ABSTRACT

Black hole X-ray binaries (BHXBs) are observed in various wavelengths from radio to GeV gamma-ray. Several BHXBs, including MAXI J1820+070 and Cygnus X-1, are also found to emit ultrahigh-energy (UHE; photon energy >100 TeV) gamma rays. The origin and production mechanism of the multi-wavelength emission of BHXBs are under debate. We propose a scenario where relativistic particles from magnetically arrested disks (MADs), which could form when BHXBs are in quiescent or hard states, produce UHE gamma rays, while electrons in the jets produce GeV gamma-ray emission. Specifically, magnetic turbulence in MADs heats up and accelerates electrons and protons, while magnetic reconnection in jets accelerates electrons. Sub-PeV gamma rays and neutrinos are produced when relativistic protons interact with the thermal protons and the radiation by thermal electrons in the disk. We discuss the perspectives of observing sub-PeV multi-messenger signals from individual BHXBs. Finally, we evaluate the integrated fluxes of the quiescent and hard-state BHXB population and find that BHXBs may contribute to the Galactic diffuse emission above ~ 100 TeV.

Keywords: Stellar mass black holes (1611); Low-mass x-ray binary stars (939); Accretion (14); non-thermal radiation sources (1119); Cosmic ray sources (328)

1. INTRODUCTION

Black hole X-ray binaries (BHXBs) consist of a stellar-mass black hole (BH) and a companion star. An accretion disk forms around the BH due to mass accretion from the companion star and other nearby material. This type of system is observed from radio to X-rays and sometimes in GeV gamma-ray (e.g., Motta et al. 2021). Recently, Large High Altitude Air Shower Observatory (LHAASO) reported the detection of ultrahigh-energy (UHE; > 100 TeV) gamma rays from several BHXBs. In particular, they find point-like gamma-ray sources associated with MAXI J1820+070 and Cygnus X-1 with spectra extending to ~ 100 TeV (LHAASO Collaboration 2024).

The origins of these ultrahigh-energy (UHE) gamma rays are unknown. Two general emission mechanisms exist—leptonic and hadronic. In a leptonic scenario,

UHE electrons up-scatter photons to the UHE regime via inverse Compton scattering (e.g., Zdziarski et al. 2009). In a hadronic scenario, neutral pions produced by the inelastic pp collisions ($p + p \rightarrow p + p + \pi$) and the photomeson production ($p + \gamma \rightarrow p + \pi$) (e.g., Pepe et al. 2015; Kantzas et al. 2021) of PeV protons decay into UHE gamma rays.

Galactic BHXBs exhibit multiple spectral states. In a hard state, the X-ray spectrum shows a hard power law with a cutoff around 30 - 100 keV (Done et al. 2007; Belloni 2010). Hard-state X-rays are typically explained as the thermal inverse Compton scattering by hot electrons in a corona (McConnell et al. 2002). The nature of the corona, however, is still under debate. Studies (e.g., Esin et al. 1997; Wang et al. 2024) have proposed that the corona may be identical to a hot accretion flow, also known as a radiatively inefficient accretion flow (RIAF; Narayan & Yi 1994; Yuan & Narayan 2014). Hot accretion flows may also occur in a quiescent state, where the mass accretion rate is low.

In a RIAF, high disk temperature yields high viscosity (Shakura & Sunyaev 1973), leading to high radial

velocity and efficient magnetic flux accumulation onto the central BH (Cao 2011; Kimura et al. 2021). As a result, magnetically arrested disks (MADs; Bisnovatyi-Kogan & Ruzmaikin 1974; Narayan et al. 2012) likely form, in which a magnetic flux threading in the BH is at a saturation level.

In Kuze et al. (2024), we developed a two-zone emission model, called the ‘Jet-MAD model’, to explain the multi-wavelength emission by nearby radio galaxies. This model consists of two emission components—MADs and jets. In MADs, we consider emission processes of thermal electrons, nonthermal electrons, non-thermal protons, and secondary particles. In jets, our model accounts for the emission processes of nonthermal electrons. Notable features of this model include the careful treatment of plasma injection into the jet, which is based on phenomena at the jet base exhibited by magnetohydrodynamic (MHD) simulations (Ripperda et al. 2022), and a consistent evaluation of plasma parameters at the jet dissipation region, derived from those determined at the jet base.

In this paper, we examine whether such a two-zone emission model explains the multi-wavelength data of BHXBs. We also investigate the role of BHXBs in producing the diffuse gamma-ray and neutrino emission of the Galactic plane recently reported by air shower gamma-ray observatories (Amenomori et al. 2021; Cao et al. 2023; Alfaro et al. 2024a) and IceCube (Icecube Collaboration et al. 2023). BHXBs that emit 10-100 TeV gamma rays and neutrinos should produce PeV cosmic rays (CRs). This motivates us to evaluate the contribution of BHXBs to the Galactic CR spectrum especially at PeV energies (cf. Cooper et al. 2020; Kimura et al. 2021; Kantzas et al. 2023).

The paper is organized as follows. We describe the Jet-MAD model in Section 2. In Section 3, we show the results of applying our model to selected BHXBs. In Section 4, we discuss the contribution of the BHXBs to the Galactic diffuse emission. We present our conclusion in Section 5.

2. JET-MAD MODEL

Studying the multi-wavelength emission from jets and MADs is well motivated as jets are efficiently produced when the accretion disk is in the MAD regime (Tchekhovskoy et al. 2011). Here we briefly describe the Jet-MAD model developed by Kuze et al. (2024). We define a MAD as an accretion flow with $\beta \lesssim 1$, where β is plasma beta. In a MAD, MHD turbulence is induced by the plasma instability, such as magnetic Rayleigh-Taylor instability (e.g., McKinney et al. 2012; Marshall et al. 2018; Xie & Zdziarski 2019). The MHD tur-

bulence heats up thermal plasma and accelerates non-thermal particles. Magnetic reconnection near the BH (Ripperda et al. 2022) accelerates the electrons emitting high-energy gamma rays (Hakobyan et al. 2023), which interact with each other, resulting in copious pair loading into the jet (Kimura et al. 2022; Chen et al. 2023). The loaded pairs move outward, and at some distance from the BH, the jets are unstable by some plasma instability (Nishikawa et al. 2016; Borse et al. 2021; Sironi et al. 2021), triggering magnetic reconnection inside the jets with the entrainment of ambient gas. This magnetic reconnection accelerates electron-positron pairs in the jets, leading to multi-wavelength photon emission. In our model, jets and MADs are physically connected through the plasma loading and energy extraction processes.

We show the condition required to form a MAD in Section 2.1. In Sections 2.2 and 2.3, we briefly explain the emission and particle acceleration inside the MADs and the jets, respectively. Very-high-energy gamma rays are absorbed through the Breit-Wheeler process ($\gamma + \gamma \rightarrow e^+ + e^-$) by the radiation field of the companion star. We estimate the optical depth of this process in Section 2.4.

2.1. Condition for MAD

We consider high-temperature plasma accreting onto the BH. We normalize the mass accretion rate, \dot{M} , and the size of the emission region, R_d , by the Eddington rate and the gravitational radius, respectively, i.e., $\dot{M}c^2 \equiv \dot{m}L_{\text{Edd}}$, $R_d \equiv rR_g = rGM_{\text{BH}}/c^2$, where L_{Edd} is the Eddington luminosity, c is the speed of light, and G is the gravitational constant. We use the notation $Q_X = Q/10^X$ unless otherwise noted. For the BH mass, we use the notation $M_1 = M_{\text{BH}}/(10M_{\odot})$.

Thermal protons in the MAD cannot cool through the radiative processes and their temperature is comparable to the virial temperature. Thermal electrons receive a significant fraction of the dissipation energy and become relativistic. Unlike protons, electrons may be efficiently cooled by radiative processes and their temperature is mildly relativistic. Thermal electrons and protons interact through the Coulomb collisions and exchange their energy. When the electron-proton relaxation timescale, t_{pe} , is shorter than the infall timescale, t_{fall} , protons cool by the Coulomb collision. This results in a low proton temperature, with which the accretion disk is no longer in the RIAF regime. Therefore, we assume that the MAD is not formed when such a condition is met.

