# **RG-Attn: Radian Glue Attention for Multi-modality Multi-agent** Cooperative Perception

Lantao Li<sup>1</sup>, Kang Yang<sup>2</sup>, Wenqi Zhang<sup>1</sup>, Xiaoxue Wang<sup>1</sup> and Chen Sun<sup>1</sup>

Abstract—Cooperative perception offers an optimal solution to overcome the perception limitations of single-agent systems by leveraging Vehicle-to-Everything (V2X) communication for data sharing and fusion across multiple agents. However, most existing approaches focus on single-modality data exchange, limiting the potential of both homogeneous and heterogeneous fusion across agents. This overlooks the opportunity to utilize multi-modality data per agent, restricting the system's performance. In the automotive industry, manufacturers adopt diverse sensor configurations, resulting in heterogeneous combinations of sensor modalities across agents. To harness the potential of every possible data source for optimal performance, we design a robust LiDAR and camera cross-modality fusion module, Radian-Glue-Attention (RG-Attn), applicable to both intraagent cross-modality fusion and inter-agent cross-modality fusion scenarios, owing to the convenient coordinate conversion by transformation matrix and the unified sampling/inversion mechanism. We also propose two different architectures, named Paint-To-Puzzle (PTP) and Co-Sketching-Co-Coloring (CoS-CoCo), for conducting cooperative perception. PTP aims for maximum precision performance and achieves smaller data packet size by limiting cross-agent fusion to a single instance, but requiring all participants to be equipped with LiDAR. In contrast, CoS-CoCo supports agents with any configuration-LiDAR-only, camera-only, or LiDAR-cameraboth, presenting more generalization ability. Our approach achieves state-of-the-art (SOTA) performance on both real and simulated cooperative perception datasets. The code will be released at GitHub in early 2025.

# I. INTRODUCTION

The famous phrase "United we stand, divided we fall" by Aesop aptly captures the essence of multi-agent cooperative perception. Shared and fused perception information can be the crucial stepping stone, akin to an oracle's insight, leading to wiser maneuvering decisions that help prevent traffic accidents as depicted in Fig. 1. (a). By overcoming the limitations of single-agent perception through the exchange of processed sensing data among multiple agents, challenges like non-line-of-sight (NLOS) occluded blind zones, partial object detection and limited detection range can be significantly mitigated. Typically, cooperative perception relies on the integration of V2X wireless communication, sensor data processing, and fusion modules to create a unified collaboration platform. Beyond intelligent traffic systems, cooperative perception can also be applied in multi-robot automation and multi-UAV (unmanned aerial vehicle) deployment for business applications such as smart logistics warehousing, factory production lines, 3D scene scanning, or panoramic photography.

Throughout the evolution of cooperative perception, advancements in single-agent perception have consistently served as a significant reference point. For instance, fundamental computer vision backbones improve feature extraction capabilities, while attention mechanisms create correlations between features. In single-agent perception, there has been ongoing debate between the use of single-modality versus multi-modality approaches for commercial deployment of autonomous driving perception systems, balancing performance and cost. However, the current situation is that multi-modality offers clear advantages in most aspects of perception, such as accuracy, robustness, and detection range. This prevailing view is supported by the superior performance of multi-modality on various public datasets compared to single-modality approaches, since one more modality yield to richer representation features of object to be detected.

Meanwhile, in the realm of cooperative perception, existing methods have predominantly focused on fusing single unified modality data (e.g., LiDAR or camera) across multiple agents as depicted in Fig. 1. (b). It was not until the recent breakthroughs with HM-ViT [1] and HEAL [2] that certain forms of heterogeneous fusion became possible as depicted in Fig. 1. (c). However, both HM-ViT and HEAL still restrict themselves by sharing one modality of sensor data per agent only, meaning the full potential of multi-modality remains untapped and invalidated in multiagent collaboration. Simply forcing fusion of multi-modality sensor data (e.g., LiDAR and camera) per agent on HM-ViT or HEAL could even lead to markedly degraded performance compared to LiDAR-only multi-agent setting, due to the poor depth estimation from the camera modality. Thus, the gap between multi-agent single-modality and full multi-agent multi-modality still exists. Moreover, alongside efforts to close this gap, maintaining fusion compatibility with singlemodality agents is crucial, raising the question: how can we fully leverage every possible sensor on every possible agent for cooperative perception? While achieving high perception performance is the primary goal, we also recognize the importance of computational efficiency and communication support-ability for future industrial applications.

