ABSTRACT

Weak-emission-line QSOs (WLQs) are an enigmatic subclass of the QSO population, as their optical/UV spectra are marked by abnormally weak (or absent) emission lines. To obtain much-needed additional clues to the origin of this and other known peculiarities of WLQs, we have determined the 'ensemble' optical variability characteristics for a large, well-defined sample of 76 radio-quiet WLQs and also for a matched control sample comprising 603 normal radio-quiet QSOs. This analysis was done using their light-curves recorded in the g and r bands, under the ZTF survey during 2018-2024, with a typical cadence of 3 days. We find that, compared to normal QSOs, WLQs exhibit systematically milder optical variability on month/year-like time scales (by a factor of $\sim 1.76\pm0.05$ in amplitude). We have independently verified this by carrying out an equivalent analysis of the V-band light-curves acquired under the CRTS during 2007- 2014, with a typical cadence of 10 days. This new observational differentiator between WLQs and normal QSOs may provide clues to understanding the intriguing nature of WLQs. It is proposed that the clumpiness of the torus material flowing into the central engine may play a key role in explaining the observed differences between the WLQs and normal QSOs.

Key words: accretion, accretion disks – galaxies: active – galaxies: nuclei – quasars: emission lines – quasars: general - quasars: supermassive black holes

1 INTRODUCTION

Variability of flux density is a key attribute of all Active Galactic Nuclei (AGN) including QSOs. It is an effective tool to probe their spatially unresolved central engines. In the case of radio-loud AGNs, particularly blazars, the optical variability is predominantly associated with the (Doppler boosted) relativistic jet (e.g., see Wagner & Witzel 1995; Blandford et al. 2019). On the other hand, radio-quiet AGNs exhibit milder optical variability on all time scales, which is often thought to arise from perturbations/instabilities in the accretion disk that feeds the central supermassive black hole (SMBH) (e.g. Ulrich et al. 1997; Siemiginowska & Elvis 1997; Kelly et al. 2009; Bauer et al. 2009), although a weak jet may also be contributing to the variability (e.g., see Blundell & Rawlings 2001; Gopal-Krishna et al. 2003; Stalin et al. 2004; Barvainis et al. 2005; Czerny et al. 2008). Among the various radio-loud sub-classes of AGNs, BL Lac objects, which are characterized by an essentially featureless optical/UV spectrum, show strong flux variability on time scales ranging from minutes to years (e.g., see Gopal-Krishna & Wiita 2018, and references therein). Curiously, this property is not shared by a special subclass of radio-quiet AGNs, called 'Weak Line quasars' (WLQs), although they too lack strong emission lines in the UV/optical spectrum (the dividing line is conventionally set at the rest-frame equivalent width EW_r < 15 Å for Ly α + N v emission lines). For this and other reasons, WLQs have remained an enigma for the past few decades (e.g., see Fan et al. 2006; Anderson et al. 2007; Plotkin et al.

* E-mail: ritishshield@gmail.com

2010; Wu et al. 2011; Meusinger & Balafkan 2014; Shemmer & Lieber 2015; Ni et al. 2018). In fact, even the possibility has been considered that WLQs might be the elusive radio-quiet analogs of BL Lacs (e.g., see Fan et al. 1999; Shemmer et al. 2009; Plotkin et al. 2010). However, the generally negative searches for strong intranight optical variability (INOV) disfavor this proposal (e.g., see Gopal-Krishna et al. 2013; Chand et al. 2014; Kumar et al. 2015; Kumar et al. 2016), so also their observed low degree of optical polarisation, p < 3% (e.g., see Smith et al. 2007; Diamond-Stanic et al. 2009; Heidt & Nilsson 2011; Kumar et al. 2018). All this reinforces the notion that WLQs are an intriguing, extreme subset of the normal QSO population, although the relationship between the two remains rather obscure.