We estimate the electron-proton relaxation timescale inside the MADs following Equation (13) of Takahara &

Kusunose (1985):

$$t_{pe} = \frac{1}{n_{p,\text{mad}}\sigma_T c} \sqrt{\frac{\pi}{2}} \frac{m_p}{m_e} \frac{1}{\ln \Lambda} (\theta_e + \theta_p)^{3/2}, \quad (1)$$

where $n_{p,\text{mad}}$ is proton number density inside the MAD, σ_T is the Thomson cross section, m_p is the proton mass, m_e is the electron mass, $\ln \Lambda$ is the Coulomb logarithm, $\theta_e = k_B T_e / (m_e c^2)$ is the normalized electron temperature, $\theta_p = k_B T_p / (m_p c^2)$ is the normalized proton temperature, and k_B is the Boltzmann constant. The radial velocity, sound velocity, and number density inside the MAD are analytically estimated to be (see Kimura et al. 2019a; Kimura & Toma 2020, for parameters for active galactic nuclei)

$$V_R \approx \frac{1}{2} \alpha V_K \simeq 1.5 \times 10^9 \alpha_{-0.5} r_1^{-1/2} \text{ cm s}^{-1}, \quad (2)$$

$$C_s \approx \frac{1}{2} V_K \simeq 4.7 \times 10^9 r_1^{-1/2} \text{ cm s}^{-1}, \quad (3)$$

$$n_{p,\text{mad}} \approx \frac{\dot{M}}{4\pi R H V_R m_p} \quad (4)$$

$$\simeq 4.1 \times 10^{16} \dot{m}_{-1} M_1^{-1} r_1^{-3/2} \alpha_{-0.5}^{-1} \text{ cm}^{-3},$$

where α is the viscous parameter (Shakura & Sunyaev 1973), $V_K = \sqrt{GM_{\text{BH}}/R_d}$ is the Keplerian velocity, and $H \approx (C_s/V_K)R \approx R/2$ is the scale height.

We estimate the infall timescale as

$$t_{\text{fall}} \approx \frac{R_d}{V_R} \simeq 9.8 \times 10^{-3} r_1^{3/2} M_1 \alpha_{-0.5}^{-1} \text{ s}. \quad (5)$$

From Equations (1) and (5), we compare t_{pe} and t_{fall} and determine whether the disk is in the MAD state. By equating t_{pe} with t_{fall} , we derive the critical mass accretion rate, \dot{m}_{crit} . Assuming $\theta_e > \theta_p$, we estimate \dot{m}_{crit} as

$$\dot{m}_{\text{crit}} \simeq 0.35 \alpha_{-0.5}^2 \theta_{e,-0.5}^{3/2}. \quad (6)$$

If $\dot{m} > \dot{m}_{\text{crit}}$, the relaxation timescale is shorter than the infall timescale, and the accretion disk is not in the MAD state. The assumption of $\theta_e > \theta_p$ is always satisfied for the MADs as long as electrons are relativistic, which is reasonable at $R_d < (m_p/m_e)R_g$.

Observations and numerical simulations both imply the existence of MADs in hard-state BHXBs. You et al. (2023) interprets the time lag of MAXI J1820+070 between the radio and X-ray bands as the MAD formation time. Using general relativistic radiation magnetohydrodynamic (GRRMHD) simulations, Moscibrodzka (2024) shows that MADs can reproduce the X-ray polarization data of Cygnus X-1 observed by Imaging X-ray Polarimetry Explorer (IXPE; Krawczynski et al. 2022).

BHXBs are in the quiescent state if the mass accretion rate is highly sub-Eddington, e.g., $\dot{m} < 0.01$. MADs may also form in such a state due to inefficient matter cooling (see Kimura et al. 2021).

2.2. MAD model

Below we summarize the emission model inside the MADs constructed by Kimura & Toma (2020) and Kuze et al. (2024). MHD turbulence in the MADs heats up the plasma and accelerates nonthermal particles (Lynn et al. 2014; Kimura et al. 2016; Zhdankin et al. 2018; Kimura et al. 2019b; Sun & Bai 2021), which emit multi-wavelength photons via synchrotron radiation.

In the MAD model, we consider five particle species: thermal electrons, primary electrons, primary protons, secondary electron-positron pairs produced by the Breit-Wheeler process, and those by the Bethe-Heitler process ($p + \gamma \rightarrow p + e^+ + e^-$).

Thermal electrons heated by the MHD turbulence emit multi-wavelength photons via synchrotron and Comptonization processes. We determine the electron temperature by balancing the heating and the cooling rates. As the electron heating process inside the MAD is still unknown (e.g., Kawazura et al. 2020), we set the electron-proton-heating ratio, Q_i/Q_e , as a parameter and set it to be 1. We calculate the cooling rates of the thermal electrons in the same manner as Kimura et al. (2015).

The MHD turbulence accelerates primary protons and electrons, emitting nonthermal synchrotron radiation. We obtain the energy distribution of nonthermal particles by solving the energy transport equation with one-zone and steady-state approximations:

$$-\frac{d}{dE_i} \left(\frac{E_i N_{E_i}}{t_{i,\text{cool}}} \right) = -\frac{N_{E_i}}{t_{\text{esc}}} + \dot{N}_{E_i,\text{inj}}, \quad (7)$$

where i is the particle species, E_i is the particle energy, N_{E_i} is the differential number spectrum, $\dot{N}_{E_i,\text{inj}}$ is the injection term, and $t_{i,\text{cool}}$ and t_{esc} is cooling and escape timescales, respectively. The injection term is assumed to be a power-law with an index s_{inj} and an exponential cutoff at a cutoff energy, $E_{i,\text{cut}}$. We determine s_{inj} using the power-law solution of the transport equation in Section 2 of Stawarz & Petrosian (2008), where a hard-sphere-like momentum diffusion coefficient, $D(p) \propto p^2$, is assumed. We estimate the cutoff energy in two ways. In one approach, it is obtained by balancing the acceleration and energy loss timescales, referred to as $E_{\text{cut,cl}}$. In the other approach, it is evaluated as the Hillas energy, $E_{\text{Hillas}} \approx e B_d R_d (V_A/c) \simeq 3.0 \times 10^{15} B_{d,6} R_{d,7} (V_A/c) \text{ eV}$, where B_d is the magnetic field strength in the MAD and $V_A/c \approx 0.71 r_1^{-1} \beta_{-1}^{-1/2}$ is the Alfvén velocity. We set the cutoff energy as the lower one of these, $E_{\text{cut}} = \min(E_{\text{cut,cl}}, E_{\text{Hillas}})$.

We account for the following energy loss processes: diffusive escape, infall to the BH, and relevant cooling processes, including synchrotron radiation, Bethe-

Heitler process, pp inelastic collision, and photomeson production.

Nonthermal protons interact with optical-to-X-ray photons through the Bethe-Heitler process and the photomeson production. These processes cause the production of secondary electron-positron pairs and pions. In the MAD model, we approximate the injection term of the secondary electron-positron pairs produced by the Bethe-Heitler process as

$$E_{\text{BH},\pm}^2 \dot{N}_{\text{BH},\pm,\text{inj}} \approx E_p^2 N_{E_p} t_{\text{BH}}^{-1}, \quad (8)$$

where $E_{\text{BH},\pm} \approx (m_e/m_p)E_p$ is the energy of the produced pairs. These pairs and pions produce high-energy gamma rays, which interact with lower-energy photons in MADs, leading to electromagnetic cascades. We estimate the optical depth of the Breit-Wheeler process, $\tau_{\gamma\gamma}$, following Coppi & Blandford (1990), and the gamma rays are attenuated by a factor of $F_{\text{atn}} \approx (1 - \exp[-\tau_{\gamma\gamma}])/\tau_{\gamma\gamma}$. The injection term of the secondary electron-positron pairs produced by the Breit-Wheeler process is approximated to be

$$E_{\gamma\gamma,\pm}^2 \dot{N}_{\gamma\gamma,\pm,\text{inj}} \approx (1 - F_{\text{atn}}) E_\gamma L_{E_\gamma}, \quad (9)$$

where $E_{\gamma\gamma,\pm} \approx E_\gamma/2$ is the pair energy and L_{E_γ} is the intrinsic differential photon luminosity of all components. Since the injection term in Equation (9) depends on the gamma-ray spectrum, we iteratively calculate the photon and the electron-positron pair spectra until they converge. The pion decay also emits high-energy neutrinos, and we calculate the neutrino spectrum based on Section 2 of Kimura & Toma (2020).

