', \kappa)$ and  $\eta = \eta(\epsilon', \delta', \kappa) > 0$  such that if  $S_0 \leq \eta$  then

$$
\Pr\left(S_n \le \epsilon' \text{ for all } n \ge n'\right) \ge 1 - \delta' \,. \tag{30}
$$

This is  $[26,$  Equation 171], and is the crux of proving [\[26,](#page-8-10) Proposition 49]. The expression for  $\eta$  is given in the penultimate displayed equation in  $[26,$  Appendix A], where  $r$  is defined slightly before as the largest positive solution of  $\kappa^r + (2\kappa)^{-r} = 2$ . In our setting,  $S_n$  will be related to  $Z^*$ . Thus, by [\(19\)](#page-3-4), we specialize to  $\kappa = 2$ . Plugging  $x = 2^r$  into  $2^{r} + 4^{-r} = 2$  yields  $x + 1/x^{2} = 2$ . The three roots of this equation are 1,  $\varphi$ , and  $-\varphi^{-1}$ , where  $\varphi = \frac{1}{2} \cdot (1 + \sqrt{5})$  is the golden ratio. Thus,  $r = \log_2(\varphi)$  and  $\eta(\delta') = \frac{1}{8} \cdot (\delta'/2)^{1/\log_2 \varphi}$ . The following result is an immediate corollary.

**Corollary 13.** Let  $S_0, S_1, \ldots$  be as in Proposition [12,](#page-3-5) with  $\kappa = 2$ . Fix  $\epsilon' > 0$  and  $\eta > 0$ . Then there exists  $n' = n'(\epsilon', \eta)$ *such that if*  $S_0 \leq \eta$  *then* 

$$
\Pr\left(S_n \le \epsilon' \text{ for all } n \ge n'\right) \ge 1 - \delta'(\eta) ,\qquad(31)
$$

*where*

<span id="page-4-0"></span>
$$
\delta'(\eta) \triangleq 2 \cdot (8\eta)^{\log_2(1+\sqrt{5})-1} . \tag{32}
$$

<span id="page-4-1"></span>The following result is of primary importance and will be used directly to prove Theorem [1.](#page-1-5)

**Proposition 14.** Let  $S_0, S_1, \ldots$  be as in Proposition [12,](#page-3-5) with  $\kappa = 2$ *. Fix*  $0 < \beta < 1/2$ *,*  $\eta > 0$ *, and*  $\delta > \delta'(\eta)$ *, where*  $\delta'(\eta)$  *is given in* [\(32\)](#page-4-0)*. Then, there exists*  $n_0 = n_0 (\beta, \delta - \delta'(\eta))$  *such that if*  $S_0 \leq \eta$  *then* 

<span id="page-4-2"></span>
$$
\Pr\left(S_n \le 2^{-2^{n\beta}} \text{ for all } n \ge n_0\right) \ge 1 - \delta. \tag{33}
$$

## <span id="page-4-6"></span>*A. Fair Labeler*

*Proof of Theorem [1:](#page-1-5)* For  $R_U$ , we first recall that any decoder operates on the output of  $W$ , after it has been labeled by λ. Thus, it effectively sees the channel  $\tilde{Q}(t|x) = 2 \cdot \tilde{Q}_1^{(0)}(t;x)$ , as defined in [\(9\)](#page-2-2). We take  $R_U$  as the capacity of this channel, which is valid by the strong converse to the coding theorem, see [\[27,](#page-8-11) Theorem 5.8.5].

We now work towards deriving  $R_L$ . Consider a polar code of length  $N = 2^n$  with non-frozen index set  $\mathcal{A} = \{0 \le i \le N :$  $Z^{\star}(\tilde{Q}_N^{(i)}) < 2^{-N^{\beta'}}\},$  where  $\beta' = \frac{\beta + 1/2}{2}$  $\frac{1}{2}$ . By the "genie-aided" decoder" argument in [\[1\]](#page-7-0), the union bound, and Lemma [4,](#page-2-10) the error probability of such a code is at most  $|\mathcal{A}| \cdot 2^{-N^{\beta'}} \leq$  $N \cdot 2^{-N^{\beta'}} < 2^{-N^{\beta}}$ , where the last inequality holds for  $N$ large enough. Thus, we must find an  $R_L$  such that for  $R < R_L$ fixed and all N large enough,  $|\mathcal{A}| \geq N \cdot R$ . Consider the set  $A' = \{0 \le i < N : \zeta_N^{(i)} < 2^{-N^{\beta'}}\},\$  where  $\zeta_1^{(0)} = Z^{\star}(\tilde{Q}_1^{(0)})$ and