Proposed explanations for the weak emission lines of WLQs include (i) a soft ionizing continuum leading to the emission deficit from the broad-line region (BLR) (Leighly et al. 2007; Laor & Davis 2011; Wu et al. 2011; Luo et al. 2015). Such scenario also includes a geometrically thick accretion disk due to super-Eddington accretion, which creates a gaseous shield around the central continuum source, capable of inhibiting photo-ionization of the BLR clouds (e.g., see Ni et al. 2018; Paul et al. 2022, and references therein). and (ii) an anemic, unusual BLR in WLQs (Diamond-Stanic et al. 2009; Shemmer et al. 2010; Nikołajuk & Walter 2012), perhaps due to their representing an early evolutionary phase of quasars so that the accretion disk is relatively recently established (e.g., see Hryniewicz et al. 2010; Liu & Zhang 2011; Meusinger & Balafkan 2014) and the BLR region is still underdeveloped (e.g., see Hryniewicz et al. 2010; Andika et al. 2020; Kumar et al. 2023). It is clear that the prospects

³Inter-University Centre for Astronomy and Astrophysics, Post Bag 4, Ganeshkhind, Pune, 411007, India

of resolving the puzzle of WLQs rest substantially on comparing them with normal QSOs in terms of additional observables. Optical variability on different time scales is one such observable. Comparison of their optical variability on hour-like time scales has been presented in a series of papers (e.g., see Gopal-Krishna et al. 2013; Chand et al. 2014; Kumar et al. 2015; Kumar et al. 2016). However, for both normal QSO and their WLQ subset, such rapid optical variability does not stand out well above the typically achieved detection threshold of 1-2% (unlike blazars), precluding a quantitative comparison of the two. An alternative is to extend the comparison to much longer (month/year-like) time scales, which is now possible, thanks to the availability of long-term optical light-curves of high sensitivity and cadence, from the Zwicky Transient Facility (ZTF survey Bellm et al. 2018). The ZTF survey scans the northern sky in g, r and i bands, using a 48-inch Schmidt telescope stationed at Mount Palomar and is equipped with a 47 sq. deg wide-field imager. This database has motivated the present study. Section 2 describes our sample selection for WLQs and the control sample of normal QSOs. In Section 3, we describe the analysis procedure, followed by presentation of the results and a brief discussion in Section 4. The last section summarises our main conclusions. Throughout, we have assumed the flat Universe with $H_0 = 70 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $\Omega_m = 0.3$ and Ω_{Λ} = 0.7.

2 THE WLQ SAMPLE

Our sample is derived from the compilation of 90 bona fide WLQs used in Kumar et al. (2023, hereafter KCJ23), which, in turn, was derived from a parent sample of 108 WLQs based on the compilations by Plotkin et al. (2010) and Meusinger & Balafkan (2014), after excluding sources showing a galaxy-like spectrum, or a significant proper motion (for detail, see KCJ23). This sample was supplemented with 13 WLQs from Luo et al. (2015), 14 WLQs from Ni et al. (2018), and 1 WLQ from Meusinger & Scholz (2022) (the remaining WLQs listed in these publications are already included in the abovementioned set of 108 WLQs). This sample containing 118 WLQs was then checked for radio loudness, by estimating the radio-loudness parameter R² for each WLQ after cross-matching it to within 5" with the 1.4 GHz catalogues from the Faint Images of the Radio Sky at Twenty-cm (FIRST; Becker et al. (1995). We found 7 of the WLQs to have R > 10 and discarding these radio-loud cases reduced the sample to 111 WLQs. Moreover, we intended to perform the Structure Function (SF) analysis for both g and r bands, and the requirement of availability of the ZTF-DR22 light-curves for both these bands was satisfied by only 88 of the WLQs. In order to compare these 88 WLQs with normal QSOs in terms of optical variability, we next assembled from the SDSS DR14 quasar catalog (Pâris et al. 2018), a preliminary 'control sample' of normal QSOs matched in the redshift-magnitude plane, allowing tolerances of 0.01 in redshift and 0.6-mag in the rband apparent magnitude. For each WLQ, these tolerances allowed selection of 10 normal QSOs into the control sample, except for 12 WLQs having very low or very high redshifts (z < 0.06, or > 3.5). The required exclusion of these 12 WLQs led to our final sample of 76 WLOs and the corresponding control sample comprising 10 normal QSOs for each WLQ. A total of 102 out of these 760 normal QSOs