In BHXBs, a standard geometrically thin disk may exist outside the MAD. Such a geometry is consistent with the IXPE observation of Cygnus X-1 (Krawczynski et al. 2022), though other geometries have also been proposed (for example, Moscibrodzka 2024). At an even larger distance, the companion star provides a radiation field. Photons from the standard disk and the companion star can be targets of the hadronic and thermal Comptonization processes. We evaluate their number densities assuming a truncation radius of the standard disk as $R_{\text{disk}} \sim 10^2 R_g$. We find that the densities of these photons are low due to their large distances from the gamma-ray emission region in the MAD. Therefore, we ignore both components in our calculation. In the hard state of Cygnus X-1, the truncation radius is estimated to be $\sim 15 R_g$ (e.g., Makishima et al. 2008), but the contribution by the disk photons is still subdominant to the MAD photons.

2.3. Jet model

In this subsection, we briefly explain the pair loading into the jet, particle acceleration, and the emission from the jet. A more detailed model description is shown in Kuze et al. (2024).

In the MAD state, magnetic reconnection periodically occurs in the vicinity of the BH where magnetic energy density is much higher than the plasma energy density (Ripperda et al. 2022). Magnetic reconnection in such a magnetic-energy dominant region accelerates the surrounding plasma particles and the accelerated electrons emit high-energy photons. These photons interact with each other and produce electron-positron pairs, forming a blob. We determine the magnetization parameter of the blob formed at the jet base, σ_\pm , by equating the pair production rate with the pair escape rate (Chen et al. 2023). We find that $\sigma_\pm \simeq 10^2 \gg 1$ is satisfied for typical BHXB parameters, showing that the jet base is highly magnetized.

The blob created at the jet base travels outward, and we assume that the blob dissipates its energy at $\sim 3 \times 10^4 R_g$ away from the BH. At the outer part of the jet, the toroidal magnetic field is dominant, where we can write $B \propto R^{-1}$ owing to the magnetic flux conservation, where R is the cylindrical radial distance from the jet axis. If the number flux of the jet plasma is conserved, i.e., $n_e \propto R^{-2}$, then the magnetization parameter conserves along the jet. However, the blob expands along the magnetic field lines due to their velocity dispersion, causing a more rapid decline in the number density. Thus, by introducing a numerical factor $\xi \simeq 10^3$, the magnetization parameter in the jet dissipation region can be written as $\xi\sigma_\pm$.

Since $\xi\sigma_\pm \gg 1$, magnetic energy is dominant as the internal energy inside the jet, and the magnetic energy dissipation accelerates the pairs. Due to the velocity difference between the jet and the ambient gas, we consider that Kelvin-Helmholtz instability (KHI) is triggered at the jet edge (Sironi et al. 2021). The KHI generates turbulence inside the jet, which induces magnetic reconnection (e.g., Yang et al. 2024). Owing to KHI, electron-proton plasma can entrain into the jet from the ambient gas. Thus, the magnetization parameter decreases due to the plasma entrainment and the magnetic reconnection. Turbulent magnetic reconnection accelerates the nonthermal particles (e.g., Hoshino 2012; Xu & Lazarian 2023). We define the magnetization parameter after plasma entrainment, σ_{ent} , given as a free parameter. This parameter determines the electron number density after plasma entrainment.

We solve the energy transport equation with the one-zone and the steady-state approximations to obtain the electron energy distribution (see Equation (7) of Kuze

Table 1. Physical quantities for each BHXB.

	Cygnus X-1	MAXI J1820+070	GRO J1655-40	GX 339-4	XTE J1118+480
$M_{\text{BH}}(M_{\odot})$	21	7.0	6.3	9.0	7.0

NOTE— M_{BH} , Γ_j , θ_j , L_{star} , T_{star} , a_{binary} , d_L , and δ are the mass of the black hole, jet Lorentz factor, jet inclination angle, the luminosity of the companion star, the temperature of the companion star, the separation distance, luminosity distance from Earth to each BHXB, and declination of each BHXB, respectively. The references for each physical quantity of individual BHXBs are Wood et al. (2021), Yoshitake et al. (2024), Koljonen et al. (2023) for MAXI J1820+070, Tetarenko et al. (2019), Miller-Jones et al. (2021) for Cygnus X-1, Saikia et al. (2019), Migliari et al. (2007), Shidatsu et al. (2016), Liu et al. (2007) for GRO J1655-40, Heida et al. (2017), Kosenkov et al. (2020), Malzac et al. (2018), Buxton et al. (2012) for GX 339-4, and Chatterjee et al. (2019), Saikia et al. (2019), González Hernández et al. (2012), McClintock et al. (2001) for XTE J1118+480.

et al. 2024). We assume that the injection term follows a power-law with an index p given as a free parameter (see Equation (8) of Kuze et al. 2024). We determine the maximum energy as $\gamma_{\text{max}} = (\delta B/B)^2 \xi \sigma_{\pm}$, where δB is the amplitude of the turbulent magnetic field.

Nonthermal electrons lose their energy through synchrotron radiation, synchrotron self-Compton scattering (SSC), adiabatic cooling, and the diffusive escape by the resonant scattering with the KHI-induced turbulence (see Appendix D of Kuze et al. 2024). Since the jet emission region is far from the BH, the photons emitted from the MADs and the companion star cannot be the dominant target photons of the inverse Compton scattering, and we ignore these components in our calculation of the jet emission.

We calculate the jet emission as $\nu_{\text{obs}} L_{\nu, \text{obs}} = \delta_D^4 \nu_{\text{src}} L_{\nu, \text{src}}$, where $\nu_{\text{obs}} L_{\nu, \text{obs}}$ is the observed luminosity, δ_D is the Doppler factor, and $\nu_{\text{src}} L_{\nu, \text{src}}$ is the intrinsic photon spectrum obtained by the jet model. We estimate the Doppler factor of each BHXB using the estimated jet Lorentz factor, Γ_j , and the jet inclination angle, θ_j (see Table 1).

2.4. Photo-attenuation by the companion star

Very-high-energy gamma rays produced in the MADs and jets may be absorbed by the radiation field of the companion star when they leave the source. We calculate the optical depth of the Breit-Wheeler process by the companion star radiation for Cygnus X-1, $\tau_{\gamma\gamma, \text{star}}$, following the method in Coppi & Blandford (1990). Figure 1 shows the phase-averaged $\tau_{\gamma\gamma, \text{star}}$ as a function of the gamma-ray photon energy. In general, the optical depth is less than unity at $E_{\gamma} \gtrsim 10^{13}$ eV. Since the magnetic field around the companion star is not

Figure 1. Optical depth of the Breit-Wheeler process by the companion star radiation for Cygnus X-1 as a function of the target photon energy (red line). The gray dashed line represents $\tau_{\gamma\gamma, \text{star}} = 1$.

strong, cascade pairs cool by the inverse Compton scattering process. We calculate the attenuation factor as $F_{\text{atn}, \text{star}} \sim 1/\tau_{\gamma\gamma, \text{star}}$. As $F_{\text{atn}, \text{star}} \lesssim 1$ at $E_{\gamma} \gtrsim 10^{13}$ eV, photons above 10 TeV are not absorbed by the companion star of Cygnus X-1.