<span id="page-4-4"></span>
$$
\zeta_N^{(i)} = \begin{cases}\n2 \cdot \zeta_{N/2}^{(i/2)} & i \text{ even,} \\
\left(\zeta_{N/2}^{((i-1)/2)}\right)^2 & i \text{ odd.} \n\end{cases}
$$
\n(34)

By [\(19\)](#page-3-4), we have for all *i* that  $\zeta_N^{(i)} \ge Z^{\star}(\tilde{Q}_N^{(i)})$ . Namely,  $\mathcal{A}' \subseteq$ A. Thus, it suffices to find an  $R_L$  such that for  $R < R_L$  fixed and all N large enough,  $|\mathcal{A}'| \ge N \cdot R$ . For any  $M = 2^m$ , we use the definition of  $\delta'(\cdot)$  in [\(32\)](#page-4-0) and define the following:

$$
R_{\rm L}(M) \triangleq \frac{1}{M} \sum_{j=0}^{M-1} \max \left\{ 1 - \delta'(\zeta_M^{(j)}), 0 \right\} \ . \tag{35}
$$

Proving the following two items will complete the proof:

- 1) For a given M and  $R < R_{\rm L}(M)$  there exists  $n_0$  such that for all  $n \ge n_0$  we have  $|\mathcal{A}'| \ge N \cdot R$ .
- 2) There exists an M such that  $R_L(M) > 0$ .

To prove the first item, assume that R, and therefore  $R_L(M)$ , are positive, otherwise the claim is trivial. For each one of the M indices  $0 \le j \le M$ , we invoke Proposition [14](#page-4-1) with  $\delta =$  $\delta'(\zeta_M^{(j)}) + (R_L(M) - R), \eta = S_0 = \zeta_M^{(j)}$ , and β'' =  $\frac{\beta' + 1/2}{2}$  $\frac{1}{2}$  in place of  $\beta$ . Denote the  $n_0$  promised by the proposition as  $n_0^{(j)}$ . Now define  $n_0^{\max} = \max_j n_0^{(j)}$ . By [\(33\)](#page-4-2), for  $n \ge m + n_0^{\max}$ the fraction of indices  $0 \le i < N$  such that  $\zeta_N^{(i)} \le 2^{-2(n-m)\beta}$ is at least

$$
\frac{1}{M} \sum_{j=0}^{M} \max \left\{ 1 - \left( \delta'(\zeta_M^{(j)}) + R_{\mathcal{L}}(M) - R \right), 0 \right\}
$$
  
\n
$$
\geq \frac{1}{M} \sum_{j=0}^{M} \max \left\{ 1 - \delta'(\zeta_M^{(j)}) - R_{\mathcal{L}}(M) + R, -R_{\mathcal{L}}(M) + R \right\}
$$
  
\n
$$
= \frac{1}{M} \sum_{j=0}^{M} \max \left\{ 1 - \delta'(\zeta_M^{(j)}), 0 \right\} - R_{\mathcal{L}}(M) + R
$$
  
\n
$$
= R.
$$

For the first item to hold, we take  $n_0 \geq m + n_{0}^{\text{max}}$  large enough such that for all  $n \ge n_0$  we have  $2^{-2(n-m)\beta''} \le 2^{-2^{n\beta'}} =$  $2^{-N^{\beta}}$  (ensuring  $|\mathcal{A}'| \ge N \cdot R$ ) and  $N \cdot 2^{-N^{\beta'}} < 2^{-N^{\beta}}$ .

