Universality, encompassing critical exponents, scaling functions, and dimensionless quantities, is fundamental to phase transition theory. In finite systems, universal behaviors are also expected to emerge at the pseudocritical point. Focusing on two-dimensional percolation, we show that the size distribution of the largest cluster asymptotically approaches to a Gumbel form in the subcritical phase, a Gaussian form in the supercritical phase, and transitions within the critical finite-size scaling window. Numerical results indicate that, at consistently defined pseudocritical points, this distribution exhibits a universal form across various lattices and percolation models (bond or site), within error bars, yet differs from the distribution at the critical point. The critical polynomial, universally zero for two-dimensional percolation at the critical point, becomes nonzero at pseudocritical points. Nevertheless, numerical evidence suggests that the critical polynomial, along with other dimensionless quantities such as wrapping probabilities and Binder cumulants, assumes fixed values at the pseudocritical point that are independent of the percolation type (bond or site) but vary with lattice structures. These findings imply that while strict universality breaks down at the pseudocritical point, certain extreme-value statistics and dimensionless quantities exhibit quasiuniversality, revealing a subtle connection between scaling behaviors at critical and pseudocritical points.

I. INTRODUCTION

Percolation theory [1] offers a fundamental framework for studying diverse systems, including materials science [2], complex networks [3], and epidemiology [4], where geometric phase transitions occur. The percolation model operates on a simple rule: each site or bond is occupied with a given probability p. As p increases and exceeds the percolation threshold p_c , the system transitions from being dominated by small, disconnected clusters to one where a giant component emerges, connecting large portions of the system.

As a system approaches the percolation threshold p_c , a series of critical behaviors emerge, with certain physical quantities either diverging or reaching finite values, often characterized by critical exponents. Importantly, these exponents do not depend on the details of the system, such as the lattice type, site or bond percolation, instead, they are determined by the spatial dimension. the range of interaction, and symmetry. Models that share the same set of critical exponents are said to belong to the same universality class. In two dimensions (2D), exact results can be derived using methods such as lattice duality/matching [5], Yang-Baxter integrability [6, 7], and local conformal invariance [8, 9]. Critical exponents, such as the correlation-length exponent $\nu = 4/3$ and the magnetic exponent $y_h = 98/41$ (also known as fractal dimension d_f), have been predicted by

Coulomb gas theory [10], conformal field theory [11], and stochastic Löewner evolutions [12], and strictly proven on the triangular lattice [13].

For a finite system of side length L, the finite-size scaling theory hypothesizes that there exists a critical finitesize scaling window $\mathcal{O}(L^{-1/\nu})$, and, within the window, the finite-size behavior of physical quantities Q would behave as

$$Q(t,L) = L^{y_Q} \hat{Q}(tL^{1/\nu}),$$
(1)

where $t = p - p_c$ is the distance to the criticality, y_Q is the critical exponent of Q, and $\tilde{Q}(x)$ is a universal function. For finite systems, the *L*-independent pseudocritical point p_L has the asymptotic behavior $p_L = p_c + aL^{-1/\nu}$, where a is an *L*-independent parameter, yielding $(p - p_c)L^{1/\nu} = (p - p_L)L^{1/\nu} + \mathcal{O}(1)$. This means that defining $t = p - p_L$ only introduces an *L*-independent shift for the argument in the scaling function $\tilde{Q}(tL^{1/\nu})$, which has no influence on the finite-size scaling. Thus, it is generally assumed that the finite-size scaling ansatz Eq. (1) is applicable both around p_c and p_L .