Using the physical quantities tabulated in Table 1, we find $\tau_{\gamma\gamma, \text{star}} \lesssim 0.1$ in other BHXBs. Thus, their companion stars do not absorb very-high-energy gamma rays.

3. PHOTON AND NEUTRINO EMISSIONS FROM INDIVIDUAL BHXBS

We apply our Jet-MAD model to five BHXBs: Cygnus X-1, MAXI J1820+070, GRO J1655-40, GX 339-4, and XTE J1118+480. We selected these BHXBs because they have better-quality observational data than other BHXBs. We list the physical quantities for each BHXB in Table 1 and the model parameter sets and derived physical quantities in Table 2.

Table 2. The list of the parameters and the physical quantities of the Jet-MAD model for various BHXBs.

Parameters of the Jet-MAD model for each BHXB					
	Cygnus X-1	MAXI J1820+070	GRO J1655-40	GX 339-4	XTE J1118+480

NOTE— L_j is the jet luminosity where the pairs are injected at the jet base and L_e is the electron luminosity at the jet dissipation region.

We note that UHE gamma rays have also been observed from SS 433 (Abeysekara et al. 2018), V4641 Sgr (Alfaro et al. 2024b), and GRS 1915+105 (LHAASO Collaboration 2024). These gamma-ray sources are extended and likely originate from structures around the binaries, such as the large-scale jets of the microquasars. Thus, we do not discuss these three objects in this paper.

Below we first analytically estimate the typical photon energies, gamma-ray luminosity, efficiencies of each physical process, and the internal optical depth of MADs in Section 3.1. We discuss the results of the photon spectra in Sections 3.2, 3.3, and 3.4 for Cygnus X-1, MAXI J1820+070, and the other BHXBs, respectively. We show the results of the neutrino spectra for five BHXBs in Section 3.5.

3.1. Typical features of photon and neutrino spectra

The jets emit the radio signals and GeV gamma rays by the synchrotron radiation and the SSC, respectively, and MADs emit very-high-energy gamma rays by the pion decay produced by the pp inelastic collisions.

The electron maximum Lorentz factor in the jets is $\gamma_{\text{max}} = (\delta B/B)^2 \xi \sigma_\pm \simeq 10^4 (\delta B/B)_{-0.5}^2 \xi_3 \sigma_{\pm,2}$, corresponding to a synchrotron photon energy

$$\begin{aligned}
 E_{\gamma,\text{max,syn}} &= \gamma_{\text{max}}^2 \frac{heB_{\text{dis}}}{2\pi m_e c} \\
 &\simeq 1.2 \times 10^3 \left(\frac{\delta B/B}{10^{-0.5}} \right)^4 \xi_3^2 \sigma_{\pm,2}^2 B_{\text{dis},3} \text{ eV},
 \end{aligned}
 \tag{10}$$

Figure 2. *Top:* Proton timescales in the MAD for Cygnus X-1 as a function of the proton energy. Here t_{loss} , t_{fall} , t_{diff} , t_{syn} , t_{BH} , t_{pp} , and $t_{p\gamma}$ are the energy loss (black solid; $t_{\text{loss}}^{-1} = t_{\text{cool}}^{-1} + t_{\text{esc}}^{-1}$, where t_{cool} is the cooling time due to various interaction processes and t_{esc} is the escape time defined as $t_{\text{esc}}^{-1} = t_{\text{diff}}^{-1} + t_{\text{fall}}^{-1}$), diffusion (green dot-dashed), synchrotron (blue dashed), Bethe–Heitler (magenta dot-dashed), pp inelastic collision (red dotted), and photomeson production (red dashed) timescales, respectively. *Middle:* Optical depth of the Breit–Wheeler process inside the MAD for Cygnus X-1 as a function of the photon energy. Low-energy photons emitted by the thermal electrons absorb the GeV–TeV gamma rays. *Bottom:* Various pion timescales inside the MAD for Cygnus X-1 as a function of the pion energy. Here $t_{\pi, \text{dec}}$, $t_{\pi, \text{syn}}$, $t_{\pi, \text{cool}}$ are the pion decay (red dashed), pion synchrotron (blue dashed), and pion cooling (blue solid), respectively.

where B_{dis} is the magnetic field at the jet dissipation region. Since the jet is in a slow cooling regime and $p < 3$, the synchrotron photon flux peaks at $E_{\gamma} \simeq E_{\gamma, \text{max, syn}}$ (see Table 2). Due to the Klein-Nishina effect, the SSC photon spectrum peaks when the electron Lorentz factor is $\gamma_e \simeq 10^3$. The corresponding SSC peak photon energy is $E_{\gamma, \text{pk, SSC}} \approx \gamma_e^2 E_{\gamma, \text{max, syn}} \simeq 1.2 \times 10^9$ eV.

The cutoff energy of the nonthermal protons in the MADs is $E_{p, \text{cut}} \sim 1 \times 10^{14}$ eV. The luminosity of nonthermal protons peaks at $E_p \sim E_{p, \text{cut}}$ since $s_{\text{inj}} \lesssim 2$ (see Table 2). Photons from the pion decay carry an energy $E_{\gamma} \simeq 0.1 E_p \sim 1 \times 10^{13}$ eV. The nonthermal proton luminosity is estimated to be $L_p \approx \epsilon_{\text{dis}} \epsilon_{\text{NT}} \dot{M} c^2 \simeq 4.0 \times 10^{34} \epsilon_{\text{dis}, -1} \epsilon_{\text{NT}, -2.5} \dot{m}_{-1} M_1 \text{ erg s}^{-1}$, where ϵ_{dis} is the ratio of the dissipation power to the accretion power and ϵ_{NT} is the ratio of the nonthermal particle energy to the dissipation energy. By denoting the fraction of the hadronic processes cooling timescale to the energy loss timescale as $f_{\pi} \sim 0.1$, the gamma-ray luminosity emitted by the hadronic processes is estimated to be

$$L_{\gamma, \text{had}} = \frac{1}{3} f_{\pi} L_p \quad (11)$$

$$\simeq 1.4 \times 10^{33} f_{\pi, -1} \epsilon_{\text{dis}, -1} \epsilon_{\text{NT}, -2.5} \dot{m}_{-1} M_1 \text{ erg s}^{-1}.$$

The prefactor $1/3$ in the above expression arises because in inelastic pp collisions neutral pions are produced with roughly $1/3$ probability. These UHE photons are attenuated by the lower-energy photons in MADs by the Breit–Wheeler process. The pion decay process also produces neutrinos with a similar luminosity to that given in Equation (11), but neutrinos are not attenuated.

We show various interaction timescales as a function of the proton energy for Cygnus X-1 in the top panel of Figure 2. For $E_p \lesssim 10^{14}$ eV, the accelerated protons will escape from the MADs diffusively, as shown in Figure 2. For $E_p \sim 10^{14}$ eV, the pp inelastic collision cooling timescale and energy loss timescale are $t_{pp} \simeq 6 \times 10^{-2}$ s and $t_{\text{loss}} \simeq 4 \times 10^{-3}$ s, respectively, and thus, the assumption of $f_{\pi} \sim 0.1$ used in Equation (11) is reasonable.

We also show the optical depth of the Breit–Wheeler process inside the MAD for Cygnus X-1 in the middle panel of Figure 2. Photons in the optical to X-ray bands emitted by the thermal synchrotron radiation and the thermal Comptonization process absorb the TeV and GeV gamma rays, respectively.