We now prove the second item. That is, it is always possible to find an M such that  $R_L(M) > 0$ . We first show that  $Z^{\star}(\tilde{Q}_1^{(0)}) < 1$ . Indeed,

$$
Z(\tilde{Q}_1^{(0)}, \xi)\Big|_{\xi=1} = 1
$$
 and  $\frac{d}{d\xi}Z(\tilde{Q}_1^{(0)}, \xi)\Big|_{\xi=1} > 1$ ,

where the inequality follows by item [2](#page-2-11) in Definition [1.](#page-2-1) Hence, for  $\xi_0 < 1$  sufficiently close to 1 it must hold that  $Z(\tilde{Q}_1^{(0)}, \xi_0) < 1$ . Thus,  $\zeta_1^{(0)} = Z^*(\tilde{Q}_1^{(0)}) < 1$ . Next, note that  $\zeta_M^{(M-1)} = \left(\zeta_1^{(0)}\right)^M$ . Take M as the smallest power of 2 that is at least  $\log_a b$  where  $a = \zeta_1^{(0)}$  and  $b = \eta(1/2) \approx 0.327254$ . For this choice,  $R_{\text{L}}(M) \ge \frac{1}{2M} > 0$ , by considering the last term in [\(35\)](#page-4-3).

## <span id="page-4-5"></span>*B. Good Labeler*

<span id="page-4-3"></span>We now show how both thresholds  $R_{\rm L}$  and  $R_{\rm U}$  can be strengthened in the case of a good labeler. We give a simplified description here. We give a full and more nuanced description in Section [VI.](#page-5-0) For  $R_L$ , we observe the following regarding the proof of Theorem [1.](#page-1-5) Any definition of  $\zeta_N^{(i)}$  that satisfies  $\zeta_N^{(i)} \geq Z^{\star}(\tilde{Q}_N^{(i)})$  for all  $0 \leq i \leq N$  is valid. Thus, for a parameter  $V = 2^v \leq M$ , and all indices  $0 \leq k \leq V$ , define  $\zeta_V^{(k)} = Z^*(\tilde{Q}_V^{(k)})$  $\mathcal{V}_{V}^{(k)}$ ). For  $N > V$ , define  $\zeta_{N}^{(i)}$  recursively according to [\(34\)](#page-4-4). This improves  $R_L(M)$ , which we now denote as  $R_L(V, M)$ , since for polarization stage v we are calculating the exact values of  $Z^{\star}(\tilde{Q}_V^{(k)})$  $\binom{N}{V}$ , as opposed to bounds on them. By Lemmas [9](#page-3-6) and [10,](#page-3-7) we can indeed calculate  $\tilde{Q}_V^{(k)}$ V efficiently.

<span id="page-5-2"></span>Fig. 3. A full binary tree, where the nodes in  $G$  are red and the nodes in  $E$ are rectangular (leaves). The node  $(d = 2, j = 2)$  is both in G and E.

To strengthen  $R_U$ , we now define  $R_U(V)$  as the average capacity of the channels corresponding to  $\tilde{Q}_V^{(k)}$  $V^{(k)}$  over  $0 \leq k < V$ . The proof of this threshold being valid is given in Section [VI.](#page-5-0) In essence, we employ a so called "block-genie" that corrects us after  $N/V$  decisions have been made. Each block of size  $N/V$  corresponds to  $N/V$  uses of one of the above channels, and hence we cannot code for this block at a rate exceeding the capacity of that channel.

<span id="page-5-0"></span>The two figures in this paper were derived with  $V = 12$ and  $M = 36$ , and pruning as described in Section [VI.](#page-5-0)

### VI. IMPROVED THRESHOLDS

In this section we give a full description of how  $R<sub>L</sub>$  and  $R_{\rm U}$  were calculated in Figures [1](#page-0-0) and [2.](#page-1-1) These methods can be applied to any setting in which a good labeler is used.

# *A. Definition of*  $R_L(\mathcal{G}, \mathcal{E})$  *and*  $R_U(\mathcal{G})$

We start by defining two sets  $G$  and  $E$ . Both sets contain depth-index pairs  $(d, j)$ , where  $d \ge 0$  and  $0 \le j < 2^d$ . We think of each pair in these sets as a vertex of a full binary tree<sup>[2](#page-5-1)</sup>. An example of such a tree is presented in Figure [3.](#page-5-2) The root of the tree is  $(d = 0, j = 0)$ . A vertex  $(d, j)$  has either no children, in which case it is a leaf, or two children:  $(d+1, 2j)$ as the left child and  $(d+1, 2j+1)$  as the right child. Hence, we can view j as representing a path of d edges labelled " $-$ " and "+" starting at the root and ending at  $(d, j)$ . The binary representation of  $j = \sum_{i=0}^{d-1} b_i 2^i$  dictates the corresponding path. Namely,  $b_i = 0$  means that the  $(d - i)$ -th edge is a "−" (left) edge, while  $b_i = 1$  means that the  $(d - i)$ -th edge is a "+" (right) edge. The set  $\mathcal E$  contains the leaves of this tree. Any path from the root to a leaf contains exactly one vertex in  $G$ . Note that if we were to delete all descendants of vertices in  $G$  from the tree, we would again have a full tree.