In this paper, we propose two novel multi-agent and multimodality cooperative perception architectures: Paint-To-Puzzle (PTP) and Co-Sketching-Co-Coloring (CoS-CoCo),

Fig. 1. (a) A typical traffic scenario where cooperative perception could be used to perceive through barriers and thus avoid collision. (b) Homogeneous modality multi-agent setting for conducting cooperative perception. (c) Heterogeneous modality multi-agent setting with a restriction on single modality per agent for conducting cooperative perception. (d) Heterogeneous full multi-modality multi-agent setting without restrictions on the number or types of modalities for conducting cooperative perception, partially covered by PTP and fully covered by CoS-CoCo.

each emphasizing different performance aspects based on the aforementioned motivations. PTP involves only one single inter-agent fusion step across all agents, with LiDAR modality as a mandatory requirement. This means that each participant performs its own cross-modality fusion before contributing to a unified fusion with all other agents. In contrast, CoS-CoCo uses a two-stage inter-agent fusion process: first fusion of LiDAR feature data among all agents equipped with LiDAR sensors, followed by fusion of camera feature data among all agents with camera sensors. Obviously, CoS-CoCo welcomes any agent with any sensor modality configuration to contribute. The choice between single-stage or two-stage cross-agent fusion affects the trade-off between PTP's lower communication bandwidth requirements and CoS-CoCo's broader diversity of sensor-sharing candidates, which leads to differences in perception performance. To enable efficient multi-modality fusion for both architectures, we design Radian-Glue-Attention (RG-Attn). RG-Attn samples the Bird's Eye View (BEV) feature map constructed from LiDAR sensor data based on the divided radians of the camera's field-of-view (FOV), enabling linear attention to each corresponding column of the camera feature map. This approach enhances the BEV feature map by incorporating the projected semantic information. Both PTP and CoS-CoCo outperform existing methods in the cooperative perception field by leveraging all available sensor sources as depicted in Fig. 1. (d), achieving dominant performance while significantly reducing training costs compared to most methods and maintaining real-time inference computational efficiency. In general, our contributions are as follows:

- We introduce RG-Attn, the first design to enable effective fusion of multi-modality data per agent for cooperative perception. RG-Attn is applicable to perform cross-modality fusion in both intra-agent and inter-agent scenarios, delivering robust and efficient performance.
- To unlock the potential of multi-modality in multi-agent cooperative perception, we propose PTP. To the best of our knowledge, PTP achieves SOTA performance on the mainstream cooperative perception datasets.
- We design CoS-CoCo as a prototype model with better

generalization ability for broader adaptability in practical heterogeneous deployment, validated in corresponding experiments on different combinations of modalities.

# II. RELATED WORKS

#### A. Single-Agent Perception

In the realm of single-agent perception tasks, a proliferation of various single-modal approaches has made their debuts in the coliseum, successively contributing to the solid foundation for both single-modality and multi-modality approaches. Benchmarks like KITTI and nuScenes [21] have ignited competition in both LiDAR point cloud track and camera vision track. Point cloud data benefits greatly from backbones like PointNet [22], pillar encoding or voxel encoding, which facilitates feature aggregation to reconstruct concise and accurate representations. Meanwhile, camera vision track pioneers have progressed from monocular vision, and then achieved explosive performance growth through the multi-view data availability and the depth estimation concept brought by LSS [13]. Transformer structures, such as ViT and Point-Transformer [14], [15], have further elevated the performance of both single-modality tracks, ushering in a new era. Recently, LiDAR-track and camera-track have converged to the BEV-based algorithms [23], [24], enabling 3D object queries and position encoding for projection, location and aggregation, irrespective of modalities.