High-energy neutrinos are emitted by the decay of charged pions produced by the hadronic processes. Since the magnetic field strength inside the MAD is high, the charged pions cool through the synchrotron radiation efficiently. If the pion cooling timescale, $t_{\pi, \text{cool}}$, is shorter than the charged pion decay timescale, $t_{\pi, \text{dec}}$,

Figure 3. Photon spectra obtained by our model for Cygnus X-1. The thick and thin lines are the photon spectra after and before internal attenuation by the Breit-Wheeler process, respectively. Data points are taken from [Zdziarski et al. \(2017\)](#); [LHAASO Collaboration \(2024\)](#). The gray solid line in the X-ray band is the soft X-ray spectrum before absorption by the interstellar medium. The sensitivity line for CTA is taken from [Actis et al. \(2011\)](#). The upper limit lines for HAWC and MAGIC are taken from [Albert et al. \(2021\)](#) and [Fernandez-Barral et al. \(2017\)](#), respectively.

neutrino spectra are suppressed by a factor of $f_{\pi, \text{sup}} \approx 1 - \exp(-t_{\pi, \text{dec}}^{-1}/t_{\pi, \text{cool}}^{-1})$, where $t_{\pi, \text{cool}}^{-1} = t_{\pi, \text{syn}}^{-1} + t_{\text{diff}}^{-1}$ and $t_{\pi, \text{syn}}$ is the pion synchrotron cooling timescale. We estimate $t_{\pi, \text{dec}}$ and $t_{\pi, \text{syn}}$ as $t_{\pi, \text{dec}} = (E_{\pi}/m_{\pi}c^2)t_{\pi, 0}$ and $t_{\pi, \text{syn}} = (6\pi m_{\pi}^4 c^3)/(m_e^2 \sigma_T B_d^2 E_{\pi})$, where E_{π} is the pion energy, m_{π} is the charged pion mass, and $t_{\pi, 0}$ is the decay time for charged pion, respectively. The bottom panel of Figure 2 shows the pion cooling timescales in Cygnus X-1. Above $E_{\pi, \text{cut}}$, charged pions lose their energy before decay into neutrinos. This cutoff energy may be estimated by equating $t_{\pi, \text{dec}}$ with $t_{\pi, \text{cool}}$ assuming that synchrotron radiation is the dominant cooling process,

$$E_{\pi, \text{cut}} \approx \sqrt{\frac{6\pi m_{\pi}^5 c^5}{m_e^2 \sigma_T B_d^2 t_{\pi, 0}}} \quad (12)$$

$$\simeq 5.6 \times 10^3 \dot{m}_{-1}^{-1/2} m_1^{1/2} r_1^{5/4} \alpha_{-0.5}^{1/2} \beta_{-1}^{1/2} \text{ GeV}.$$

We tabulate $E_{\pi, \text{cut}}$ of each BHXB in Table 2. A corresponding suppression of the neutrino spectrum is then expected at $E_{\nu} \approx 0.25 E_{\pi, \text{cut}}$.

3.2. Cygnus X-1

Figure 3 presents our model for the multi-wavelength emission from Cygnus X-1. The MAD pion decay com-

ponent shows up around ~ 10 TeV, explaining the LHAASO data. GeV-to-TeV gamma rays are also produced in the MAD but attenuated by the optical and X-ray photons through the Breit-Wheeler process, which explains the non-detection of this source at 0.1-10 TeV. Due to the Klein-Nishina effect, attenuation of the sub-PeV gamma rays is moderate (see middle panel of Figure 2).

As $\sigma_{\text{ent}} \ll 1$ in the jet model, the magnetic energy density is comparable to the energy density of the emitted photons, leading to efficient SSC. Moreover, the jet has a large emission power due to the high δ_D of Cygnus X-1. As a result, the jet SSC component explains the GeV gamma-ray data.

Our model does not account for the X-ray data at 3-100 keV. This is because the MAD formation condition (as discussed in Section 2.1) restricts \dot{m} and subsequently a harder Comptonization spectrum. A recent X-ray polarization study suggests that the Faraday effect would depolarize X-ray photons if magnetic fields are strong in the X-ray emitting region ([Barnier & Done 2024](#)). Consequently, as is the case here, the MAD is not expected to be the source of 2-10 keV X-rays of Cygnus X-1. To reproduce the X-ray data, other components,

Figure 4. Same as Figure 3, but for MAXI J1820+070. We take the data points (gray) when MAXI J1820+070 is in the hard state from Yoshitake et al. (2024). Cyan bow-tie and blue solid line are the faintest X-ray data after 400 days of the outburst in 2015 (Özbey Arabacı et al. 2022). The upper limit lines of Fermi, VERITAS, H.E.S.S., and MAGIC are taken from Abe et al. (2022). The sub-PeV data points are taken from LHAASO Collaboration (2024)

such as outer hot accretion flow or standard disks inside the MAD supplying the seed photons, are necessary.

The missing 3-100 keV component, however, does not impact the sub-PeV gamma-ray flux. This is because it does not attenuate UHE gamma rays yet barely contributes to the photomeson production (see top panel of Figure 2).

3.3. MAXI J1820+070

Figure 4 presents our result for MAXI J1820+070. MAXI J1820+070 has been in a quiescent state with a few weak outbursts during the LHAASO operation time (Yoshitake et al. 2024). We show the X-ray data taken during the decay phase of the small outbursts of MAXI J1820+070, which is slightly higher than the quiescent state (cyan bow-tie and blue solid line in Figure 4). This is motivated since the average X-ray flux of this source is likely in between the quiescent flux and the peak of the outbursts during the LHAASO observation time.

Our model explains both the X-ray and sub-PeV gamma-ray data. A higher ϵ_{NT} is used, comparing to that of Cygnus X-1 (see the next subsection and Section 5 for discussion on ϵ_{NT}). High electron temperature and number density are needed to reproduce the X-ray data by Comptonization in the MAD. To achieve these, we

use high β and low α compared to the models of other BHXBs (see Table 2).

MAXI J1820+070 has a low mass accretion rate. This yields low photon and proton number densities and consequently a long hadronic interaction time. While, owing to high β and low \dot{m} , the magnetic field inside the MAD is low, leading to a long acceleration timescale. Thus, the proton maximum energy is determined by $E_{p,max} = E_{cut,cl} \simeq 3 \times 10^{14}$ eV, corresponding to a peak of the pion decay photons at $E_\gamma \simeq 3 \times 10^{13}$ eV.

As the jet power scales to δ_D^4 (see Section 2.3) and $\delta_D \lesssim 1$ in MAXI J1820+070, the jet component of this source is rather weak and does not appear in Figure 4. The jet parameters are not constrained by the multi-wavelength observation, and we have adopted the parameter values of the jet component of Cygnus X-1.

3.4. Other BHXBs

Figure 5 shows the results for GRO J1655-40, GX 339-4, and XTE J1118+480. Since \dot{m} of these three BHXBs are close to Cygnus X-1, we use the same plasma parameters as those for Cygnus X-1. Our model explains the X-ray data of these three BHXBs. This suggests that MAD may work as a coronal plasma in most cases. Since the magnetic fields are strong in the MAD, this