For now, we assume that  $G$  and  $E$  are given (we will latter describe how to choose them). Our thresholds are now denoted  $R_{\text{L}}(\mathcal{G}, \mathcal{E})$  and  $R_{\text{U}}(\mathcal{G})$ . For  $R_{\text{L}}(\mathcal{G}, \mathcal{E})$ , we generalize [\(35\)](#page-4-3) to

$$
R_{\mathcal{L}}(\mathcal{G}, \mathcal{E}) = \sum_{(d,j)\in \mathcal{E}} \frac{1}{2^d} \cdot \max\left\{1 - \delta'(\zeta_{2^d}^{(j)}), 0\right\}, \quad (36)
$$

<span id="page-5-1"></span><sup>2</sup>A binary tree in which each node has either two children or no children.

where  $\zeta_{2d}^{(j)}$  $2^{d}$  is defined recursively in [\(34\)](#page-4-4), with the following starting conditions:

<span id="page-5-3"></span>
$$
\zeta_{2^d}^{(j)} = Z^{\star}(\tilde{Q}_{2^d}^{(j)}) \,, \quad \text{for all } (d, j) \in \mathcal{G}. \tag{37}
$$

Note that with respect to the simplified description in Section [V-B,](#page-4-5) if we define:

$$
\mathcal{G}(V) = \{(d, j) : d = v \text{ and } 0 \le j < V = 2^v\}, \quad (38)
$$
  

$$
\mathcal{E}(M) = \{(d, j) : d = m \text{ and } 0 \le j < M = 2^m\},
$$

then  $R_{\text{L}}(V, M) = R_{\text{L}}(\mathcal{G}(V), \mathcal{E}(M))$ . For  $R_{\text{U}}(\mathcal{G})$ , we have

<span id="page-5-7"></span><span id="page-5-5"></span>
$$
R_{\mathcal{U}}(\mathcal{G}) = \sum_{(d,j)\in\mathcal{G}} \frac{1}{2^d} \cdot I\left(\tilde{Q}_{2^d}^{(j)}\right) ,\qquad (39)
$$

where  $I(\tilde{Q}_{2d}^{(j)})$  $\begin{pmatrix} j \\ 2^d \end{pmatrix}$  is the mutual information corresponding to the joint distribution  $\tilde{Q}_{2d}^{(j)}$  $\mathcal{Q}_2^{(1)}$ . That is, the capacity of the channel corresponding to  $\tilde{Q}_{2^d}^{(j)}$ . Note that with respect to the simplified description in Section [V-B,](#page-4-5)  $R_U(V) = R_U(\mathcal{G}(V))$ .

Computationally, given G and E, the calculation of  $R_L(\mathcal{G}, \mathcal{E})$ and  $R_U(\mathcal{G})$  is implemented as follows. We carry out a preorder scan of the tree starting from the root. That is, we scan the root, scan the subtree rooted at its left child recursively, and then the subtree rooted at its right child recursively. The first node scanned is thus the root, for which  $\tilde{Q}_1^{(0)}(\xi)$  is given. Assume we are currently scanning a node  $(d, j)$  which is not the root. Hence, this node has a parent,  $(d', j') = (d - 1, \lfloor j/2 \rfloor)$ .

