Figure 1: We propose a new text-conditioned motion synthesis model: MotionPCM, capable of real-time generation with improved performance. Lighter colours represent earlier time points.

Abstract

Diffusion models have become a popular choice for human motion synthesis due to their powerful generative capabilities. However, their high computational complexity and large sampling steps pose challenges for real-time applications. Fortunately, the Consistency Model (CM) provides a solution to greatly reduce the number of sampling steps from hundreds to a few, typically fewer than four, significantly accelerating the synthesis of diffusion models. However, its application to text-conditioned human motion synthesis in latent space remains challenging. In this paper, we introduce **Motion-PCM**, a phased consistency model-based approach designed to improve the quality and efficiency of real-time motion synthesis in latent space.

1 Introduction

Driven by the development of multimodal, human motion synthesis has become capable of responding accordingly with different conditional inputs, including text [Lin *et al.*, 2018; Zhang *et al.*, 2022], action categories [Tevet *et al.*, 2023; Chen *et al.*, 2023], action sequence [Dai *et al.*, 2025] and music [Li *et al.*, 2021]. These developments can bring immense potentials in areas, such as game industry, film production and virtual reality.

MotionDiffuse [Zhang *et al.*, 2022] is the first work to apply the diffusion model to generate human motion, achieving remarkable performance. However, MotionDiffuse processes the entire motion sequence with the diffusion model, leading to high computational resource demands and significant time consumption. To alleviate these issues, MLD [Chen *et al.*, 2023] utilising a Variational Autoencoder (VAE) [Kingma, 2013] to compress the motion sequence into latent codes before sending them to the diffusion model. This approach greatly boosts the speed and quality of motion synthesis

Figure 2: Differences between Consistency/Latent Consistency Models and Phased Consistency Models in multi-step sampling.

but still requires tens of inference steps with the help of DDIM [Song *et al.*, 2020a], making it impractical to implement motion synthesis in real time.

Building upon MLD, MotionLCM [Dai et al., 2025] utilise the Latent Consistency Model (LCM) [Luo et al., 2023], enabling few-step inference and thus achieving real-time motion synthesis with a diffusion model. However, LCM's design suffers from several issues, including consistency issues caused by accumulated stochastic noise during multistep sampling as shown in Figure 2. In addition, LCM suffers from significantly degraded sample quality in low-step settings. Identifying these flaws of LCM, Phased Consistency Model (PCM) [Wang et al., 2024] introduces a refined architecture to address these limitations. Taking Figure 2 as an example, PCM is trained with two sub-trajectories, enabling efficient 2-step deterministic sampling without introducing stochastic noise. Experimental results on image generation tasks demonstrate that PCM outperforms LCM in different step generation settings. Nevertheless, the performance of PCM on human motion generation tasks remains unexplored.

In this paper, we incorporate PCM into the motion synthesis pipeline and propose a new motion synthesis approach, **MotionPCM**, allowing real-time motion synthesis with improved generation quality (see Figure 3). Similar to MotionLCM, our model is distilled from MLD, but differently, we split the entire trajectory into *N* segments where *N* corresponds to the number of inference steps. Instead of forcing all points in the trajectory to the original, we only map points in a certain interval to the start of that interval, ensuring consistent predictions for the start of the interval across different points within it. This design allows us to achieve *N*-step sampling deterministically, avoiding the accumulation of stochastic errors. Furthermore, inspired by PCM and CTM [Kim *et al.*, 2023], we employ an additional discriminator to provide extra supervision, enhancing performance in low-step settings.

We summarise our main contributions as follows:

- Leveraging the multi-interval design of PCM, we propose MotionPCM, an improved pipeline for real-time motion synthesis.
- Introducing an additional discriminator for extra supervision significantly enhances the quality of motion synthesis.

Figure 3: Comparison of other motion synthesis methods with our method. AITS represents the time required to generate a motion sequence from a textual description.