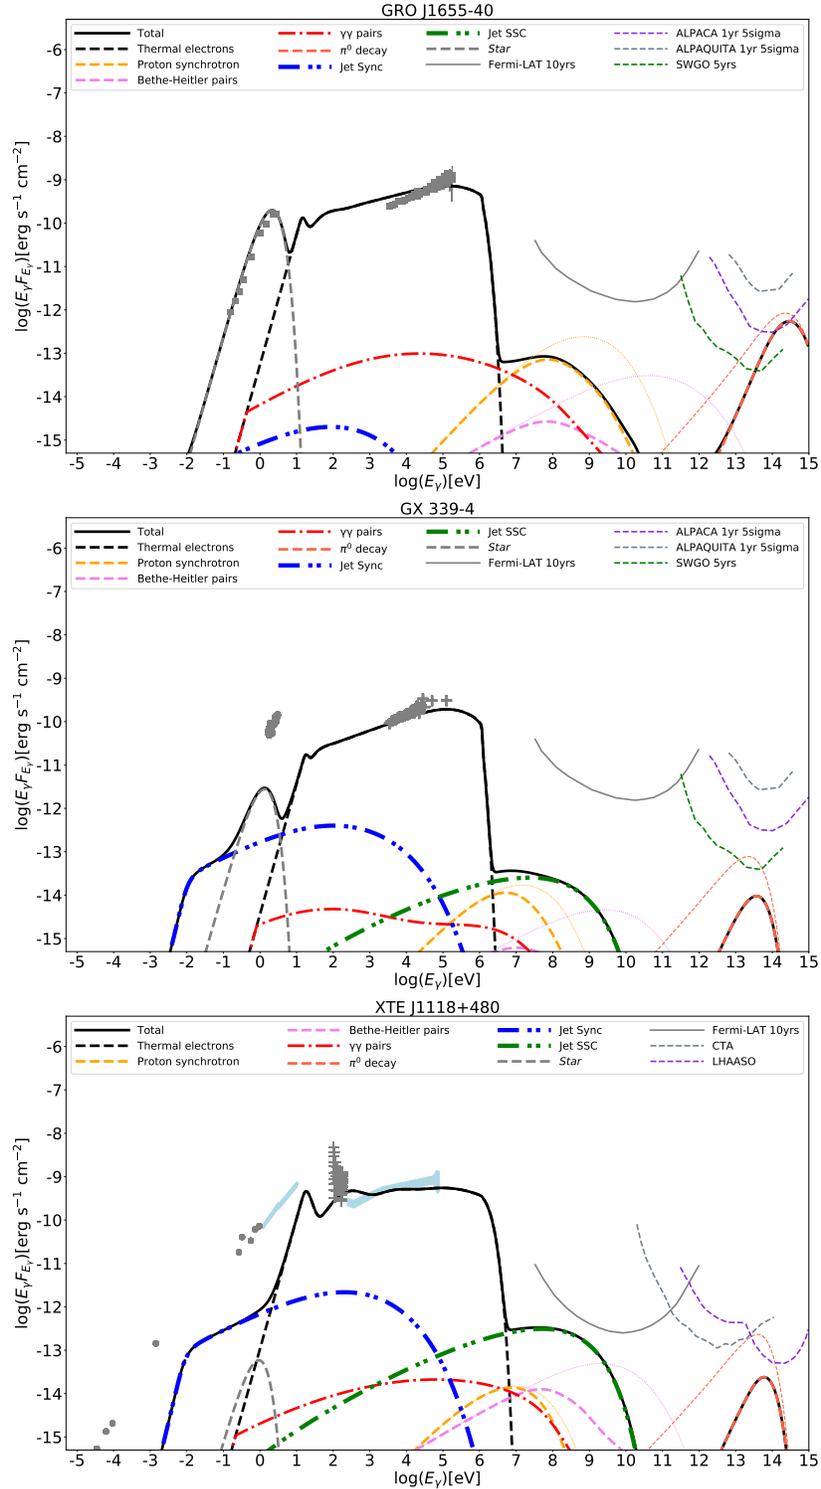

Figure 5. Same as Figure 3, but for GRO J1655-40 (*top*), GX 339-4 (*middle*), and XTE J1118+480 (*bottom*). Data points are taken from Migliari et al. (2007) for GRO J1655-40, Gandhi et al. (2010) for GX 339-4, and Chaty et al. (2003) for XTE J1118+480. The Fermi sensitivity line is taken from https://www.slac.stanford.edu/exp/glast/groups/canda/lat_Performance.htm. The ALPACA, LHAASO, and SWGO sensitivity lines are taken from Kawashima & The ALPACA Collaboration (2022), Cao et al. (2019), and Huentemeyer et al. (2019), respectively.

result suggests that the X-ray polarization would be low in the soft X-ray band. An observation of such a feature by IXPE may test our model.

XTE J1118+480 is not detected by LHAASO (LHAASO Collaboration 2024), and our model is consistent with the non-detection. GX 339-4 and GRO J1655-40 are in the southern sky, outside the field of view of the current-generation air shower gamma-ray observatories. Figure 5 suggests that GRO J1655-40 may be a favored target for future southern hemisphere observatories such as Andes Large area PArticle detector for Cosmic ray physics and Astronomy (ALPACA) (Kawashima & The ALPACA Collaboration 2022) and Southern Wide-Field Gamma-Ray Observatory (SWG0) (Huentemeyer et al. 2019).

The jet luminosities of GRO J1655-40, GX 339-4, and XTE J1118+480 are boosted by $\delta_D^4 \simeq 0.02, 2.9,$ and $1.08,$ respectively. This explains why the jet component is faint in GRO J1655-40 but presents in the other two sources. We again adopt the parameter values of Cygnus X-1 for the jet components in these three sources as the models are not constrained by observations.

Our model does not reproduce the optical data of GX 339-4 and the radio-to-optical data of XTE J1118+480. In both systems, the companion star is not massive, and additional optical emitting components may be present. In GX 339-4, optical photons may come from the standard disk located outside the MAD. In XTE J1118+480, the radio-to-optical spectrum almost follows a single power-law. These photons may come from nonthermal electrons in the jet and RIAFs (e.g., Markoff et al. 2001; Yuan et al. 2003). In both jets and RIAFs, the inner parts are optically thick for the synchrotron self-absorption (SSA) process, whereas the outer parts are SSA thin. Such a feature creates a power-law spectrum as the SSA peak frequency depends on the radius. We speculate that the RIAF and jet could explain optical-IR and radio data, respectively.

In both GX 339-4 and XTE J1118+480, the low-mass companion star is fainter than the accretion disk. As a result, the photometric data does not constrain the luminosity of the companion star. We estimate the star luminosity using the mass-luminosity relationship. The uncertainty of this subdominant component does not affect our results.

3.5. Neutrino emissions

Figure 6 shows the neutrino spectra from the MADs. For Cygnus X-1, we calibrate ϵ_{NT} using LHAASO data. The predicted neutrino flux is below the sensitivities obtained by IceCube 10-year data (Aartsen et al. 2020). Our model shows that the neutrino flux from Cygnus

Figure 6. *Top:* Neutrino spectrum obtained by the MAD model for Cygnus X-1. Black, red dashed, and blue dashed lines are the total neutrino emission from MAD, neutrino emission by the photomeson production, and neutrino emission by the pp inelastic collisions, respectively. The thin black dotted line is the total neutrino emission before pion suppression. IceCube sensitivities obtained by 10-year data (light-blue) are taken from Aartsen et al. (2020). KM3NeT sensitivity curves (gray) are taken from Ye et al. (2022). The dashed and dot-dashed lines represent the neutrino spectra with E_ν^{-2} and E_ν^{-3} , respectively. *Bottom:* Same as the top panel but for the other BHXBs. Black solid, red dashed, blue dot-dashed, and green dot-dot-dashed curves correspond to neutrino spectra of MAXI J1820+070, GRO J1655-40, GX 339-4, and XTE J1118+480, respectively. For comparison, gray and light-blue lines are the KM3NeT and IceCube sensitivities, respectively, assuming E^{-2} (dashed) and E^{-3} (dot-dashed) spectra, for a source at declination $\delta = 0.0$. IceCube sensitivities are taken from Aartsen et al. (2020).

X-1 is $\approx 5 \times 10^{-13} \text{ erg s}^{-1} \text{ cm}^{-2}$ at $E_\nu \simeq 3 \times 10^{12} \text{ eV}$. This obtained neutrino flux is slightly lower than the sensitivity of the future neutrino experiment, KM3NeT (Adrián-Martínez et al. 2016), and KM3NeT might be able to detect the neutrino emission from MAD of Cygnus X-1 by taking a long operation time (see top panel of Figure 6). Future neutrino detectors that improve the point-source sensitivities at TeV-PeV energies, such as IceCube-Gen2 (Aartsen et al. 2021), TRIDENT (Ye et al. 2022), P-ONE (Twagirayezu et al. 2023), and

HUNT (Huang et al. 2023), have the potential to detect the neutrinos from Cygnus X-1.