- If the path from the root to  $(d, j)$  has not yet traversed a vertex in  $G$ , then by induction we have already calculated  $\tilde{Q}_{2^{d'}}^{(j')}(\xi)$ , and now calculate  $\tilde{Q}_{2^{d}}^{(j)}$  $\mathcal{Q}_2^{(1)}(\xi)$  according to either  $(2\tilde{1})$  or [\(27\)](#page-3-2), depending on the parity of j.
	- If  $(d, j) \in \mathcal{G}$ , then we also calculate  $Z^*(\tilde{Q}_{2^d}^{(j)}(\xi))$  and set  $\zeta_{2d}^{(j)}$  $Z_2^{(j)} = Z^{\star}(\tilde{Q}_{2^d}^{(j)})$  $\binom{J}{2^d}$ , in accordance with the starting condition [\(37\)](#page-5-3).
- If the path from the root to  $(d, j)$  has already traversed a vertex in  $G$ , then by induction we have already calculated  $\zeta_{2d'}^{(j')}$  $\zeta_{2^{d'}}^{(j')}$  and now calculate  $\zeta_{2^{d}}^{(j)}$  according to [\(34\)](#page-4-4).
	- If  $(d, j) \in \mathcal{E}$ , we do not recursively continue the scan, since we have reached a leaf.

We now describe how we chose  $G$  and  $E$  and calculated  $R_{\rm L}$  and  $R_{\rm U}$  in Figures [1](#page-0-0) and [2.](#page-1-1) We set parameters  $d_{\mathcal{G}} = 12$ and  $d_{\mathcal{E}} = 36$  as the maximal depth of a vertex in  $\mathcal{G}$  and  $\mathcal{E}$ , respectively. We further set a numeric threshold  $\epsilon = 10^{-3}$  that allows us to add vertices to  $G$  and  $E$  at a depth shallower than  $d_{\mathcal{G}}$  and  $d_{\mathcal{E}}$ , respectively, in case sufficient polarization has already occurred. Conceptually, we carry out a pre-order scan of a perfect binary tree<sup>[3](#page-5-4)</sup> of height  $d_{\mathcal{E}}$ , trimming it as we go along. That is,  $G$  and  $E$  are generated dynamically as the scan progresses. We initialize variables  $R_{\rm L} = R_{\rm U} = 0$ . Each time a vertex is added to  $G$ ,  $R_U$  is incremented according to [\(39\)](#page-5-5). Each time a vertex is added to  $\mathcal{E}$ ,  $R_{\rm L}$  is incremented according to [\(36\)](#page-5-6).

<span id="page-5-6"></span><span id="page-5-4"></span><sup>3</sup>A full binary tree in which all the leaves are at the same depth.

During the scan of vertex  $(d, j)$  as described in the itemed list above:

- If the path from the root to  $(d, j)$  has not yet traveresed a vertex in  $\mathcal{G}$ , we add  $(d, j)$  to both  $\mathcal{G}$  and  $\mathcal{E}$  and increment  $R_U$  and  $R_L$  if
	- $-I(\tilde{Q}_{2^d}^{(j)}(\xi)) < \epsilon$ , or  $-1-\delta'(Z^{\star}(\tilde{Q}_{2^{d}}^{(j)}(\xi))) > 1-\epsilon.$

Otherwise, we add  $(d, j)$  to G and increment  $R_U$  if  $d =$  $d_G$ .

• If the path from the root to  $(d, j)$  has already traversed a vertex in  $\mathcal{G}$ , we add  $(d, j)$  to  $\mathcal{E}$  and increment  $R_L$  if

$$
- 1 - \delta'(\zeta_{2d}^{(j)}(\xi)) > 1 - \epsilon, \text{ or} - \zeta_{2d}^{(j)}(\xi) > 1, \text{ or} - d = d_{\mathcal{E}}.
$$

The curves for  $R_L, R_U$  and C in Figure [1](#page-0-0) are plotted with respect to a BI-AWGN channel quantized by a labeler  $\lambda$  to have 8 possible outputs. At the input we assume a normalized BPSK mapping from  $\mathcal{X} = \{0, 1\}$  to  $\mathcal{X}' = \{1, -1\}$  such that  $x' = 1 - 2x$ . At the output we assume that the labeler maps  $\mathcal{Y} = \mathbb{R}$  to  $\{-4, -3, -2, -1, 1, 2, 3, 4\}$ . The channel is defined by the above two mappings and by the relation  $y = x' + \nu$ , where  $\nu$  is the realization of a Gaussian random variable with zero mean and variance  $\sigma^2$ . The labeler is