On the other hand, multi-modality approaches focus on the intrinsic relationships between LiDAR and camera data. This began with PointPainting [15] to add camera semantic information as an additional dimension to the LiDAR point cloud data, and delved into DETR-like structures [16] to exploit attention mechanisms for representation relationship discovery. BEV-based multi-modality fusion methods [9], [10] have emerged as a powerful platform for performing cross-modality mutual adaptation and attention, thanks to BEV's ability to provide unified positional encoding and convenient query mechanisms for attention. Within the multimodality domain, a recent trend [11], [12] has emerged that the relatively poor estimated depth from camera source should be abandoned for the cross-modality fusion. Instead, they directly projected camera features via attention mechanisms onto the BEV space previously formed by point cloud data, thereby establishing a more robust cross-modality correspondence.

# B. Multi-Agent Cooperative Perception

Multi-agent cooperative perception offers unique technical advantages by approaching perception problems from a more comprehensive perspective. With the increasing richness of cooperative perception datasets [7], [8], the field has seen the rise and fall of various technical approaches and research directions. Early techniques focused on early raw data fusion [19] for source data original richness and late fusion [20] of detection results for less communication overhead. More recent studies [1], [2], [3] have utilized the intermediate features for fusion to achieve the balance between model performance and V2X bandwidth requirements.

Within the cooperative perception framework. Who2Comm series [6] focused on the priority of messages to transfer, FedBEVT [25] explored federated learning for cooperative perception, while Coopernaut and ICOP [4], [5] demonstrated how cooperative perception could enhance end-to-end (E2E) autonomous driving. The evolution of intermediate fusion methods has spanned concatenationbased, transformer-based, and pyramid-based approaches. Most existing works have focused on the single modality until recent HM-ViT [1] and HEAL [2] introduced multimodality. However, both HM-ViT and HEAL limited their solution to only one modality of shared data per agent. The existing gap is how much can we improve if fully leverage all possible sensor sources to pursue an oracle-like vision, this critical issue is addressed in this paper.

# III. METHODOLOGY

We first introduce the LiDAR and camera cross-modality fusion module as depicted in Fig. 2., and then expand on the design of two cooperative perception architectures that implement this fusion module as illustrated in Fig. 3. (a) and (b).

#### A. Radian-Glue-Attention (RG-Attn)

Since the generally inaccurate depth estimation from camera data is avoided, the key to successful cross-modality fusion lies in effectively projecting camera feature semantics onto the BEV feature space generated by the LiDAR backbone. Suppose the solid BEV feature map  $F_i^{\text{bev}} \in \mathbb{R}^{C_1 \times H_1 \times W_1}$ and camera feature  $F_{ik}^{cam} \in \mathbb{R}^{C_2 \times H_2 \times W_2}$  are generated from collaborative agents, where j and i denotes the sequence number of agents and ik identify the camera k equipped on agent *i*. Since we do not limit the fusion to occur within a single system, the transformation matrix  $T_{i \rightarrow i}$  of agent i to agent j considering the BEV gird size in reality world, along with the sensor k to its boarding agent transform  $t_{ik \rightarrow i}$  are utilized for locating the camera sensor's location  $t_{ik \rightarrow j}$  on the BEV feature map of agent j as  $T_{i \rightarrow j} \times t_{ik \rightarrow i}$ . The rotation part  $R_{i \rightarrow j}$  out of transformation matrix  $T_{i \rightarrow j}$  and the rotation matrix  $R_{ik \rightarrow i}$  of camera k to its mounted agent *i* to form  $R_{ik \rightarrow j}$  as  $R_{i \rightarrow j} \cdot R_{ik \rightarrow i}$ , will transfer the horizontal FOV angular interval  $\left[-\frac{\theta_{\rm FOV}}{2}, \frac{\theta_{\rm FOV}}{2}\right]$  from camera k on agent i to agent j  $\left[\theta_{ik \rightarrow j}^{\rm start}, \theta_{ik \rightarrow j}^{\rm end}\right]$  as  $\left[ \operatorname{atan} \left( R_{ik \rightarrow j} \cdot u \left(-\frac{\theta_{\rm FOV}}{2}\right) \right), \operatorname{atan} \left( R_{ik \rightarrow j} \cdot u \left(\frac{\theta_{\rm FOV}}{2}\right) \right) \right]$ , where *u* stands for the angle unit vector.