In the bottom panel of Figure 6, we present the neutrino spectra of the other BHXBs. For comparison, we show the point-source sensitivities of IceCube and KM3NeT with track-like events for a source at $\delta = 0$. We note that these sensitivities depend on the source declination. The neutrino flux of MAXI J1820+070 is about half that of Cygnus X-1 and could be detected by future neutrino detectors. For GRO J1655-40, \dot{m} is lower, whereas β is higher compared to the other hard state BHXBs (see Table 2). Consequently, the magnetic field inside the MAD is weaker, causing inefficient proton synchrotron cooling. This results in higher pion production efficiency and higher $E_{p,\text{max}}$. On the other hand, the neutrino spectrum at $E_\nu \gtrsim 10^4$ GeV is strongly suppressed due to the pion suppression, making the detection of high-energy neutrinos more difficult. The other two BHXBs are not observable even with the next-generation detectors. These high-energy neutrino signals are crucial for testing our model.

In the jet, magnetic reconnection also accelerates the entrained protons, and the accelerated protons can emit neutrinos through the hadronic processes. However, due to low proton and photon number density, hadronic processes inside the jet are inefficient. Thus, neutrino luminosity from the jets is much lower than that from the MADs.

4. DIFFUSE EMISSION FROM THE QUIESCENT AND HARD STATES BHXBS

We evaluate the contributions by MADs in BHXBs to PeV CRs, diffuse gamma-rays, and diffuse galactic neutrinos. We discuss the diffuse gamma-ray and neutrino emission in Section 4.1 and CR spectra in Section 4.2.

4.1. Galactic neutrino and TeV gamma-rays

To estimate the diffuse gamma-ray and neutrino fluxes from BHXBs, we first need to estimate the number of BHXBs in our galaxy. This number is largely uncertain and is suggested to be $\sim 10^4$ based on a binary population synthesis (Yungelson et al. 2006) and $\sim 10^3$ based on the event rate of the BH X-ray transients (Corral-Santana et al. 2016) and the recent binary population synthesis (Shao & Li 2020). Thus we adopt a range of $10^3 - 10^4$ for the total BHXB population.

We then evaluate the luminosity of BHXBs in the Galaxy. For a simple estimation, we assume that all quiescent BHXBs have $\dot{m} = 10^{-4}$ and $M_{\text{BH}} = 10M_\odot$ and hard-state BHXBs have $\dot{m} = 0.05$ and $M_{\text{BH}} = 10M_\odot$, respectively. The other model parameters are set to be the same as those of MAXI J1820+070 for quiescent

Figure 7. Contribution to the diffuse gamma rays and neutrinos from the BHXBs. The blue dashed and red solid lines show the gamma-ray and neutrino emission from the quiescent state BHXBs and the hard state BHXBs, respectively. *Top:* Diffuse TeV gamma-ray spectra from the BHXBs. Data points are taken from Cao et al. (2023). *Bottom:* Galactic neutrino spectra from the BHXBs. Data points are taken from Icecube Collaboration et al. (2023).

BHXBs and Cygnus X-1 for hard BHXBs, except with $\beta = 0.1$ in the latter case.

We assume that BHXBs are uniformly distributed in our Galaxy within 15 kpc from the Galactic center. We randomly position $10^3 - 10^4$ BHXBs and evaluate their distances to the Earth. Using these distances, we calculate the total flux of the gamma rays and the neutrinos as

$$F_{\text{tot}} = \sum_{i=1}^{N_{\text{BHXB}}} \frac{L_{\text{fiducial}}}{4\pi D_i^2} \cdot f_{\text{duty}}, \quad (13)$$

where F_{tot} is the total flux, L_{fiducial} is the luminosity of the fiducial BHXB, D_i is the distance between Earth to each BHXB, i is the i -th BHXB, and f_{duty} is the duty cycle of the quiescent and hard states. Based on 19 years of X-ray observation of all known BHXBs, Tetarenko et al. (2016) finds a median duty cycle of 2.7% for the hard state (see Figure 9 of Tetarenko et al. 2016). BHXBs in quiescent states are usually undetectable unless they are nearby. We set $f_{\text{duty}} \simeq 0.027$ and 1 for the hard and quiescent states, respectively.

Figure 7 shows that hard-state BHXBs may contribute to 30% of the diffuse gamma-ray emission observed by LHAASO at $E_\gamma \sim 100$ TeV, whereas quiescent BHXBs barely contribute due to their inefficient pion production. Due to the pion suppression, BHXBs do not contribute to the Galactic diffuse neutrino emission.

The Galactic diffuse emission observed by air shower gamma-ray observatories may largely arise from the cosmic-ray sea interacting with the interstellar medium (ISM) (Fang & Murase 2023; Fang et al. 2024a; Lipari & Vernetto 2024), although it may also include a contribution from unresolved sources (Vecchiotti et al. 2022). Pulsar halos have been suggested as such sources (Dekker et al. 2024; Yan et al. 2024). Our results imply that hard-state BHXBs may also be a promising contributor to the diffuse gamma-ray emission from the Galactic plane.

4.2. CRs from the quiescent and hard states BHXBs

Inside the MAD, the MHD turbulence accelerates the protons, and the protons escape from the MAD diffusively. We estimate the escaped CR luminosity and evaluate the contribution of the BHXBs to the CR spectra. We calculate the CR injection rate to the ISM as

$$E_p L_{E_p} = \frac{t_{\text{loss}}}{t_{\text{diff}}} E_p^2 \dot{N}_{E_p, \text{inj}} N_{\text{BHXB}} f_{\text{duty}}, \quad (14)$$

where t_{diff} is the diffusive escape timescale, $\dot{N}_{E_p, \text{inj}}$ is the primary proton injection term of the MAD model. The escaped CRs propagate in the ISM and arrive on Earth. The confinement time inside the ISM, t_{conf} , is provided by the grammage, $X_{\text{esc}} = n_{\text{ISM}} \mu m_p c t_{\text{conf}}$, where n_{ISM} is the ISM number density and μ is the ISM mean atomic mass. Based on the boron-to-carbon ratio measurements, the grammage of CRs is estimated to be $X_{\text{esc}} \simeq 2.0(E_p/250 \text{ GeV})^{-s} \text{ g cm}^{-2}$, where $s = 0.46$ for $E_p < 250$ GeV and $s = 0.33$ for $E_p > 250$ GeV (Aguilar et al. 2016; Murase & Fukugita 2019; Adriani et al. 2022). Then, the CR escape rate from the ISM is estimated to be $E_p U_{E_p} V_{\text{gal}}/t_{\text{conf}} \approx E_p U_{E_p} c M_{\text{gas}}/X_{\text{esc}}$, where U_{E_p} is the differential energy density of the CR and $M_{\text{gas}} \simeq 8 \times 10^9 M_\odot$ is the total gas mass in our galaxy (Nakanishi & Sofue 2016). CR escape rate should balance with the CR injection rate, and we estimate the CR intensity, $\Phi_p = c U_{E_p}/(4\pi E_p)$, as (e.g., Kimura et al. 2018)

$$E_p^2 \Phi_p \approx \frac{E_p L_{E_p} X_{\text{esc}}}{4\pi M_{\text{gas}}}. \quad (15)$$

We show the CR spectra from the quiescent and hard states BHXBs in Figure 8. BHXBs cannot contribute significantly to the observed CR spectra in both states. This comes from the low mass accretion rate for the

quiescent state BHXBs and low ϵ_{NT} and duty cycle for the hard state BHXBs. Kimura et al. (2021) have estimated the CR spectrum from the MAD of the quiescent state of BHXBs (QBHXBs) and showed that the CRs from QBHXBs can explain the PeV CRs (see their Figure 5). In their scenario, the magnetic reconnection and the turbulence accelerates the protons inside the MAD. Kimura et al. (2021) considers the flat \dot{m} distribution in the range of $\dot{m} = 10^{-5} - 10^{-2}$, and they involve the contribution by the BHXBs with a higher \dot{m} than that we assume in this paper. Owing to this, the QBHXBs can reproduce the observed CR spectra. Without specifying the nature of the corona, Fang et al. (2024b) considers a general scenario where protons are accelerated by a turbulent magnetic field and magnetic reconnection in a BHXB corona in hard and soft states, respectively. The work suggests that CRs from BHXB coronae may significantly contribute to the Galactic CR spectra.