• Experiments on a large-scale public dataset demonstrate that our approach achieves the state-of-the-art performance in terms of speed and generation performance, with efficient sampling requiring fewer than four steps.

2 Related Work

2.1 Motion Synthesis

Motion synthesis seeks to generate human motion under various conditions to support a wide range of applications [Zhang *et al.*, 2022; Zhang *et al.*, 2023a; Ghosh *et al.*, 2021]. The evolution of motion synthesis models has mirrored advances in machine learning, moving from deterministic methods with limited variability towards generative approaches—such as VAEs and GANs [Xia *et al.*, 2015; Kingma, 2013; Goodfellow *et al.*, 2020]—and more recently, diffusion models, which have further transformed the field by utilising noisebased iterative refinement [Zhang *et al.*, 2022; Tevet *et al.*, 2023].

Among the earliest works to adopt diffusion models for motion generation is [Zhang et al., 2022]. By capitalising on the advantages of diffusion models in probabilistic mapping and realistic synthesis, it demonstrates that diffusion-based methods can outperform earlier approaches, particularly in conditional generation scenarios (e.g., text-driven or actionconditioned). Nevertheless, human motions exhibit high diversity and often differ significantly in distribution from their conditional modalities, making it challenging to learn a robust probabilistic mapping from such modalities to human motion sequences [Chen et al., 2023]. Furthermore, raw motion capture data can be redundant and noisy. To mitigate these issues, subsequent research-exemplified by the Motion Latent-based Diffusion model (MLD) [Chen et al., 2023] uses a VAE to produce representative, low-dimensional latent codes from the motion sequence and perform the diffusion process within that latent space.

While latent-space diffusion mitigates some of the aforementioned challenges, efficiency remains a critical bottleneck due to the computational cost of multi-step sampling. To overcome this, inspired by consistency models [Song *et al.*, 2023; Luo *et al.*, 2023], MotionLCM [Dai *et al.*, 2025]) takes MLD as the teacher model to distill the model so that motion generation can be achieved in a low sampling step. It also incorporates an explicit control network to control the motion generation based on the given motion sequence. Besides, identifying some drawbacks of the VAE design of MLD, MotionLCM-v2 [Dai *et al.*, 2024] further improves VAE network by introducing a trainable linear layer after the VAE latent tokens to strengthen multimodal signal modulation, while removing unnecessary ReLU activations to preserve negative components in text features, thereby achieving further performance gains.

2.2 Acceleration of Diffusion Models

Since the advent of Denoising Diffusion Probabilistic Models (DDPMs) [Ho *et al.*, 2020], researchers have been striving to overcome the limitations of sequential sampling by achieving a more favourable balance between quality and speed. A key advance came with Denoising Diffusion Implicit Models (DDIMs) [Song *et al.*, 2020a], which transform DDPM's stochastic diffusion process into a deterministic one, eliminating the randomness of Markov chains and introducing the possibility of skip sampling to accelerate generation. Subsequently, Consistency Models (CMs) [Song *et al.*, 2023] take a further step by imposing a consistency constraint that directly maps noisy inputs to clean outputs without iterative denoising, enabling single-step generation and substantially improving speed.

Latent Consistency Model (LCM) [Luo et al., 2023] builds on CMs by operating in a latent space, unlike CMs, which work in the pixel domain. This approach enables LCM to handle more challenging tasks, such as text-to-image generation, with improved efficiency. As a result, LCM can serve as a foundational component to accelerate latent diffusion models, which has been employed in motion synthesis like MotionLCM [Dai et al., 2025]. However, it still faces limitations-particularly in balancing efficiency, consistency, and controllability with varying inference steps, thereby leaving room for further refinement. Analysing the reasons behind these challenges, Phased Consistency Model (PCM) [Wang et al., 2024]) partitions the ODE path into multiple sub-paths and enforce consistency within each sub-path. Additionally, PCM incorporates an adversarial loss, further improving the quality of image generation. In this paper, we apply PCM to the domain of motion synthesis and propose a new method, MotionPCM, for generating high-quality motion sequences in real time.