Fig. 2. RG-Attn structure enables cross-modality fusion between LiDAR BEV and camera 2D features. Camera sensor parameters (i.e., FOV, range, transform to LiDAR) configure the segmented grid sector for sampling the LiDAR BEV map to generate Queries. Camera features with learnable positional embedding provide Keys and Values. The BEV map's sampled width matches the camera feature width, allowing linear cross-modality multi-head attention. The fused features, after grid sector inversion, are concatenated with the original BEV map.

After determining the relative transform and the horizontal FOV range of camera k from agent i on the target BEV map of agent *j*, the most fundamental and intuitive geometric relationship between the camera feature matrix and the intersecting BEV feature map within its perception region is that the camera's horizontal FOV defines the angular range of its feature matrix projection on the BEV feature map. Therefore, segment the FOV by the width  $W_2$  of the camera feature matrix  $F_{ik}^{cam} \in \mathbb{R}^{C_2 \times H_2 \times W_2}$ , generating  $W_2$ sub-sectors to correspond with each column of the camera feature matrix. Divide each sub-sector along radius by grid number h to create segmented gridded sub-sectors, and define the camera feature fusion maximum range R on the BEV feature map, the correspondence between all the grids of the sector and the overlapping partial grids of BEV feature map could be established by using bilinear sampling, as we just draw a circular gridded sector with fixed radius R, coordinates of the sector's center  $(t_{ik \rightarrow j})$ , central angle of the sector  $\left|\theta_{ik \rightarrow j}^{\text{start}}, \theta_{ik \rightarrow j}^{\text{end}}\right|$ , angular segment granularity  $W_2$  and the radial segment granularity h on the target BEV map for later sampling and reverse sampling purpose. The camera feature fusion maximum range R is defined in terms of the granularity of the BEV grid's side length, which we set to half of the BEV rectangle's diagonal length to balance distortion levels and fusion range, and we set grid number h to  $H_1$ . All the correspondence parameters form the sampling configuration set  $Set_{ik\to j}$  as  $(t_{ik\to j}, \left[\theta_{ik\to j}^{\text{start}}, \theta_{ik\to j}^{\text{end}}\right], W_2, h, R)$ .

Fig. 3. In both the PTP and CoS-CoCo architectures, a single vehicle is designated as the ego vehicle to complete the full fusion process, while other vehicles perform preliminary steps before providing input to the ego vehicle. However, this process can also be fully and mutually carried out on each agent. (a) PTP requires only a single round of cross-agent fusion, as each participant contributes either a cross-modality fused BEV or a pure LiDAR-generated BEV. (b) CoS-CoCo incorporates all sensor sources from each participant, regardless of the sensor modality configuration (e.g., LiDAR-only, camera-only, or LiDAR-camera-both) in a two-stage cross-agent fusion process.

Thus, a grid sector sampling module is ready to extract a sector-shape sub-area of the original BEV and sample it into a rectangle-like feature space as  $F_{ik \rightarrow j}^{\text{sub-bev}} \in \mathbb{R}^{C_1 \times H_1 \times W_2}$  as:

$$F_{ik \to j}^{\text{sub-bev}} = \text{GridSectorSample}(F_j^{\text{bev}}, Set_{ik \to j}).$$
(1*a*)

Cross-modality fusion is then carried out by implementing a multi-head attention mechanism, with the linear layer generating queries from  $F_{ik \rightarrow j}^{\text{sub-bev}}$ , and keys and values from  $F_{ik}^{\text{cam}}$  as:

$$\overline{F}_{ik \to j}^{\text{fus-bev}} = \text{Attn}(\text{LN}(F_{ik \to j}^{\text{sub-bev}}), \text{ LN}(F_{ik}^{\text{cam}}), \text{ LN}(F_{ik}^{\text{cam}})). (1b)$$

The semantic information of camera feature matrix is "glued" onto the corresponding areas of the sampled BEV space based on the radians. Subsequently, grid sector inversion is applied to map the enhanced but distorted feature back to the original scale of the BEV feature map as:

$$F_{ik \to j}^{\text{fus-bev}} = \text{GridSectorInverse}(\overline{F}_{ik \to j}^{\text{fus-bev}}, Set_{ik \to j}).$$
(1c)