$$
\lambda(y) = \begin{cases}\n4 & q_3 \leq y, \\
3 & q_2 \leq y < q_3, \\
2 & q_1 \leq y < q_2, \\
1 & 0 \leq y < q_1, \\
-1 & -q_1 \leq y < 0, \\
-2 & -q_2 \leq y < -q_1, \\
-3 & -q_3 \leq y < -q_2, \\
-4 & y < -q_3,\n\end{cases} (40)
$$

where we used  $q_1 = 0.2$ ,  $q_2 = 0.6$ , and  $q_3 = 1.2$  to define the labeler regions. For Figure [2](#page-1-1) we have a BSC with  $\mathcal{Y} = \{0, 1\}$ and the labeler is  $\lambda(y) = 1-2y$ . Note that both labelers above are good labelers.

We now state and prove two propositions that justify  $R_L(\mathcal{G}, \mathcal{E})$  and  $R_U(\mathcal{G})$  as valid thresholds. These are generalizations of claims and proofs made in Section [V](#page-3-8) for simpler choices of  $R_{\rm L}$  and  $R_{\rm U}$ .

## <span id="page-6-0"></span>*B. Justification of*  $R_L(\mathcal{G}, \mathcal{E})$

## **Proposition [1](#page-1-5)5.** *Setting*  $R_L = R_L(\mathcal{G}, \mathcal{E})$  *in Theorem 1 is valid.*

*Proof:* Recall that in Theorem [1](#page-1-5) we assume that  $R <$  $R_{\text{L}}(\mathcal{G}, \mathcal{E})$ , and our aim is to prove the existence of a family of polar codes with growing lengths such that their rates are at least R and their word error probabilities at most  $2^{-N^{\beta}}$ , where  $N$  is the codeword length.

As in Section [V-A,](#page-4-6) we use the recursive relation  $(34)$  to define  $\zeta_N^{(i)}$ , where now the starting conditions are  $\zeta_{2^d}^{(j)}$  $\begin{array}{cc} \mathbf{C}^{(1)} & = \\ \mathbf{C}^{d} & \end{array}$  $Z^\star(\tilde Q_{2^d}^{(j)}$  $2^{(1)}_{2^d}$  for  $(d, j) \in \mathcal{G}$ . Note that by the definition of  $\mathcal{E}$ and  $G$  and our description of the steps carried out when a

node is scanned, the value of  $\zeta_{2d}^{(j)}$  calculated during the scan 2 of  $(d, j) \in \mathcal{E}$  is the same  $\zeta_{2^d}^{(j)}$  $2^d$  defined by the above recursion. Again by [\(19\)](#page-3-4), we have for all N large enough and  $0 \le i <$ N that  $\zeta_N^{(i)} \geq Z^*(\tilde{Q}_N^{(i)})$ . Namely,  $A' \subseteq A$ , where A and  $A'$ are defined in Section [V-A.](#page-4-6) Thus, it suffices to show that for  $R < R_{\text{L}}(\mathcal{G}, \mathcal{E})$  fixed and all N large enough,  $|\mathcal{A}'| \ge N \cdot R$ .

Assume that R, and therefore  $R_{\text{L}}(\mathcal{G}, \mathcal{E})$  are positive, otherwise the claim is trivial. As before, denote  $\beta' = \frac{\beta + 1/2}{2}$  $\frac{1}{2}$ . For each one of the pairs  $(d, j) \in \mathcal{E}$ , we invoke Proposition [14](#page-4-1) with  $\delta = \delta'(\zeta_{2^d}^{(j)}) + (R_{\rm L}(\mathcal{G}, \mathcal{E})) - R$ ,  $\eta = S_0 = \zeta_{2^d}^{(j)}$ , and  $\beta'' =$  $\frac{\beta'+1/2}{2}$  in place of  $\beta$ . Denote the  $n_0$  promised by the propo-2 sition as  $n_0^{(d,j)}$ . Now define  $n_0^{\max} = \max_{(d,j)\in\mathcal{E}} n_0^{(d,j)}$  and  $d_{\mathcal{E}}^{\max} = \max_{\substack{(a,j) \in \mathcal{E} \\ \text{max}_{j} \in \mathcal{E}}} d$ . Thus, for any  $(d, j) \in \mathcal{E}$ ,  $2^{-2(n-d)\beta}$ ≤  $2^{-2(n-d_{\mathcal{E}}^{\max})\beta^{N}}$ . Hence, by [\(33\)](#page-4-2), for  $n \geq d_{\mathcal{E}}^{\max} + n_{0}^{\max}$  the fraction of indices  $0 \le i < N$  such that  $\zeta_N^{(i)} \le 2^{-2(n-d_{\mathcal{E}}^{\max})\beta''}$ is at least