Figure 1. The kernel smooth probability distribution function (PDF) of the variability amplitude (ψ) for the r-band (upper panel) and g-band (lower panel) light-curves of the WLQ sample (blue solid line) and the matched control sample of normal QSOs (red dashed line). The median values of ψ are also shown. The distributions of ψ in the g-band and r-band among the WLQs and the normal QSOs are significantly different, with the KS-test P_{null} of 2.68× 10⁻¹⁵ and 4.34× 10⁻¹⁴, respectively.

had to be discarded as their ZTF g- and r-band light-curves failed to meet our selection criterion of minimum of 100 data points per light-curve (which was also followed for our WLQ sample selection) and another 55 QSOs had to be excluded for being radio-loud (R > 10). Thus, we were finally left with a control sample of 603 normal QSO, for our sample of 76 WLQs (see Table A1).

3 ANALYSIS

We have used the ZTF light-curves to determine the distributions of variability amplitude (ψ) for our WLQ sample and the control sample of normal QSOs. For each light-curve, ψ was computed using the relation (Heidt & Wagner 1996):

$$\psi = \sqrt{(A_{max} - A_{min})^2 - 2\sigma^2} \tag{1}$$

Here $\sigma^2 = <\sigma_i^2>$, with σ_i being the rms photometric uncertainty for the i^{th} data point in the light-curve. A_{max} and A_{min} are, respectively, the maximum and minimum amplitudes in the light-curve. The distributions of ψ for the two optical bands are shown in Fig. 1 for the WLQ sample and the control sample of normal QSOs. The corresponding median values of ψ are $0.35\pm0.03~\&~0.62\pm0.01$ for the r-band, respectively and $0.40\pm0.04~\&~0.72\pm0.01$ for the g-band. Thus, based on the ZTF light-curves spanning ~ 6 years, it is evident that, compared to normal QSOs, WLQs exhibit significantly milder variability, in both bands. Furthermore, variability amplitude appears to be greater in the g-band, consistent with the well-known trend for the optical variability of AGN to increase towards higher frequencies (Hawkins 2002; Wilhite et al. 2008; Sun et al. 2014). Below,

https://www.ztf.caltech.edu

² Radio loudness (R) of a QSO is usually characterised in terms of the ratio of its flux densities at 5 GHz and at 2500 Å in the rest frame, R being > 10 and < 10 for radio-loud and radio-quiet quasars, respectively (e.g., see Kellermann et al. 1989).

we present Structure-Function analysis to investigate the time scales associated with the weaker optical variability of WLQs, compared to normal OSOs.

The Structure Function quantifies variability in a data sequence by measuring the magnitude difference between two observations in a light curve, separated by a chosen time lag, Δt , defined in the emitter's rest-frame. The strength of SF analysis lies in the mutual independence of the different bins of Δt (e.g., de Vries et al. 2005; De Cicco et al. 2022). Such a statistical approach can be readily applied to a large sample of objects, for quantitatively estimating their 'ensemble' variability over a range of (intrinsic) time scales. Various definitions of SF exist in the literature (e.g., Hawkins 2002; de Vries et al. 2005; Meusinger et al. 2011; Graham et al. 2014; Kozłowski 2017). Here, we shall compute the modified SF, defined as (Di Clemente et al. (1995)):

$$SF(\Delta t) = \sqrt{\frac{\pi}{2} \langle |m(t + \Delta t) - m(t)| \rangle^2 - \langle \sigma^2 \rangle}$$
 (2)