3 Preliminaries

Given $x(0) \sim p_0$, the data distribution, a traceable diffusion process defined by $\alpha_t x_0 + \sigma_t \epsilon$ is normally used to transform x(0) to $x(T) \sim p_T$, a prior distribution. Equivalently, scorebased diffusion models [Song *et al.*, 2020b] define a continuous Stochastic Differential Equation (SDE) as the diffusion process:

$$dx_t = f(x_t, t)dt + g(t)dw_t,$$
(1)

where $(w_t)_{t\in[0,T]}$ is the standard *d*-dimensional Wiener process, $f : \mathbb{R}^d \times \mathbb{R}^+ \to \mathbb{R}^d$ is a \mathbb{R}^d -valued function and $g : \mathbb{R}^+ \to \mathbb{R}$ is a scalar function. The reverse-time SDE transforms the prior distribution back to the original data distribution. It is expressed as:

$$dx_t = [f(x_t, t) - g(t)^2 \nabla_x \log p_t(x_t)] dt + g(t) d\bar{w}_t, \quad (2)$$

where \bar{w} is again the standard *d*-dimensional Wiener process in the reversed process, $p_t(x_t)$ represents the probability density function of x_t at time *t*. To estimate score $\nabla_x \log p_t(x)$, a score-based model $s_\theta(x, t)$ is trained to approximate $\nabla_x \log p_t(x)$ as much as possible.

There exists a deterministic reversed-time trajectory [Song *et al.*, 2020b], satisfying an ODE, known as the probability flow ODE (PF-ODE):

$$dx_t = [f(x_t, t) - \frac{1}{2}g(t)^2 \nabla_x \log p_t(x_t)]dt.$$
 (3)

Rather than using $s_{\theta}(x, t)$ to predict the score, consistency models [Song *et al.*, 2023] directly learn a function $f_{\theta}(\cdot, t)$ to predict the solution of PF-ODE by mapping any points in the ODE trajectory to the origin of this trajectory, x_{ϵ} , where ϵ is a fixed small positive number. Formally, for all $t, t' \in [\epsilon, T]$, it holds that:

$$f_{\theta}(x_t, t) = f_{\theta}(x_{t'}, t') = x_{\epsilon}.$$
(4)

However, for multi-step sampling, CM will introduce random noise at each step since generating intermediate states along the sampling trajectory involves reintroducing noise, which accumulates and causes inconsistencies in the final output. To address this issue, PCM [Wang *et al.*, 2024] splits the solution trajectory of PF-ODE into multiple sub-intervals with M+1 edge timesteps $s_0, s_1, ..., s_M$, where $s_0 = \epsilon$ and $s_M = T$. Each sub-trajectory is treated as an independent CM, with a consistency function $f^m(\cdot, \cdot)$ defined as: for all $t, t' \in [s_m, s_{m+1}]$

$$f^{m}(x_{t},t) = f^{m}(x'_{t},t') = x_{s_{m}}.$$
(5)

[Lu *et al.*, 2022] shows an exact solution from timestep *t* to *s* for PF-ODE:

$$x_s = \frac{\alpha_s}{\alpha_t} x_t + \alpha_s \int_{\lambda_t}^{\lambda_s} e^{-\lambda} \sigma_{t_\lambda(\lambda)} \nabla \log P_{t_\lambda(\lambda)}(x_{t_\lambda(\lambda)}) \, d\lambda \tag{6}$$

where $\lambda_t = \ln \frac{\alpha_t}{\sigma_t}$ and t_{λ} is an inverse function with λ_t . Using an epsilon (noise) prediction network $\epsilon_{\theta}(x_t, t)$, this solution can be approximated as:

$$x_s = \frac{\alpha_s}{\alpha_t} x_t - \alpha_s \int_{\lambda_t}^{\lambda_s} e^{-\lambda} \epsilon_\theta(x_{t_\lambda(\lambda)}, t_\lambda(\lambda)) \, d\lambda.$$
 (7)