The inversion process utilizes the same geometric correspondence and reverses the sampling direction. Finally, the enhanced feature map  $F_{ik \rightarrow j}^{\text{fus-bev}}$  and the original feature map  $F_j^{\text{bev}}$  are concatenated to output  $F_{j+ik}^{\text{fus-bev}} \in \mathbb{R}^{C_1 \times H_1 \times W_1}$  as:

$$F_{j+ik}^{\text{fus-bev}} = \text{Cat}(F_j^{\text{bev}}, F_{ik \to j}^{\text{fus-bev}}).$$
(1d)

The overall process of RG-Attn, as described from equation (1a) to equation (1d), could be succinctly expressed by the following equation:

$$F_{j+ik}^{\text{fus-bev}} = \text{RG-Attn}(F_j^{\text{bev}}, F_{ik}^{\text{cam}}).$$
(1)

# B. Paint-To-Puzzle (PTP)

The core concept in the design of PTP is that every agent strives to create the most accurate fused BEV feature map before engaging in cross-agent fusion. As depicted in Fig. 3. (a), agents equipped with both LiDAR and cameras "**paint**" individual perceived scenarios and then "**puzzle**" them together. Consequently, the RG-Attn cross-modality fusion module is applied only within single-agent system in PTP, creating  $F_{ik\rightarrow i}^{\text{fus-bev}}$  multiple times, depending on the number *n* of cameras equipped on agent *i*. These semantically enriched features are then concatenated to form  $F_{i+\sum_{k=1}^{n}ik}^{\text{fus-bev}}$  as:

$$F_{i+\sum_{k=1}^{n}ik}^{\text{fus-bev}} = \text{RG-Attn}(F_i^{\text{bev}}, \{F_{ik}^{\text{cam}} \mid k = 1, 2, \dots, n\}), \quad (2a)$$

where  $i \in AgentsSet_{LiDAR+camera}$ . For collaborative agents equipped with LiDAR only, the original BEV feature map is retained as input for the subsequent "puzzle" part.

The Pyramid Fusion module from HEAL [2] is adopted as the backbone for the "puzzle" part, fusing all BEV feature maps into a richer BEV space as:

$$F_{\text{PTP}} = f_{\text{pyramid fusion}} \left( F_{i+\sum_{k=1}^{n} ik}^{\text{fus-bev}}, F_{m}^{\text{bev}} \right), \qquad (2b)$$

where  $i \in AgentsSet_{LiDAR+camera}$  and  $m \in AgentsSet_{LiDAR_only}$ . The multi-scale fusion structure and foreground awareness enhance the fusion of semantically glued features or original LiDAR features from entirely different perspectives. This process excludes camera-only collaborative agents due to their lack of a solid and relatively accurate depth-rooted BEV map. Only one unified format of shared perception payload is required.

# C. Co-Sketching-Co-Coloring (CoS-CoCo)

As depicted in Fig. 3. (b), CoS-CoCo could be clearly divided into two stages of fusion: **Co-Sketching**, which involves the fusion of LiDAR BEV feature maps among LiDAR-equipped agents to provide the basic skeleton of the perceived surrounding environment, and **Co-Coloring**, which projects camera features onto the skeleton formed in the first stage. Similar to the BEV feature map fusion in PTP, the Pyramid Fusion module is employed in the Co-Sketching stage to fuse all available BEV feature maps into a robust, unified BEV feature map  $F_{pyr}^{bev} \in \mathbb{R}^{C_1 \times H_1 \times W_1}$  as:

$$F_{pyr}^{\text{bev}} = f_{\text{pyramid fusion}} \left( F_l^{\text{bev}} \right), \qquad (3a)$$

where  $l \in AgentsSet_{LiDAR}$ , indicating that every collaborative agent equipped with LiDAR "co-sketches" the solid skeleton.

In the Co-Coloring stage, every feature matrix from all available camera sensor sources and corresponding encoders is subsequently "glued" onto the unified BEV feature map  $F_{pyr}^{bev}$  by leveraging the robustness and flexibility of our RG-Attn cross-modality fusion module in heterogeneous agent settings. Depending on the total number of camera-equipped agents and the corresponding number of cameras onboard, the Co-Coloring process can be represented as:

$$F_{\text{CoS-CoCo}} = \text{RG-Attn}(F_{pyr}^{\text{bev}}, \{F_{ck}^{\text{cam}} \mid k = 1, 2, \dots, n\}), (3b)$$

where  $c \in AgentsSet_{camera}$  and *n* is the number of cameras per agent in the set. The key advantage of CoS-CoCo is that it re-integrates camera-only collaborative agents into the cooperative system, though it requires two different formats of cooperative perception payloads.