$$
\sum_{(d,j)\in\mathcal{E}}\frac{1}{2^d}\max\left\{1-\left(\delta'(\zeta_{2^d}^{(j)})+R_{\mathrm{L}}(\mathcal{G},\mathcal{E})-R\right),0\right\}
$$
  
\n
$$
\geq \sum_{(d,j)\in\mathcal{E}}\frac{1}{2^d}\max\left\{1-\delta'(\zeta_{2^d}^{(j)})-R_{\mathrm{L}}(\mathcal{G},\mathcal{E})+R,-R_{\mathrm{L}}(\mathcal{G},\mathcal{E})+R\right\}
$$
  
\n
$$
=\sum_{(d,j)\in\mathcal{E}}\frac{1}{2^d}\left(\max\left\{1-\delta'(\zeta_{2^d}^{(j)}),0\right\}-R_{\mathrm{L}}(\mathcal{G},\mathcal{E})+R\right)
$$
  
\n
$$
\stackrel{\text{(a)}}{=} \sum_{(d,j)\in\mathcal{E}}\frac{1}{2^d}\left(\max\left\{1-\delta'(\zeta_{2^d}^{(j)}),0\right\}\right)-R_{\mathrm{L}}(\mathcal{G},\mathcal{E})+R
$$
  
\n
$$
=R,
$$

where (a) follows since the Kraft inequality  $[28,$  Equation 5.8] is tight on full binary trees, as can easily be proven by induction.

We take  $n_0$  in Theorem [1](#page-1-5) such that  $n_0 \geq d_{\mathcal{E}}^{\max} + n_0^{\max}$ . We further require that  $n_0$  is large enough so that for all  $n \ge n_0$ we have  $2^{-2(n-d_E^{\max})\beta} \leq 2^{-2^{n\beta'}} = 2^{-N^{\beta'}}$ . By the above, this ensures that  $|\mathcal{A}'| \geq N \cdot R$ . Lastly, we require that  $n_0$  is large enough such that for all  $n \ge n_0$  we have  $N \cdot 2^{-N^{\beta}} \le 2^{-N^{\beta}}$ . This ensures that the word error rate is at most  $2^{-N^{\beta}}$ . Г

## *C. Definition of block-genie and justification of*  $R_{\text{U}}(G)$

Our aim now is to prove an analogous claim to Proposi-tion [15](#page-6-0) for  $R_U$ . This is Proposition [16](#page-7-2) below. In the proof of Proposition [16](#page-7-2) we use a "block-genie", a concept we now define. Recall that in the seminal paper [\[1\]](#page-7-0), a genie-aided decoder is used. That is, a variant of SC decoding, in which at stage *i* the genie reveals  $u_1^{i-1}$ . Thus, at stage *i*, the relevant distribution is  $W_N^{(i)}$ , given in [\(4\)](#page-1-6). The genie-aided decoder is used since it is easier to analyze than SC decoding, but still has exactly the same word error rate as the SC decoder. Our block-genie will have this property as well.

The block-genie-aided SC decoder is defined in Algo-rithms [A](#page-7-3) to [C.](#page-7-4) For a code of length  $N$  and a received word  $y_0^{N-1}$ , decoding is preformed by calling Algorithm [C](#page-7-4) with  $(\lambda(y_0), \lambda(y_1), \ldots, \lambda(y_{N-1}))$  and  $d = j = 0$ . Note that the set  $G$  is used in Algorithm [C.](#page-7-4) Conceptually, we break

the task of decoding  $u_0, u_1, \ldots, u_{N-1}$  into the decoding of  $|\mathcal{G}|$  blocks. We assume a code of length  $N = 2^n$ , where  $n \geq d_{\mathcal{G}}^{\max} = \max_{(d,j) \in \mathcal{G}} d$ . For  $(d, j) \in \mathcal{G}$ , the corresponding block is  $u_i, u_{i+1}, \ldots, u_{i+T-1}$ , where  $i = j \cdot T$  and  $T = 2^{n-d}$ . When decoding this block, the genie has already revealed  $u_1^{i-1}$  and thus the relevant distribution under the MSA is  $\tilde{Q}_{2^d}^{(j)}$  $2^d$ (applying  $\tilde{f}$  in place of f in Algorithm [C\)](#page-7-4). Specifically, after this block has been decoded, the genie corrects any errors the decoder may have introduced. This is done by invoking the GenieCorrect function defined in Algorithm [B](#page-7-5) and used at the bottom of Algorithm [C.](#page-7-4)