The solution needs to know the noise predictions throughout the entire interval between time s and t, while consistency models can only access to x_t for a single inference. To address this, [Wang *et al.*, 2024] parameterises $F_{\theta}(x, t, s)$ as follows:

$$F_{\theta}(x,t,s) = x_s = \frac{\alpha_s}{\alpha_t} x_t - \alpha_s \hat{\epsilon}_{\theta}(x_t,t) \int_{\lambda_t}^{\lambda_s} e^{-\lambda} d\lambda \quad (8)$$

١

Figure 4: The pipeline of our proposed MotionPCM. In the training phase, a pre-trained VAE encodes the motion sequence to a latent code z_0 , which goes n + k diffusion steps to produce $z_{t_{n+k}}$. $z_{t_{n+k}}$ is denoised to \hat{z}_{t_n} through a teacher network and an ODE solver. \hat{z}_{t_n} is passed through a target network to predict \hat{z}_{s_m} . Simultaneously, $z_{t_{n+k}}$ is denoised to \hat{z}_{s_m} through the online network directly. A consistency loss within the time interval $[s_m, s_{m+1}]$ is applied by comparing \tilde{z}_{s_m} and \hat{z}_{s_m} . Additionally, adversarial training is performed by introducing different noises to \tilde{z}_{s_m} and z_0 , generating \tilde{z}_s and z_s respectively. These are then compared through a discriminator to enforce realism and improve model performance. The trainable components include the online network and the discriminator, whereas the encoder and teacher networks remain frozen during training. The target network is updated using exponential moving average.

To satisfy the boundary condition of each sub-trajectory of the PCM, i.e., $f^m(x_{s_m}, s_m) = x_{s_m}$, a parameterised form f^m_{θ} below is typically employed:

$$f^m_{\theta}(x_t, t) = c^m_{\text{skip}}(t)x_t + c^m_{\text{out}}(t)F_{\theta}(x_t, t, s_m)$$
(9)

where $c_{\text{skip}}^m(t)$ gradually increases to 1 and $c_{\text{out}}^m(t)$ progressively decays to 0 as t decreases over the time interval from s_{m+1} to s_m . In fact, in Eq. (8), the boundary condition $F_{\theta}(x_{s_m}, s_m, s_m) = \frac{\alpha_{s_m}}{\alpha_{s_m}} x_{s_m} - 0 = x_{s_m}$ is inherently satisfied, and as a result, the simplified form shown below can be used directly:

$$f^m_\theta(x,t) = F_\theta(x,t,s_m) \tag{10}$$

4 Method

As shown in Figure 4, we introduce MotionPCM, a novel framework for real-time motion synthesis. To provide a clear understanding of our method, we divide our method into four main segments. Section 4.1 explains the use of a Variational Autoencoder (VAE) and latent diffusion model as pre-training models to initialise the framework. Section 4.2 describes the integration of the phased consistency model within the motion synthesis pipeline. Section 4.3 details the design and role of the discriminator, which provides adversarial loss to enforce distribution consistency while improving overall performance. Section 4.4 illustrates the process of generating motion sequences from a prior distribution using PCM during inference.

4.1 VAE and Latent Diffusion Model for Motion Data Pre-training

Following the two-stage training approach of MLD [Chen *et al.*, 2023], we first employ a VAE [Kingma, 2013] to compress motion sequences into a lower-dimensional latent space. More specifically, the encoder maps motion sequences $x \in \mathbb{R}^{L \times d}$, where *L* is the frame length and *d* is the number of features, to a latent code $z_0 = \mathcal{E}(x) \in \mathbb{R}^{N \times d'}$ where *N* and *d'* are much smaller than *L* and *d*. Then a decoder is used to reconstruct the motion sequence $\hat{x} = \mathcal{D}(z_0)$. This process significantly reduces the dimensionality of the motion data, accelerating latent diffusion training in the second stage. Building upon this, MotionLCM-V2 [Dai *et al.*, 2024] introduces an improved VAE to enhance the representation quality of motion data. In our work, we adopt the improved VAE proposed by MotionLCM-V2 as the backbone.