It is noted that the definition of p_L is not unique. At various pseudocritical points p_L and critical point p_c , representing different ensembles, it is generally believed that the same finite-size scaling behavior can be observed. However, different finite-size behaviors have also been reported for p_c and p_L of different definitions. For example, the finite-size scaling of explosive percolation at p_c is shown to be abnormal [14, 15], which was initially misidentified as a discontinuous phase transition [16–19]. Recently, it is found that explosive percolation obeys the standard finite-size scaling theory around

^{*} yjdeng@ustc.edu.cn

[†] lim@hfut.edu.cn

the dynamic pseudocritical point [20, 21], indicating the non-equivalence of ensembles. Another example is the high-dimensional percolation model, where the finite-size scaling is dependent on the boundary conditions [22, 23]. For free boundary conditions in d dimensions, the fractal dimension at p_L is $d_f = 2d/3$, in agreement with that under periodic boundary conditions [24–26], while $d_f = 4$ at p_c [27, 28]. Besides, a study also suggests that by defining a dynamic pseudocritical point, the observables, such as the size of the largest cluster, follow the extreme-value Gumbel distribution across different models [29].

In this work, we demonstrate that, even in 2D, where finite-size scaling behaviors at pseudocritical and critical points are generally considered identical, there may still be differences in their universality. Through extensive simulations, we observe that the probability distribution of the largest-cluster size asymptotically approaches a Gumbel distribution in the subcritical phase, a Gaussian distribution in the supercritical phase, and varies based on the sample position within the critical finite-size scaling window. At a pseudocritical point, this distribution retains a universal form across different lattices but differs from the critical point. Moreover, the critical values of certain dimensionless quantities, such as wrapping probabilities [30-32], and Binder cumulants [33, 34], still take finite constant values at pseudocritical points. However, their magnitudes are significantly different from those at the critical point. Our data suggest that these dimensionless quantities are identical for bond and site percolation, but different for various lattices. All these suggest that although universality at criticality may break at the pseudocritical point, some extreme-value statistics and dimensionless quantities can exhibit a form of quasi-universality, indicating a nuanced relationship between scaling behaviors at critical and pseudocritical points.

The remainder of this paper is organized as follows. In Sec. II, the simulation details and sampled quantities are described. Section III presents our numerical results. Finally, a brief summary and discussion are given in Sec. IV.

II. SIMULATION

A. Models

We study percolation on 2D lattices with the periodic boundary conditions, including

- (a) Bond percolation (BP) on square and triangular lattices;
- (b) Site percolation (SP) on square and triangular lattices;
- (c) Equivalent-neighbor bond percolation (EBP) [35] on square lattices.

FIG. 1. Illustration of the EBP on the square lattice with different interaction range r. (a) For r = 1, each site i (e.g., the red site) connects to all its neighbors j within the range $|x_i - x_j| \leq r$ and $|y_i - y_j| \leq r$ (indicated by blue), where (x, y) is the site coordinates. Gray sites are outside the interaction range r = 1 and cannot form bonds with the red site. (b) For r = 2, in addition to the blue sites, more bonds (indicated by green) are formed with the red site. Under periodic boundary conditions, each site has $z = (2r+1)^2 - 1$ neighbors, and the total number of bonds in the system is $zL^2/2$. Each bond is occupied with an equal probability p, and unoccupied with probability 1 - p.

For BP, each bond are occupied with a probability p, and the percolation threshold is $p_c = 0.5$ and $p_c = 2\sin(\pi/18)$ for square and triangular lattices, respectively [5]. For SP, the occupied probability p refers to site, and $p_c = 0.59274621(13)$ [36] for square lattices, $p_c = 0.5$ [37] for triangular lattices. EBP takes the same rule as BP, but bonds can be inserted between sites within a distance of $2r \times 2r$, where r is an adjustable parameter. Specifically, a site i with coordinates (x_i, y_i) on square lattice has a probability p to couple to each site j satisfying $|x_i - x_j| \leq r$ and $|y_i - y_j| \leq r$, as shown in Fig. 1. For finite r, EBP increases coordination number without changing the spatial dimension, thus it also belongs to 2D percolation universality [35, 38]. Without loss of generality, we set r = 5 so that a site has 120 neighbors.

B. Ensembles

A conventional method for studying the finite-size scaling of percolation operates as follows: all occupied bonds or sites are introduced into the system simultaneously, with the occupation probability p serving as the control parameter. This generates a configuration of occupied bonds or sites. By setting $p = p_c$, critical observables can be sampled and averaged over different realizations. This approach is referred to as the conventional ensemble.