Note that for  $\mathcal{G} = \emptyset$ , [A](#page-7-3)lgorithms A to [C](#page-7-4) simply describe SC decoding, without any help from a genie. Moreover, for  $\mathcal{G} = \mathcal{G}(N)$  as defined in [\(38\)](#page-5-7), [A](#page-7-3)lgorithms A to [C](#page-7-4) describe Arıkan's genie-aided SC decoding. For the above two choices of  $G$ , as well as for any other valid choice, the word error probability is the same, since correction are made only after decisions on  $\hat{u}_i$  have been made in Algorithm [A.](#page-7-3)

<span id="page-7-2"></span>**Proposition [1](#page-1-5)6.** *Setting*  $R_U = R_U(\mathcal{G})$  *in Theorem 1 is valid.* 

*Proof:* Fix  $\Delta > 0$  and consider a code with rate  $R \geq$  $R_U(\mathcal{G}) + \Delta$ . Denote the information set of this code as A and its length as  $N = 2<sup>n</sup>$ , Thus  $|\mathcal{A}| = N \cdot R$ . Assume that  $n \geq d_{\mathcal{G}}^{\max} = \max_{(d,j) \in \mathcal{G}} d.$ 

Consider the block corresponding to  $(d, j) \in \mathcal{G}$ . The number of indices in this block is  $T = 2^{n-d}$ . Of these, denote the indices in A by

$$
\mathcal{A}_{(d,j)} = \{j \cdot T \leq i < j \cdot (T+1) : i \in \mathcal{A}\} \ .
$$

Thus, the rate at which this block is coded for is

$$
R_{(d,j)} \triangleq |\mathcal{A}_{(d,j)}|/2^{n-d}.
$$

Since every index  $0 \le i \le N$  is contained in exactly one block,

$$
R = \sum_{(d,j)\in\mathcal{G}} \frac{1}{2^d} R_{(d,j)} .
$$

Thus, by the above and  $(39)$ ,

$$
\Delta \leq R - R_{\mathrm{U}}(\mathcal{G}) = \sum_{(d,j) \in \mathcal{G}} \frac{1}{2^d} \left( R_{(d,j)} - I\left(\tilde{Q}_{2^d}^{(j)}\right) \right) .
$$

By the pigeon-hole principle and the Kraft inequality being tight for a full binary tree, there exists at least one  $(d, j) \in \mathcal{G}$ such that

$$
R_{(d,j)} - I\left(\tilde{Q}_{2^d}^{(j)}\right) \geq \Delta.
$$

By the strong converse to the coding theorem [\[27,](#page-8-11) Theorem 5.8.5], the probability of misdecoding such a block converges to 1, as the block size tends to infinity. Thus, the word error rate must converge to 1 as  $N$  tends to infinity, since all blocks have lengths that tend to infinity with N.

#### Algorithm A: Make Decision

<span id="page-7-3"></span>MakeDecision $(\lambda, i)$ if  $i \in \mathcal{A}$  then  $\hat{u}_i =$  $\int 0 \quad \lambda \geq 0$ 1  $\lambda < 0$ else  $\hat{u}_i = 0$ return  $\hat{u}_i$ 

# <span id="page-7-5"></span>Algorithm B: Genie Correct

GenieCorrect $(i, T)$ **return**  $(u_i, u_{i+1}, \ldots, u_{i+T-1}) \cdot B_T \cdot F^{\otimes t}$ /\*  $B_T$  is the bit reversal matrix,  $t=\log_2 T$ ,  $F=\left(\begin{array}{cc} 1 & 0 \ 1 & 1 \end{array}\right)$ , and  $\otimes$  is the Kronecker product \*/