# IV. EXPERIMENTS AND RESULTS

# A. Datasets

To validate the effectiveness of our full multi-modality, multi-agent solution against previous approaches, we utilize the DAIR-V2X and OPV2V datasets for training and evaluation. Our primary focus is on DAIR-V2X during the derivation of the model design, as it is based on real-world cooperative perception data collected in Beijing Yizhuang Autonomous Driving Demonstration Zone, presenting practical challenges. The DAIR-V2X dataset contains 9K frames, each comprising raw data from a vehicle agent and a roadside unit (RSU) agent, with LiDAR and camera data available from both agents, though each agent is equipped with only one camera. Conversely, the CARLA-simulated OPV2V dataset provides over 11K frames across diverse scenarios, with each frame of scenario containing raw data from 2 to 7 vehicles. Each vehicle in OPV2V is equipped with one LiDAR and four cameras in a unified manner.

In our experiments with both datasets, we consider three types of agents: LiDAR-only, camera-only, and LiDAR-camera-equipped. In OPV2V, all four cameras (800x600 resolution) are utilized for camera-equipped agents, with the default 64-channel 360° LiDAR for LiDAR-equipped agents, and no additional data enhancements are applied. For DAIR-V2X, both the RSU and vehicle provide 1920x1080 camera data, with notable variations in sensor placement heights. The RSU's LiDAR has 300 channels with a 100° FOV, while the vehicle's LiDAR is 40-channel with a 360° FOV.

# B. Settings

**Implementation details:** We adopt unified encoders for raw data processing: PointPillar [18] for LiDAR point cloud and the first five sequential five layers of ResNet101 for camera images. The LiDAR BEV map is down-sampled 2x and further reduced to a shape of [64, 128, 256] using 3 consecutive ConvNeXt [17] blocks, with a grid size of [0.4m, 0.4m]. The feature matrix for each camera sensor after the encoder is in shape [8, 144, 256], as we fix the target channel, width and height of the output to deal with the different resolution specification in two datasets. In both PTP and CoS-CoCo, multi-head attention is configured with an embedding dimension of 64, attention heads of 8, and a dropout rate of 0.1. The pyramid fusion conducts multi-level fusion with widths (i.e., the last dimension of BEV map feature shape) at 256, 128 and 64 consequently. For fair comparison with existing SOTA approaches, the detection range in both training and evaluation is set to  $x \in [-102.4m, +102.4m], y \in [-51.2m, +51.2m]$ . Object detection task head is added, and average precision (AP) is calculated at different intersection-over-union (IoU) thresholds.

**Training configurations:** Three loss function regarding the classification, regression and direction are used, incorporating foreground map output into loss calculation. We use Adam optimizer, with an initial learning rate set to 0.2 and decrease by 0.1 from epoch 15 to 25 for OPV2V and from epoch 35 to 40 for DAIR-V2X. On an NVIDIA RTX 6000 Ada, the training process with 30 epochs for both OPV2V and 40 epochs for DAIR-V2X in total no matter the model is PTP or CoS-CoCo, costs approximately 6 hours for training on DAIR-V2X if setting batch size to 4. But for the OPV2V case, the number of agents can reach up to 7 and each vehicle's four-camera setup significantly increase computational demand, resulting in around 36 hours of training time due to GPU memory constraints.

# C. Quantitative & Visualization Results

As shown in Table I, we compare the evaluation results of our approaches against best performance results of existing methods under identical conditions (i.e., collaborative agents set to 2 for DAIR-V2X and 4 for OPV2V, with a fixed detection range) to ensure a fair comparison. The only distinction is that the compared methods rely solely on LiDAR data from all collaborative agents for their peak performances as reported in the corresponding published papers, CoBEVT and HEAL present performance degradation when incorporating camera data features compulsively by contrasting the AP30 column of Table I and last column of Table II (where both LiDAR and camera modalities are enabled for both agents). In contrast, our approach leverages the additional positive benefits of camera data, which could be reflected by the comparison between HEAL and our proposed methods as we build the cross-modality fusion module based on the LiDAR-only structure of HEAL (i.e., both of our proposed models deliver the same performance as HEAL if restricted to LiDAR-only cross-agent fusion).