The observed CRs may come from other source classes. In particular, CRs with $E_p \lesssim 10^6$ GeV could come from the Galactic supernova remnants (SNRs; e.g., Helder et al. 2012; Ackermann et al. 2013; Fang et al. 2022). CRs with $E_p \gtrsim 3 \times 10^7$ GeV could come from binary neutron-star merger remnants (Kimura et al. 2018; Rodrigues et al. 2018) and Sgr A*'s past activities (Fujita et al. 2017; Kuze et al. 2022).

Magnetic reconnection in the jets of BHXBs also accelerates the entrained protons. At the initial phase of the plasma entrainment, the entrained protons are subdominant of the internal energy. Then, the proton magnetization parameter is the same as σ_\pm , leading to proton maximum Lorentz factor as $\gamma_{p, \text{max}} \approx (\delta B/B)^2 \xi \sigma_\pm$. With our BHXB parameter sets (see Table 2), the proton maximum energy is estimated to be $E_p \sim 10^4$ GeV. Thus, the jets of hard-state BHXBs do not significantly contribute to the CR spectra above the knee.

Our estimation does not account for the luminosity function of BHXBs. Based on a relationship between radio and jet kinetic luminosities, Heinz & Grimm (2005) suggests that the mean jet kinetic luminosity of BHXBs is $\langle L_j \rangle \approx 2.5 \times 10^{37} \text{ erg s}^{-1}$. In our Jet-MAD model, the jet luminosity at the jet base is calculated as $L_j = \eta \dot{M} c^2$, where $\eta \approx 0.58$ is the fraction of accretion luminosity to the jet kinetic luminosity (see Section 2.2 of Kuze et al. 2024). With our fiducial values $M = 10 M_\odot$ and $\dot{m} = 0.05$, $L_j \simeq 4.0 \times 10^{37} \text{ erg s}^{-1}$, which is consistent with the findings of Heinz & Grimm (2005).

5. CONCLUSION

We have investigated the high-energy radiation of BHXBs by applying our Jet-MAD model to five BHXBs. We find that hadronic processes in the MAD may

Figure 8. CR spectrum predicted by our Jet-MAD model for the quiescent state (blue dashed line) and the hard state (red solid line). The experimental data for protons and all-particle CR energy spectra are taken from [Apel et al. \(2013\)](#), [Aartsen et al. \(2019\)](#) and [Amenomori et al. \(2008\)](#), [Abbasi et al. \(2018\)](#), and [Cao et al. \(2024\)](#), respectively.

explain the UHE gamma-ray sources associated with Cygnus X-1 and MAXI J1820+070 recently detected by LHAASO (see Figures 3 and 4). Among southern-sky sources, future gamma-ray detectors such as ALPACA and SWGO may detect GRO J1655-40 (see Figure 5). Comptonization by thermal electrons roughly explains the X-ray spectra of the BHXBs, except Cygnus X-1, where additional components are needed to explain the 3-100 keV data.

Inside the jet, relativistic electrons accelerated by magnetic reconnection produce multi-wavelength emission via synchrotron and SSC radiation. The jet emission explains the GeV gamma-ray observation of Cygnus X-1 and is too faint to be detected in other sources.

Our model predicts high-energy neutrino emission from the MADs. Future TeV-PeV neutrino detectors such as IceCube-Gen2, KM3NeT, P-ONE, TRIDENT, and HUNT have the potential to detect Cygnus X-1 and MAXI J1820+070 (see Figure 6). The MADs of these objects have weak magnetic fields, allowing efficient pion production before synchrotron cooling.

We evaluate the contribution of BHXBs to the Galactic diffuse gamma-ray and neutrino fluxes. Our results suggest that hard-state BHXBs may contribute up to a few 10% of the diffuse gamma rays. The BHXB population, which is largely unresolved by air shower gamma-ray observatories, may plausibly explain the Galactic diffuse emission together with the diffuse cosmic-ray sea. This population, however, barely contributes to the neutrino emission of the Galactic plane as a result of the pion suppression.

MHD turbulence accelerates the CR protons in the MAD up to PeV, and they escape diffusively from the MAD to the ISM. We evaluate the contribution of the

quiescent and the hard BHXBs to the CR spectra observed on Earth. We find that BHXBs barely contribute to the observed CR spectra due to low \dot{m} for the quiescent state and low ϵ_{NT} and low duty cycle for the hard state.

To explain the LHAASO data, relatively low and high values of ϵ_{NT} are chosen for Cygnus X-1 and MAXI J1820+070, respectively. This may be understood by considering the formation process of a MAD. Cygnus X-1 has a high \dot{m} , and then, the standard disk will be located close to the BH. In the standard thin disk, the magnetorotational instability (MRI) and subsequent disk dynamo will create a large-scale poloidal field, and these large-scale fields are accumulated onto the BH (e.g., [Salvesen et al. 2016](#); [Hayashi et al. 2024](#)). MRI dynamo changes the polarity of the large-scale fields in 10 – 20 dynamical timescales, and thus, the magnetic fields accumulated on the BH would disappear by magnetic reconnection within several dynamical timescales of the inner radius of the standard accretion disk. Thus, the MAD formation is rather unlikely for BHXBs with high \dot{m} . Nevertheless, we speculate that the MAD can form even for the high \dot{m} BHXBs, although the MAD state does not continue for a long time. This may cause a lower value of ϵ_{NT} , as nonthermal particles are efficiently produced only in the MAD state. On the other hand, MAXI J1820+070 has a low \dot{m} , and then, the standard disk would be located far from the BH, leading to the formation of a persistent MAD state. This might cause a higher value of ϵ_{NT} , which is consistent with the cases with radio galaxies and quiescent X-ray binaries ([Kuze et al. 2022](#); [Kimura et al. 2021](#)). Therefore, it may be natural to use a higher ϵ_{NT} for MAXI J1820+070 than that of the other BHXBs. Future modeling of ϵ_{NT} as a function of mass accretion rate remains as a future work.

A feature of our model is that photons at different wavelengths originate from distinct emission regions. In particular, the MAD emits both X-rays and sub-PeV gamma rays, whereas the jet produces radio signals and GeV gamma rays. As a result, one should expect time variability correlations between X-ray and TeV gamma-ray bands, as well as between radio and GeV gamma-ray bands. The sizes of the emission regions correspond to a variability timescale of $\sim 10^{-3}$ s in the MAD, and $\sim 10^{-1}$ s in the jet. Although current-generation gamma-ray detectors cannot resolve such rapid variability in BHXBs, long-term monitoring and a multi-wavelength campaign combined with variability analyses could identify the high-energy radiation our model predicts to occur during the hard state, which typically lasts for a few to several months.

Our model suggests that individual BHXBs including Cygnus X-1 and MAXI J1820+070 are promising multimessenger targets for future UHE gamma-ray and high-energy neutrino detectors. These future observations can test our model and are crucial to understanding the nonthermal phenomena near BHs.

ACKNOWLEDGMENTS

We would like to thank Hirofumi Noda, Megumi Shidatsu, and Chris Done for their useful comments and discussions. Discussions for this paper were performed many times at Science Lounge of FRIS CoRE. This

work is partly supported by JSPS KAKENHI grant Nos. 22K14028, 21H04487, and 23H04899 (S.S.K.). This work is also supported by JST SPRING, grant No. JPMJSP2114 (R.K.). R.K. acknowledges the support of the JSPS Overseas Challenge Program for Young Researchers. S.S.K. acknowledges support from the Tohoku Initiative for Fostering Global Researchers for Interdisciplinary Sciences (TI-FRIS) of MEXTs Strategic Professional Development Program for Young Researchers.
