

Impact of Tracking Resolutions on ϕ -Meson Spin Alignment Measurement

Measurements of global spin alignment of vector mesons in relativistic heavy-ion collisions can provide unique insights into spin-orbit interactions and vector meson dynamics in the Quark-Gluon Plasma (QGP) produced in those collisions. The global spin alignment is measured by the 00th coefficient of the spin density matrix, ρ_{00} , via the polar angle (θ^*) of the decay-daughter momentum in the parent rest frame with respect to the direction of the orbital angular momentum of the collision. Such measurements are affected by the angular and momentum resolutions of the reconstructed tracks in the experiment. Such effects are nontrivial because of kinematic complications caused by the boost to the parent rest frame, and could be important given that the global spin alignment signal is weak. In this paper, we investigate the effects of experimental tracking resolutions on measurements of the $\phi(1020)$ meson ρ_{00} . We study these effects for two methods of ρ_{00} measurements, the conventional method analyzing the ϕ -meson yield versus $\cos^2 \theta^*$ and the invariant mass (m_{inv}) method utilizing $\langle \cos^2 \theta^* \rangle$ versus m_{inv} . Using typical resolution values from experiments, we find that the effect of track resolution on ρ_{00} is small, well within typical measurement uncertainties.

I. INTRODUCTION

A large orbital angular momentum (OAM) is present in non-central heavy-ion collisions [1, 2]. This large OAM produces a vorticity field in the Quark-Gluon Plasma (QGP) which can polarize spin-1/2 quarks in the medium [1, 3–5]. These polarizations impact final state hadron production and can be measured by parity-violating weak decays of hyperons and by parity-conserving strong decays of vector mesons [1]. A finite global spin polarization of the Λ -hyperon has indeed been observed, suggesting the presence of an ultra-strong vorticity field in the QGP [6]. Finite global spin alignment of ϕ -meson has recently been reported by the ALICE [7] and STAR [8] experiments, with opposite signs. Global spin alignment is measured by the angular distribution of a daughter kaon from the $\phi \rightarrow K^+ K^-$ decay [7, 8],

$$\frac{dN}{d \cos \theta^*} \propto (1 - \rho_{00}) + (3\rho_{00} - 1) \cos^2 \theta^*, \quad (1)$$

where θ^* is the polar angle of the kaon's momentum vector in the ϕ -meson rest frame with respect to the global OAM in the lab frame. The parameter ρ_{00} is the 00th coefficient of the spin density matrix. A uniform angular distribution gives $\rho_{00} = 1/3$. The deviation of ρ_{00} from 1/3 indicates a finite spin alignment. Since all known physics mechanisms yield only negligible $\rho_{00} - 1/3 \sim 10^{-4}$, the relatively large values of $\sim 1\%$ measured of $\rho_{00} - 1/3$ may suggest novel physics mechanisms such as fluctuations of the strong color field [5, 9].

In experiments, charged-particle trajectories are reconstructed from hit information recorded in tracking devices. Measurement resolutions can cause inaccuracies in the reconstructed track parameters. Moreover, because of small-angle multipole scattering of charged particles in detector materials, the particle trajectories will derail, the magnitude of which being dependent on the amount of detector materials they traverse. These physics processes will cause inaccuracies in the reconstructed particle kinematics even with a perfect detector. Since ρ_{00} is

measured through the angular distribution of the decay daughters, the angular resolution of the reconstructed tracks is important. Because θ^* is measured in the parent rest frame, both angular and momentum resolutions can impact the Lorentz boost, which can unpredictably affect the measurement.

In this article, we investigate the effects of angular and momentum resolutions on ρ_{00} measurements using toy-model simulations.