Here, m(t) and $m(t + \Delta t)$ are the apparent magnitudes at times t and $t + \Delta t$ within a QSO light-curve, with t defined in the QSO's rest-frame. The term $\langle |m(t + \Delta t) - m(t)| \rangle$ represents the average of the absolute values of the magnitude differences for all pairs of data points in the entire set of light-curves of a QSO sample, where each pair is separated by a chosen time lag Δt defined in the rest-frame of the corresponding QSO. The error σ on the magnitude difference for a pair is the square root of the quadratic sum of the rms errors of the two magnitude values (assuming a Gaussian-error distribution). The term $\langle \sigma^2 \rangle$ represents the average of σ^2 , taken over all the pairs in the chosen bin of rest-frame time lag Δt . The factor $\frac{\pi}{2}$ accounts for the assumption that both intrinsic variability and the noise on individual data points follow Gaussian distributions (Wilhite et al. 2008). The statistical uncertainty for each point of the computed 'ensemble' SF is estimated by properly propagating the computed errors on the magnitude differences for all the pairs within the respective bin of Δt . The derived ensemble SFs for our WLQ sample and for the control sample of normal QSOs (both radio-quiet) are displayed in Fig. 2a and 2b, for the r-band and g-band light-curves. Note that the error bars on the symbols plotted are smaller than their sizes. As an independent check on these ZTF-based ensemble SFs, we have repeated the SF computation using the light-curves taken from the Catalina Real-Time Transient Survey (CRTS) (Drake et al. 2009). Note that only 69 out of the 76 WLQs in our ZTF sample fall within the CRTS region. Also, with a limiting magnitude V ~ 20 in a single exposure, CRTS is less sensitive compared to the ZTF survey for which the limiting magnitude is ~ 21 (g-band). To make an allowance for this, we have reset the magnitude limit at 1-mag brighter level, for defining the WLQ sample from the CRTS. The sample size available for computing the SF thus got reduced to 51 WLQs (all radio-quiet). Fig. 3 shows the SF (V-band) computed for this WLQ sample, together with the SF (V-band) computed for its control sample which consists of 361 normal (radio-quiet) QSOs, selected in the same manner as for our ZTF-based analysis.

4 RESULTS AND DISCUSSION

Fig. 2a, 2b and Fig. 3 display the most salient and statistically robust findings from the present work based on the ZTF and CRTS surveys. The computed ensemble SFs for the light-curves drawn from these two surveys consistently show that on month/year-like time scales, WLQs exhibit systematically milder optical variability, compared to normal QSOs (recall that the members of both the WLQ sample and

Figure 2a. The computed ensemble Structure Function (SF) for the WLQ sample (orange) and for the control sample of normal QSOs (blue), derived using their ZTF r-band light-curves. The error bar on each plotted symbol is smaller than the symbol size. The two insets compare the computed SFs in g-band and r-band for the WLQs and normal QSOs.

Figure 2b. The computed ensemble Structure-function (SF) for the WLQ sample (orange) and for the control sample of normal QSOs (blue), derived using their ZTF *g*-band light-curves. The error bar on each plotted symbol is smaller than the symbol size.

the control sample of normal QSOs are radio-quiet, minimizing any contamination from jet-related optical continuum). The ensemble variability amplitudes for the two QSO types are thus found to differ typically by a factor of $\sim 1.76\pm0.05$, for the month/year-like time scales probed here. Although a hint for such a difference was present in an earlier study, based on a much smaller sample of WLQs with their CRTS (V-band) light-curves then available for just a 3-year time-span (see Kumar et al. 2018), the difference between the optical variability levels of WLQs and normal QSOs is recognized, for the first time, in the present study.

The slopes of the SFs (ZTF) of the WLQs and of their control sample of normal QSOs have been determined by straight-line fitting to the SFs on the log-log scale. This gave power-law slopes of $0.55\pm0.05~\&~0.41\pm0.04$ in the r-band and $0.51\pm0.06~\&~0.34\pm0.04$ in the g-band, for the WLQs and normal QSOs, respectively (Fig. 2a, 2b). The corresponding slopes for the SF (CTRS) are found to be

Figure 3. The computed ensemble Structure-function (SF) for the sample of 51 WLQs (orange) and for the control sample 361 normal QSOs (blue), based on the V-band light-curves taken from the CRTS survey. The error bar on each point is smaller than the symbol size.

0.41±0.06 and 0.18±0.01, respectively (Fig. 3). These estimates are broadly consistent with the power-law slopes of 0.36 ± 0.01 (Bauer et al. 2009) and 0.246±0.008 (Vanden Berk et al. 2004), estimated for normal OSOs. Note that a SF slope of ~ 0.44 has been theoretically predicted for the accretion disk instability model of flux variability (Hawkins 2002).