In contrast, the event-based ensemble represents the percolation process as a dynamic bond or site insertion process [20, 21, 29]. Initially, all bonds or sites are in an unoccupied state. Then, at each time step T, a bond or site is randomly selected and changed to the occupied

state. By dynamically recording the size of the largest cluster, $C_1(T)$, a special time step T_{\max} can be identified, where the gap $\Delta = C_1(T) - C_1(T-1)$ reaches its maximum value. Let E denotes the total number of bonds and V denotes the total number of sites. The time step T_{\max} corresponds to a pseudocritical point, $p_L = T_{\max}/E$ or $p_L = T_{\max}/V$, which fluctuates from realizations to realizations. Using the recorded sequence of occupied bonds or sites, the configuration at p_L can be reconstructed, allowing any quantities of interest to be sampled. The ensemble average is then obtained as the mean of the observables measured at this dynamic pseudocritical point p_L .

C. Sample quantities

For each realization of a percolation model, the following observables are sampled at both p_c and p_L ,

- (a) The size of the *i*-th largest cluster C_i .
- (b) The second moment of cluster-size distribution $S_2 = \sum_i C_i^2$ and the fourth moment $S_4 = \sum_i C_i^4$, where the sum \sum_i runs over all clusters.
- (c) The indicators \mathcal{R}_2 and \mathcal{R}_0 for the existing of wrapping clusters. $\mathcal{R}_2 = 1$ when having a cluster wrapping along both directions, otherwise $\mathcal{R}_2 = 0$. Similarly, $\mathcal{R}_0 = 1$ when having no wrapping cluster, otherwise $\mathcal{R}_0 = 0$.

From these observables, we can calculate the following quantities,

- (a) The mean size of the *i*-th largest cluster $C_i = \langle C_i \rangle$.
- (b) The probability distribution $f_{C_i}(x)$ for the size of the *i*-th largest cluster with i = 1, 2, 3.
- (c) The second order Binder cumulant $B_2 = \langle C_1 \rangle^2 / \langle C_1^2 \rangle$.
- (d) The fourth order Binder cumulant $B_4 = \langle S_2^2 \rangle / (3 \langle S_2^2 \rangle^2 2 \langle S_4 \rangle).$
- (e) The wrapping probabilities $R_2 = \langle \mathcal{R}_2 \rangle$ and $R_0 = \langle \mathcal{R}_0 \rangle$.
- (f) The critical polynomial $P_B = \langle \mathcal{R}_2 \mathcal{R}_0 \rangle$.

Here, $\langle \cdot \rangle$ denotes the ensemble average.

III. RESULTS

A. The size distribution of the largest cluster

The percolation transition is often characterized by the size of the largest cluster C_1 , which scales as $C_1 \sim \ln V$ below p_c , $C_1 \sim V$ above p_c , and $C_1 \sim L^{d_f}$ at criticality. For a occupied probability p, the largest-cluster size

varies across different realizations. To investigate the universal behavior of C_1 , we first examine the size distribution $f_{C_1}(x)$ of the largest cluster.

Extreme-value theory predicts that the maximum of a large number of independent and identically distributed random variables follow the Gumbel distribution. To test whether $f_{C_1}(x)$ conforms to the Gumbel distribution, we define x as (see Appendix A)

$$x \equiv \pi \frac{\mathcal{C}_1 - \mathcal{C}_1}{\sqrt{6}\sigma(\mathcal{C}_1)} + \gamma, \qquad (2)$$

where C_1 refers to the largest-cluster size in a single realization, $C_1 \equiv \langle C_1 \rangle$ is its mean, $\sigma(C_1)$ is its standard deviation, and $\gamma \approx 0.5772$ is the Euler constant. With this rescaling, if C_1 follows the Gumbel distribution, the probability distribution $f_{C_1}(x)$ should match the standard Gumbel distribution. To validate this, we simulate BP on square lattices with side length L under the conventional ensemble and plot $f_{C_1}(x)$ for various L and pin Fig. 2.