In the second stage, we train a latent diffusion model in the latent space of this enhanced VAE, following MLD. Here, the latent diffusion model is an epsilon prediction network. Readers are referred to [Chen *et al.*, 2023] for more details. This trained diffusion model will be used as the teacher network to guide the distillation process in our work.

4.2 Accelerating Motion Synthesis via PCM

Definition. Following the definition of PCM [Wang *et al.*, 2024], we split our solution trajectory z in the latent space into M sub-trajectories, with edge timestep $\{s_m \mid m = 0, 1, 2, \dots, M\}$ where $s_0 = \epsilon$ and $s_M = T$. In each sub-time interval $[s_m, s_{m+1}]$, the consistency function f^m is defined as Eq. (5). We train f_{θ}^m in Eq. (10) to estimate f^m , applying consistency constraint on each sub-trajectory, i.e.,

 $f_{\theta}^m(z_t,t) = f_{\theta}^m(z'_t,t') = z_{s_m}$ for all $t,t' \in [s_m,s_{m+1}]$ and $m \in [0,M) \cap \mathbb{Z}$.

PCM Consistency distillation. Once we obtain the pretrained VAEs and latent diffusion model from Section 4.1, we can get the meaningful latent code z_0 from VAE and use this latent diffusion model as our frozen teacher network to distill our MotionPCM model, i.e., online network in Figure 4. Following [Dai *et al.*, 2025], online network (f_{θ}) is initialised from the teacher network with trainable weights θ , while the target network (f_{θ^-}) is also initialised from the teacher network but updated using Exponential Moving Average (EMA) of the online network's parameters. We obtain $z_{t_{n+k}}$ by applying forward diffusion with n + k steps to z_0 , positioning it within the time interval $[s_m, s_{m+1}]$.

This work focuses on text-conditioned motion generation where Classifier-free Guidance (CFG) [Ho and Salimans, 2022] has been used frequently to align conditions in diffusion models. Following previous works [Chen *et al.*, 2023; Dai *et al.*, 2025; Luo *et al.*, 2023], we also employ CFG in our framework. To distinguish $\hat{\epsilon}_{\theta}$ used in consistency model, we use $\tilde{\epsilon}_{\theta}$ to represent the diffusion model, which corresponds to our teacher network. It can be express as:

$$\tilde{\epsilon}(z_{t_{n+k}}, t_{n+k}, w, c) = (1+w)\tilde{\epsilon}(z_{t_{n+k}}, t_{n+k}, c) - w\tilde{\epsilon}(z_{t_{n+k}}, t_{n+k}, \emptyset)$$
(11)

where c denotes text condition, the guidance scale w is uniformly sampled from $[w_{min}, w_{max}]$, and \emptyset indicates an empty condition (i.e., a blank text input). $\hat{z}_{t_n}^{\phi}$ is then estimated from $z_{t_{n+k}}$ by performing k-step skip using $\tilde{\epsilon}(z_{t_n+k}, t_{n+k}, w, c)$, followed by an ODE solver ϕ , such as DDIM [Song *et al.*, 2020a]. To efficiently perform the guided distillation, [Dai *et al.*, 2025; Luo *et al.*, 2023] add w into an augmented consistency function $f_{\theta}(z_t, t, w, c) \mapsto z_0$. Similarly, in our work, we extend our phased consistency function to $f_{\theta}^m(z_t, t, w, c) \mapsto z_{s_m}$.