It is relevant to consider the possibility that in our redshift and r-band magnitude matching (see Sect. 2), the flux contributed by any emission line falling within the r-band, depending on source redshift, would be expectedly higher for normal QSOs in comparison to the WLQs which have distinctly weak or absent emission lines. As a result, the control sample would be systematically less luminous than the WLQ sample, in terms of (line-less) continuum luminosity. Now, the net contribution of the emission lines in a standard OSO spectrum at some reference redshift, to the observed photometric band would vary as the spectrum sweeps past the band with changing redshift. This variation is reflected in the published K-correction values (defined as $m_{intrinsic} = m_{observed} - K(z)$), which also include the redshift-dependent differential contribution coming from the underlying continuum falling within the observed photometric band. Thus, the maximum range observed in the K(z) values amounts to an upper limit to the flux contributed by any emission lines falling within the observed photometric band. Therefore, for a conservative estimate of the expected emission-line contribution to the observed luminosity we draw a histogram of the K-correction values for a normal QSO (Table 4 of Richards et al. 2006), covering the range 0.5 < z < 3.5 which essentially overlaps the z-range for our control sample of normal QSOs.

As seen from Fig. A2, the range spanned by the K-correction values (-0.4-mag to +0.2-mag) amounts to a maximum change $\Delta m = 0.6$ mag ³, implying that emission lines could have brightened the normal QSO (having strong emission lines) by at most 0.6-mag, vis-à-vis the WLQ. Thus, the optical continuum luminosity of our WLQs sample could be systematically higher than the value for the QSO control sample, by a factor of 1.7, at the most. Could this luminosity mismatch account for the milder optical variability observed for the WLQs, as compared to the normal QSOs, given that optical variability is known to anti-correlate with optical luminosity (e.g., MacLeod et al. 2010; Caplar et al. 2017; Laurenti et al. 2020)? To check this we use the analytical fit to the anti-correlation (Eq. 9 of Laurenti et al. 2020), from which it follows that in order to account for the 1.76±0.05 times milder variability of the WLQs (see above), the WLQ sample would have to be systematically ~ 20 times more luminous in the optical than the control sample of normal QSOs. This requirement is an order-of-magnitude larger than the estimated maximum brightening of a normal QSO, at any z within the range considered here, due to the contribution from emission-lines within the r-band (see above). Therefore, the distinctly milder optical variability of WLQs, as found here, is extremely unlikely to be an artifact resulting from the inability to remove the emission-line contribution from the published magnitudes of each QSO, particularly the normal QSOs which constitute the control sample.

Furthermore, at least qualitatively, the observed milder optical variability of the WLQs (which are thought to be accreting at a higher Eddington rate, see Sect. 1), seems consistent with the observed anti-correlation between optical variability and (dimensionless) accretion rate (Lu et al. 2019). From a theoretical perspective, it is tempting to explore the possibility of a common physical cause underlying the abnormally weak broad emission-lines in WLQs and their milder optical continuum variability, in comparison to the general QSO population. Conceivably, both these exceptionalities of WLQs, as found here, may be traceable to the physical conditions near the inner edge of the dusty torus which not only feeds the accretion disk, but also whose part that extends inside the dust sublimation radius can be identified as the BLR clouds (Antonucci 2023). For a given amount of material flowing from the torus into the BLR, if the degree of clumpiness is higher (e.g., see Wang et al. 2017), the broad-line emissivity would clearly be enhanced. At the same time, the optical continuum which arises mainly from the accretion disk, may also exhibit stronger variability. The latter expectation derives from the theoretical model according to which a (variable) optical/UV light-curve arises mainly from cascades of expanding optically-thick shocks between colliding clumps of matter flowing in the accretion disk (Türler 2005; Ishibashi & Courvoisier 2009). Conversely, if the material flowing inward from the inner edge (i.e., the dust sublimation radius) of the torus is more homogenous (i.e., less clumpy), one would expect not only a weaker line emission from the BLR, the defining characteristic of WLOs, but also a less variable optical continuum from the accretion disk, as indeed found here using the extensive sets of well-sampled optical light-curves. It would be interesting to explore in detail this simplified proposal in order to visualize the physical process underlying the WLQ phenomenon.