In the subcritical phase $(p \ll p_c)$, Fig. 2(a) illustrates that $f_{C_1}(x)$ asymptotically converges to the Gumbel distribution as L increases. This observation indicates that C_1 asymptotically follows extreme-value statistics in the subcritical phase. Such behavior is reasonable, as for $p \ll p_c$, the system only forms small clusters of similar sizes. The finite correlation length ensures that these clusters are effectively uncorrelated in sufficiently large systems and can be treated as independent random variables. Consequently, $f_{C_1}(x)$ adheres to the Gumbel distribution for large systems. A similar trend is observed for the second-largest cluster, as shown in the inset of Fig. 2(a), which presents the probability distribution $f_{C_2}(x)$.

As p approaches p_c , the correlation length diverges, introducing correlations between clusters. Consequently, the distribution $f_{C_1}(x)$ deviates significantly from the Gumbel distribution at $p = p_c$, as shown in Fig. 2(b). Similarly, the size distribution $f_{C_2}(x)$ for the secondlargest cluster also deviates from the Gumbel distribution (see inset). Additionally, the distributions $f_{C_1}(x)$ and $f_{C_2}(x)$ differ markedly in this regime.

In the supercritical phase $(p \gg p_c)$, the largest cluster corresponds to the unique percolating cluster (~ V), while the other clusters are significantly smaller ($\ll V$). Consequently, C_1 is no long the maximum value selected from a set of random variables, leading to a clear deviation from the Gumbel distribution. Instead, as shown in Fig. 2(c), $f_{C_1}(x)$ asymptotically converges to a Gaussian distribution, indicating that C_1 obeys the central limit theorem for sufficiently large systems. Furthermore, the remaining clusters behave similarly to those in the subcritical phase. As a result, $f_{C_2}(x)$ and $f_{C_3}(x)$ again asymptotically follow the Gumbel distribution, as shown in the inset of Fig. 2(c).

The critical region can also be identified by a dynamic pseudocritical point p_L , i.e., in the event-based ensemble. In Fig. 3(b), we present the probability density function

FIG. 2. The probability distribution $f_{C_1}(x)$ of the largest-cluster size C_1 for various side length L and probability p. Here, the data are collected from BP on square lattice. In (a) and (b), x is defined as Eq. (2), and $x = (C_1 - C_1)/\sigma(C_1)$ in (c). With this rescaling, if C_1 follows a Gumbel/Gaussian distribution, $f_{C_1}(x)$ matches the standard Gumbel/Gaussian distribution, indicated by the red/blue line. For the same reason, the arguments x for the size distributions of the second and third largest clusters, $f_{C_2}(x)$ and $f_{C_3}(x)$, in the insets of (a) and (c) are also defined as Eq. (2). (a) In the subcritical phase, both $f_{C_1}(x)$ and $f_{C_2}(x)$ (see inset) asymptotically approaches a Gumbel distribution. (b) At the percolation threshold p_c , $f_{C_1}(x)$ and $f_{C_2}(x)$ (see inset) are different, and clearly not a Gumbel distribution. (c) In the supercritical phase, $f_{C_1}(x)$ asymptotically approaches a Gaussian distribution. The inset shows that $f_{C_2}(x)$ and $f_{C_3}(x)$ asymptotically approaches a Gaussian distribution.

 $f_{C_1}(x)$ sampled at p_L . Notably, this distribution does not follow the Gumbel distribution, similar to the behavior observed at p_c . Moreover, the form of $f_{C_1}(x)$ differs between p_L and p_c . In fact, within the critical finite-size scaling window $\mathcal{O}(L^{-1/\nu})$, the shape of $f_{C_1}(x)$ depends on the sample position p. In Figs. 2(a) and (c), we illustrate $f_{C_1}(x)$ sampled at different positions in the critical finite-size scaling window, i.e., $p = p_L \pm aL^{-1/\nu}$ with a = 1. The results show that all the distributions deviate from the Gumbel form and vary with the sample position p. The simulation results for some other models also suggest the deviation of $f_{C_1}(x)$ from the Gumbel distribution at pseudocritical points [39].