Following CMs [Song *et al.*, 2023; Wang *et al.*, 2024], the phased consistency distillation loss is then defined as follows:

$$\mathcal{L}_{PCD}(\theta, \theta^{-}) = \mathbb{E}[d(f_{\theta}^{m}(z_{t_{n+k}}, t_{n+k}, w, c), f_{\theta^{-}}^{m}(z_{t_{n}}^{\phi}, t_{n}, w, c))$$
(12)

where d is Huber loss [Huber, 1992] in our implementation. The online network's parameters θ are updated by minimising \mathcal{L}_{PCD} through the standard gradient descent algorithms, such as AdamW [Loshchilov, 2017]. Meanwhile, as mentioned earlier, the target network's parameters, θ^- is updated in EMA fashion: $\theta^- = \mu \theta^- + (1 - \mu) \theta$.

4.3 Discriminator

Building on the work of [Kim *et al.*, 2023; Wang *et al.*, 2024], which demonstrated that incorporating an adversarial loss from a discriminator can enhance the image generation quality of diffusion models in few-step sampling settings, we integrate an additional discriminator with adversarial loss into our motion synthesis pipeline.

A pair of \tilde{z}_s and z_s is sent to the discriminator as illustrated in Figure 4. More specifically, we first compute the solutions $\tilde{z}_{s_m} = f_{\theta}^m(z_{t_{n+k}}, t_{n+k}, w, c)$ and $\hat{z}_{s_m} = f_{\theta^-}^m(z_{t_n}^{\phi}, t_n, w, c)$ through the online network and target network, respectively. Following [Wang *et al.*, 2024], noise is added to \tilde{z}_{s_m} , producing \tilde{z}_s for $s \in [s_m, s_{m+1}]$. However, unlike [Wang *et al.*, 2024], where \hat{z}_{s_m} is used to produce z_s , we derive z_s from z_0 directly since [Kim *et al.*, 2023] highlights that leveraging direct training signals from data label is a key to achieve optimal performance. Inspired by [Wang *et al.*, 2024], we then apply an adversarial loss as follows:

$$\mathcal{L}_{adv} = \text{ReLU}(1 + f_D(z_s, s, c)) + \text{ReLU}(1 - f_D(\tilde{z}_s, s, c))$$
(13)

where f_D is a discriminator, ReLU is an non-linear activation function. The loss is optimised using a min-max strategy [Goodfellow *et al.*, 2020].

The total loss combining phased consistency distillation loss and adversarial loss is expressed as:

$$\mathcal{L}_{all} = \mathcal{L}_{PCD} + \lambda \mathcal{L}_{adv} \tag{14}$$

where λ is a hyper-parameter.

4.4 Inference

During inference, we sample z_T from a prior distribution, such as standard normal distribution $\mathcal{N}(0, 1)$. Based on the transition map defined in [Wang *et al.*, 2024]: $f_{m,m'}(x_t, t) =$ $f^{m'}(\cdots f^{m-2}(f^{m-1}(f^m(\mathbf{x}_t, t), s_m), s_{m-1})\cdots, s_{m'})$ which transform any point x_t on *m*-th sub-trajectory to the solution point of *m'*-th trajectory, we can get the solution estimation $\hat{z}_0 = f_{M-1,0}(x_T, T)$. Finally, the human motion

sequence \hat{x} is generated through the decoder $\mathcal{D}(\hat{z}_0)$.

5 Numerical Experiments

Dataset. We base our experiments on the widely used HumanML3D dataset [Guo *et al.*, 2022a], which comprises 14,616 distinct human motion sequences accompanied by 44,970 textual annotations. In line with previous studies [Dai *et al.*, 2025; Chen *et al.*, 2023; Guo *et al.*, 2022a], we employ a redundant motion representation that includes root velocity, root height, local joint positions, velocities, root-space rotations, and foot-contact binary indicators to ensure a fair comparison across methods.