We further assess our method's performance across various combinations of agent numbers and modalities on the DAIR-V2X dataset, as presented in Table II, where "+" separates two agents, "L" stands for LiDAR, "C" for camera, and "LC" for agent equipped with both LiDAR and camera. All models are trained only once with full multi-modality multi-agent setting (i,e,. LC+LC), and directly used for all the inferences with different settings. The performances of HEAL and CoBEVT for conducting multi-modality, are achieved by their BEV fusion module to fuse all BEV feature maps from different modalities and agents, decreased by 5.6% and

CoS-CoCo (Ours)	0.705	0.712	0.848	0.854	

19.9% in DAIR-V2X AP30 compared to LiDAR-only case, reflecting their negatives of incorporating camera modality.

The corresponding communication budget for sharing the cooperative perception intermediate data is 4.56 Megabytes for PTP and 6.25 Megabytes for CoS-CoCo, representing one uncompressed data frame per agent. The inference time for PTP or CoS-CoCo is approximately 40 milliseconds when two collaborative agents are involved, with the RG-Attn module requiring no more than 4 milliseconds per fusion.

In addition to the quantitative results, visualizations of the intermediate cross-modality fusion via the RG-Attn module and the final object detection outcomes of our methods versus the previous SOTA method are shown in Fig. 4., respectively.

# D. Performance Analysis

Fusion Effectiveness: Both PTP and CoS-CoCo surpass the existing methods, as shown in Table. I, largely due to the effective cross-modality fusion capabilities of the RG-Attn module. PTP achieves dominant performance on both datasets, surpassing the previous SOTA method HEAL by 3.0% in DAIR-V2X AP30 and 1.9% in OPV2V AP70, extracting the maximum potential from the current RG-Attn design. This is attributed to the intra-agent fusion process, where camera semantic features are effectively "glued" to the intact sampled LiDAR-derived BEV feature map, fully transforming the camera features to enhance the BEV map. However, when conducting the cross-modality fusion in inter-agent stage of CoS-CoCo, the intersection area for sampling the BEV map to align with camera's FOV might reach the boundary of LiDAR feature map, depending on the relative distance between two agents. Such cases can result in abnormal and fragmentary semantic information projection, leading to less effective fusion. The evident contrast can be observed in perception results visualization from Fig. 4. (b) to (d) consequently, with more objects identified and more

(d) PTP (LiDAR-camera-both multi-agent fusion)

Fig. 4. The BEV map before RG-Attn and the cross-modality fused BEV map after RG-Attn is shown in (a), based on one frame of cross-modality data from DAIR-V2X RSU. Visualization of cooperative perception results comparing our methods against the previous SOTA method—HEAL are given from (b) to (d), the ground truth and the predicted bounding boxes are in corresponding colors.

accurate bounding boxes given incrementally.

**Generalization:** On the other hand, CoS-CoCo delivers more robustness and adaptability as shown in Table II, where performance does not fall off a cliff due to the heterogeneous modality settings. The CoS-CoCo model for evaluation does not require any additional training or re-training process to integrate agents with different modality configurations, reflecting its greater potential for real-world applications.

Ablation Component: The LiDAR-only cross-agent fusion setting for PTP or CoS-CoCo, representing the absence of RG-Attn for cross-modality fusion, leads to a performance degradation of 3.0% in AP30 and 2.7% in AP50 on DAIR-V2X, significantly higher than experimental error. Fig. 4. (a) can also reflect the essential functionality of RG-Attn, as the output BEV feature map exhibits a more distinct feature distribution.

# V. CONCLUSION AND FUTURE WORK

We view our work as an initial step toward achieving comprehensive multi-agent, multi-modality fusion in cooperative perception, with significant room for further performance improvements. The RG-Attn module could be refined to perform cross-modality fusion more accurately, and the overall framework could be expanded to integrate the strengths of both PTP and CoS-CoCo. In general, we have demonstrated the accuracy and efficiency of our novel designs for cooperative perception in this paper. We hope this work encourages further discussions and advancements in the field of multi-modality multi-agent cooperative perception.