Furthermore, the definition of p_L is not unique. In addition to the maximum gap used in this paper, one could define p_L based on the maximum point of the second moment of the cluster-size distribution, or the size of the second largest cluster. These pseudocritical points, defined in various ways, are all distributed around p_c within the critical finite-size scaling window $\mathcal{O}(L^{-1/\nu})$. Consequently, as indicated by Fig. 3, the distribution $f_{C_1}(x)$ at p_L should vary with the definition of p_L . This lack of universality contrasts with the critical point p_c , where the distribution $f_{C_1}(x)$ is independent of lattice types and whether site or bond percolation is considered.

However, for a given definition of p_L , as illustrated in Fig. 4, the size distribution of the largest cluster $f_{C_1}(x)$ at p_L for different 2D lattices – such as BP an SP on square and triangular lattices, and EBP on square lattices – collapses onto a single curve. This observation suggests a quasi-universality in the event-based ensemble for a specific definition of p_L .

B. Dimensionless quantities

At criticality, in addition to the universal distribution of observables, several dimensionless quantities take universal values across different lattices and for both site and bond percolation. For example, the wrapping probabilities at p_c exhibit the universal relation $R_2 = R_0$ for planar lattices. Consequently, the critical polynomial has the universal value $P_B \equiv R_2 - R_0 = 0$ at p_c , with $R_2 = R_0 = 0.30952628$ [32, 36] for square lattices under periodic boundary conditions. Moreover, for BP on square lattices with periodic boundary conditions, the Binder cumulants are $B_2 = 0.96017(1)$ [40] and $B_4 = 0.87048(5)$ [41, 42].

As shown in Fig. 5, at the pseudocritical point p_L , the critical polynomial P_B also asymptotically approaches a constant for large systems. However, unlike at p_c , it does not exhibit a universal value across different lattices. To determine these values, we perform least-squares fits of the P_B data using the finite-size scaling ansatz:

$$O(L) = O_{\infty} + a_1 L^{-y_1} + a_2 L^{-y_2}, \qquad (3)$$

where O_{∞} is the asymptotic value for infinite lattices, y_1 and y_2 are the correction exponents, and a_1 and a_2 are nonuniversal amplitudes. We set a lower cutoff of the side length L_{\min} on the data and monitor the residual χ^2 as L_{\min} increased. When subsequent increases in L_{\min} no longer reduced χ^2 by more than one unit per degree of freedom (DF), the fits were deemed stable. The fit results are summarized in Table I, showing that P_B takes negative values because $p_L < p_c$ in 2D, leading to $R_0 > R_2$.

From Table I, we conclude that $P_B = -0.7390(6)$ and $P_B = -0.7394(2)$ for BP and SP on square lattices, respectively. These two values are consistent within their

FIG. 3. The probability distribution $f_{C_1}(x)$ of the largest-cluster size C_1 in the event-based ensemble for various side length L. Here, the data are collected from BP on square lattices, and C_1 are rescaled as x defined in Eq. (2). The sample positions are (a) $p = p_L - aL^{-1/\nu}$, (b) $p = p_L$, and (c) $p = p_L + aL^{-1/\nu}$, with a = 1 for simplicity. All these distributions are deviated from the standard Gumbel distribution, indicated by the red lines.

FIG. 4. The probability distribution $f_{C_1}(x)$ in the eventbased ensemble for different percolation models at pseudocritical point p_L . All cases have a side length of L = 1024. The red line represents the standard Gumbel distribution.

error bars, indicating that P_B is independent of bond or site percolation for a given lattice. The data obtained from the triangular lattice also support this conclusion; however, the value, $P_B = -0.7527(5)$ is different from that on square lattices. For EBP, it also exhibits a differentiated value, $P_B = -0.7371(7)$. The differences between these values are significantly larger than their error bars, confirming that P_B at p_L is not universal across different lattices. In summary, at the pseudocritical point p_L , the critical polynomial P_B exhibits quasi-universal behavior: it depends on the lattice type but is independent of whether bond or site percolation is considered.