Evaluation metrics. Following [Guo et al., 2022a; Chen et al., 2023], we evaluate our model using the following metrics: (1) Average Inference Time per Sentence (AITS), which measures the time required to generate a motion sequence from a textual description, with lower values indicating faster inference; (2) R-Precision, capturing how accurately generated motions match their text prompts by checking whether the top-ranked motions align with the given descriptions, where higher scores indicate better accuracy; (3) Frechet Inception Distance (FID), assessing how closely the distribution of generated motions resembles real data, where lower scores indicate better quality; (4) Multimodal Distance (MM Dist), quantifying how well the motion features align with text features, with lower values signalling a tighter match between motions and prompts; (5) Diversity, which calculates variance through motion features to indicate the variety of generated motions across different samples; and (6) MultiModality (MModality), measuring generation diversity conditioned on the same text by evaluating how many distinct yet valid motions can be produced for a single prompt.

Implementation details. We conduct our experiments on a single NVIDIA RTX 6000 GPU with a batch size of 128 motion sequences fed into our model. The model is trained over 384K iterations using an AdamW [Loshchilov, 2017] optimiser with parameters $\beta_1 = 0.9$, $\beta_2 = 0.999$ and an initial learning rate 2e - 4, which gradually decays following a cosine decay learning rate schedule. For the loss function, we set $\lambda = 0.1$. The guidance scale ranges between $w_{min} = 5$, and $w_{max} = 15$ and the Exponential Moving Average (EMA) rate is set as $\mu = 0.95$. Additionally, we use DDIM [Song *et al.*, 2020a] as our ODE solver and skip step k = 100.

5.1 Text-to-motion synthesis

In this section, we evaluate the performance of our proposed MotionPCM method on the text-to-motion task. We compare our approach with other baseline methods using the widely adopted HumanML3D dataset, conducting each experiment 20 times to establish results within a 95% confidence interval [Dai *et al.*, 2025; Guo *et al.*, 2022a]. Following previous studies [Dai *et al.*, 2025; Guo *et al.*, 2022a], we employ the following evaluation metrics: Average Inference Time per Sentence (AITS), R-Precision, Frechet Inception Distance (FID), Multimodal Distance (MM Dist), Diversity, and MultiModality (MModality).

For benchmark comparisons, we select the most renowned

and widely used models in the field. In particular, MotionLCM-v2 [Dai *et al.*, 2024], the improved version of MotionLCM-v1 [Dai *et al.*, 2025], is primarily compared with our method in different sampling steps. As illustrated in Table 1, our method achieves a sampling speed comparable to MotionLCM-v2 in terms of AITS while significantly outperforms it in R-Precision Top-1, Top-2 and Top-3, FID, and MM Dist across different sampling steps. Furthermore, our 4-step variant also outperforms the counterpart of MotionLCM-V2 in terms of Diversity while underperforming in MModality. These results demonstrate that our model is more superior than MotionLCM-V2 although both support real-time inference.

Compared to other approaches, the speed of our method surpasses most alternatives by a large margin, demonstrating its time efficiency. Our method with 1-step sampling can support motion synthesis over 30 frames per second, thereby making it possible for real-time applications. Regarding R-Precision, our method achieves the highest accuracy across Top-1, Top-2 and Top-3 metrics with our 2-step variants compared to other approaches. This consistent improvement highlights the reliability of MotionPCM in accurately aligning generated motions with textual descriptions. Similarly, in FID and MM Distance metrics, our method achieves the best scores with its 4-step and 2-step variants respectively. These results further highlight MotionPCM's capability to generate high-quality and semantically consistent motions. Although

Table 1: Performance comparison of various methods across multiple metrics on HumanML3D dataset. The best results are in **bold**, and the second best results are <u>underlined</u>. \downarrow means the lower is better while \uparrow means the higher is better. \rightarrow represents the closer to the value of Real is better.

Figure 5: Qualitative comparison of motion synthesis methods. Lighter colours represent earlier time points.

our method does not achieve the best scores in Diversity compared to [Xie *et al.*, 2024], our 4-step variant ranks second. In terms of MModality metrics, our method falls short of achieving superior performance compared to other approaches.