5 CONCLUSIONS

In an attempt to find additional observational clues for understanding the various peculiarities exhibited by 'weak-line QSOs' (WLQs) in the optical/UV/X-ray bands, we have found a new observational differentiator between WLOs and normal OSOs, namely the optical variability on month/year-like time scales. We assembled a

³ The K-corrections given by these authors are actually for the i-band, but the 0.6-magnitude range should be a fairly good approximation for the r-band.

⁴ This AGN accretion disk model, an alternative to the standard 'geometrically thin, optically thick accretion disk' paradigm, was inspired by the observed quasi-simultaneity of the variable optical and UV light-curves (e.g., see Courvoisier & Clavel 1991; Collin-Souffrin 1991; Alloin et al. 1985), as well as the independent argument by Antonucci et al. (1989) based on the optical polarisation vector of jetted AGN.

well-defined sample of 76 WLQs and a control sample of 603 normal QSOs (both radio-quiet), via matching the two in the redshiftmagnitude plane. Using the g- and r-band light-curves for these two samples, recorded in the recently concluded major optical survey ZTF with a typical cadence of 3 days, we have shown that as a class, WLQs exhibit distinctly milder optical variability, as compared to the normal QSOs, on month/year-like time scales. Based on a Structure-Function analysis of the ZTF light-curves for these two matched samples of QSOs, the 'ensemble' optical variability of WLQs is estimated to be typically lower by a factor of ~ 1.7 in amplitude, on month/year-like time scales. An independent confirmation to this finding has come from the use of the V-band light-curves for a well-defined sample of 51 WLQs and its control sample of 362 normal QSOs, taken from the CRTS survey database. This result has motivated a simplified, basic scenario linking the abnormal weakness of the broad emission lines of WLQs and their milder optical flux variability (compared to normal QSOs), to a common physical cause, namely the clumpiness of the torus material accreting into the central engine and its immediate environment. Further exploration of this newly found observational clue to the WLQ phenomenon, can be expected to play a significant role in understanding the working of this intriguing subclass of Active Galactic Nuclei.

APPENDIX A: SOME EXTRA MATERIAL

This paper has been typeset from a TEX/LATEX file prepared by the author.

6 Kumar et al.

Figure A1. The normalized distribution of redshift as well as the r-band magnitude for the present sample of 76 WLQs and the control sample consisting of 603 normal QSOs matched in redshift and r-band magnitude (Sect. 2). The solid red line represents the WLQ sample whereas the dashed blue line represents the control sample of normal QSOs. The samples of WLQs and normal QSOs are statistically indistinguishable in terms of both redshift and r-band magnitude, with KS-test P_{null} of 0.98 and 0.95 respectively.

Figure A2. The distribution of K-Correction factor for the QSOs taken from Table 4 of Richards et al. (2006) within the redshift range of 0.5<z<3.5.

Table A1. Basic parameters of the 76 WLQs in our sample.

Source Name	RA (Degree)	DEC (Degree)	Z	r _{mag} (SDSS)
J001444.03-000018.5	3.68	-0.005	1.55	18.22±0.02
J001514.88-103043.6	3.81	-10.51	1.17	19.60±0.02
J005713.01+004205.7	14.304	0.702	1.54	19.88±0.02
_	_	_	_	_

Note: The entire table is available in online version. Only a portion of this table is shown here to display its form and content.

Table A2. Basic parameters of the 603 QSOs in the control sample.

Source Name	RA (Degree)	DEC (Degree)	Z	r _{mag} (SDSS)
J000139.21+204000.2	0.413	20.666	1.542	18.19±0.02
J000155.68-073508.6	0.482	-7.5857	2.756	19.54±0.02
J001223.31-010922.7	3.097	-1.156	1.4305	19.47±0.03
_	_	_	_	_

Note: The entire table is available in online version. Only a portion of this table is shown here to display its form and content.