Moreover, by fitting the values of R_0 at p_L to the finitesize scaling ansatz in Eq. (3), we also determine R_0 for various percolation systems, as listed in Table II. These results indicate that although the value of R_0 differs at p_c and p_L , the universal behavior remains consistent, as

 R_0 does not depend on whether bond or site percolation is used, but does vary with the lattice type (boundary).

In addition to the wrapping probabilities, we analyze the Binder cumulants at the pseudocritical point p_L for several percolation models. The fitting results for B_2 and B_4 are presented in Table III and Table IV, respectively. By comparing the fitting results for different L_{\min} , we estimate the final values as $B_2 = 0.88617(5)$ and $B_4 = 0.5148(3)$ for BP on square lattices, $B_2 = 0.8860(2)$ and $B_4 = 0.51495(4)$ for SP on square lattices, and

FIG. 5. Asymptotic behaviors of P_B in the event-based ensemble for different percolation models at p_L . The curves are obtained by fitting results in Table I. Unlike the case at p_c , where $P_B = 0$ universally holds, at p_L , the value of P_B is nonzero and no longer universal across different lattices.

 $B_2 = 0.8850(8)$ and $B_4 = 0.5150(8)$ for EBP. When compared to the values at p_c ($B_2 = 0.96017(1)$ and $B_4 = 0.87048(5)$), the values of B_2 and B_4 at p_L are significantly smaller. Nevertheless, within the error bars, these fit results further support the quasi-universality at p_L , consistent with the findings for wrapping probabilities.

IV. DISCUSSION

In summary, we investigate the universality of the distribution for the largest-cluster size and various dimensionless quantities in 2D percolation models within the event-based ensemble. Our numerical results reveal that the size distribution of the largest cluster asymptotically follows a Gumbel distribution in the subcritical phase and a Gaussian distribution in the supercritical phase. Within the critical finite-size scaling window, the distribution is neither Gumbel nor Gaussian, due to correlations induced by the diverging correlation length. Instead, the distribution varies with the sample position in the critical finite-size scaling window, highlighting the nonuniversality of the distribution of the largestcluster size at pseudocritical points of different definitions. However, for a given pseudocritical point definition, this distribution remains universal across different lattices and bond or site percolation models, indicating a quasi-universality. For the wrapping probabilities and the critical polynomial, our numerical results also support a quasi-universality – while their values depend on the lattice type, they are independent of whether bond or site percolation is considered. Similarly, the Binder cumulants also exhibit this quasi-universal behavior.

Our findings suggest that the strict universality observed at the critical point is broken at the pseudocritical point, yet a quasi-universality persists. Recent studies on explosive percolation and rigidity percolation further indicate that quantities extracted at dynamic pseudocritical points tend to be less noisy and more reliable than those extracted at the critical point [20, 21, 43]. These findings underscore subtle differences in critical behavior across various pseudocritical points, emphasizing that the choice of pseudocritical points may significantly influence the accuracy of scaling behavior analysis in certain models.

The standard Gumbel distribution is a special case where $\mu = 0$ and $\beta = 1$, yielding

$$f(x) = e^{-x - e^{-x}}.$$
 (6)

From Eq. (5), the mean and standard deviation of a Gumbel distribution are given by

$$\langle X \rangle = \mu + \gamma \beta, \tag{7}$$

$$\sigma(X) = \frac{\pi\beta}{\sqrt{6}},\tag{8}$$

where $\gamma \approx 0.5772$ is the Euler constant. This implies that the standard Gumbel distribution has a mean of γ and a standard deviation of $\pi/\sqrt{6}$.

For any random variable X following a Gumbel distribution Eq. (5), it is easy to verify that the rescaled random variable

$$X' \equiv \frac{X - \langle X \rangle}{\sigma(X)} \frac{\pi}{\sqrt{6}} + \gamma \tag{9}$$

should conform to the standard Gumbel distribution.