Figure 5 demonstrates a qualitative comparison of motion generation between our MotionPCM model, MotionLCM-v2 [Dai *et al.*, 2024], and MLD [Chen *et al.*, 2023]. Each row features a prompt alongside the motions generated by the three models, clearly demonstrating the advantages of our method over the others.

For the first prompt, "The rigs walk forward, then turn around, and continue walking before stopping where he started," MotionLCM-v2 does not perform the turning action. MLD moves to the left initially but fails to return to the starting position when turning back. In contrast, our method accurately executes the entire sequence as described, aligning closely with the prompt. In the case of the second prompt, "a person walks with a limp leg," our model produces a motion that reasonably reflects the limp. MotionLCM-v2 exaggerates the limp, while MLD fails to depict the limp entirely. For the third prompt, "a man walks forward a few steps, raises his left hand to his face, then continues walking in a circle," our model effectively completes the described actions. MotionLCM-v2 does not generate the circular walking pattern, and MLD produces an indistinct circle without the hand-raising gesture. These findings emphasise the ability of MotionPCM to generate detailed and accurate motion sequences.

Overall, these results demonstrate that MotionPCM is capable of producing high-quality motions in real time while maintaining superior alignment with the given textual descriptions, outperforming existing benchmarks in motion synthesis.

5.2 Ablation studies

We conduct ablation studies on single-step sampling, as shown in Table 2 to demonstrate the effectiveness of our network design. When using a skip step k = 20, instead of 100 steps in our implementation, almost all evaluation metrics get degrade dramatically. This exception may be due to the increased number of time points requiring more training iterations to achieve proper convergence.

Methods		R-Precision ↑		FID .l.	MM Dist	Diversity \rightarrow	MModality 1
	Top 1	Top 2	Top 3	*			
Ours (Full Model)	$0.556^{\pm.002}$	$0.750^{\pm.002}$	$0.840^{\pm.002}$	$0.054^{\pm.003}$	$2.739^{\pm.007}$	$9.689^{\pm.078}$	$1.764^{\pm.074}$
$\overline{\text{ODE skip step } k = 20}$	$0.541^{\pm.001}$	$0.738^{\pm.002}$	$0.831^{\pm.002}$	$0.097^{\pm.005}$	$2.804^{\pm.006}$	$9.744^{\pm.091}$	$1.882^{\pm.071}$
w/o EMA	$0.553^{\pm.003}$	$0.746^{\pm.002}$	$0.836^{\pm.002}$	$0.054^{\pm.003}$	$2.769^{\pm.006}$	$9.685^{\pm.087}$	$1.774^{\pm.064}$
w/o discriminator	$0.547^{\pm.003}$	$0.745^{\pm.003}$	$0.837^{\pm.002}$	$0.101^{\pm.006}$	$2.785^{\pm.008}$	$9.622^{\pm.088}$	$1.771^{\pm.065}$

Table 2: Ablation studies for single-step sampling on HumanML3D dataset.

In addition, if we replace the target network with the online network directly—equivalent to setting $\mu = 0$ in the exponential moving average (EMA) update, a slightly worse performance is observed compared to training using an EMA way with $\mu = 0.95$, highlighting the effectiveness of EMA.

Last not least, removing a discriminator and its adversarial loss leads to much worse performance, indicating the importance of the discriminator in enhancing model performance, particularly in low-step sampling scenarios.

6 Conclusion

In this paper, we introduce **MotionPCM**, a novel motion synthesis method that enables real-time motion generation while maintaining high quality. By incorporating phased consistency into our pipeline, we effectively reduce accumulated random noise in multi-step sampling, achieving deterministic sampling. Additionally, the introduction of a discriminator significantly improves sampling quality.

While our method has been validated on a single largescale dataset, future work will focus on evaluating its effectiveness on more datasets to further assess its generalisability.