II. SIMULATION AND ANALYSIS DETAILS

A. Track Angular and Momentum Resolutions

The two-dimensional angular spread due to multiple small-angle scattering of singly-charged particles in detector materials is given by [10]

$$\sigma_{\text{ms}} \approx \frac{13.6 \text{MeV}/c}{\beta p} \sqrt{\frac{x}{X_0}} \approx \frac{13.6 \text{MeV}/c}{\beta \sqrt{pp_{\perp}}} \sqrt{\frac{x_{\perp}}{X_0}}, \quad (2)$$

where p and β are particle momentum magnitude and velocity in units of the speed of light, and x/X_0 is the amount of materials the particle traverses in units of the radiation length. It is convenient to use the transverse material length x_{\perp}/X_0 , independent of the particle's polar angle.

In addition, tracking accuracy is affected by the detector position resolution. The angular resolution of the track trajectory is given by the position resolution over the typical track length, which is more or less fixed by the size of the detector. Thus, the detector position resolution impacts the angular resolution in an approximately uniform way.

Experimentally, one typically measures p_{\perp} and pseudorapidity η . Within a given η range close to midrapidity, p is approximately proportional to p_{\perp} on average. The average effect of multiple scattering is therefore inversely proportional to $\beta_{\perp} p_{\perp}$. Thus, the standard deviations in

the polar (θ) and azimuthal (ϕ) angles can be parameterized with the following function:

$$\sigma_{\delta\theta, \delta\phi} = \sqrt{\left(\frac{A_{\theta, \phi}}{\beta_{\perp} p_{\perp}}\right)^2 + B_{\theta, \phi}^2}, \quad (3)$$

where $\beta_{\perp} \equiv p_{\perp}/\sqrt{p_{\perp}^2 + m^2}$ (m is the particle rest mass). Note that we have used β_{\perp} in place of β , which are not strictly proportional to each other. They are equal for midrapidity particles. However, in practice, Eq. (3) is a good parameterization for angular resolutions. While $A_{\theta} \approx A_{\phi} \approx \sigma_{\text{ms}}$, B_{θ} and B_{ϕ} can differ depending on the position resolutions (granularity) in the polar and azimuthal directions.

The inverse of the particle p_{\perp} is determined by the track curvature in the transverse plane (ρ_{\perp}), $1/p_{\perp} \approx \rho_{\perp}/(0.3B)$ where B is the detector magnetic field. Track curvature is equal to the angular bend of the track over the detector range (L), so the precision of p_{\perp} and ϕ are related by $\delta\rho_{\perp} \sim \delta\phi/L$. The relative momentum resolution is therefore given by the azimuthal resolution multiplied by p_{\perp} ,

$$\sigma_{\delta p_{\perp}/p_{\perp}} = \frac{1}{0.3BL} \sqrt{\left(\frac{A_{\phi}}{\beta_{\perp}}\right)^2 + (B_{\phi} p_{\perp})^2}, \quad (4)$$

where B, L and p_{\perp} are in the units of Tesla, meter, and GeV/c, respectively.

Typically in experiments, the angular and momentum resolutions are obtained from GEANT simulation of *Monte Carlo* (MC) tracks going through the detector materials [11]. To illustrate the effects of tracking resolution on spin alignment measurements, we consider the STAR Time Projection Chamber (TPC) [12] as a typical detector. The amount of STAR TPC transverse material is approximately $x_{\perp}/X_0 \approx 1\%$. This would give $\sigma_{\text{ms}} \sim 0.00136$ for a $p_{\perp} = 1$ GeV/c light hadron at midrapidity. Typical position granularity gives an angular resolution on the order of per mille for straight-line tracks (high p_{\perp}). We therefore use the following parameters in our subsequent simulations:

$$A_{\theta} = A_{\phi} = 0.0015 \text{ GeV}/c, \quad (5a)$$

$$B_{\theta} = B_{\phi} = 0.0010. \quad (5b)$$

We take the typical $B = 0.5$ Tesla and $L = 1$ m (like for the STAR detector [13]) for momentum resolution.

B. Setup of Toy-Model Simulations

We generate ϕ mesons and kaons to mimic real data events, according to the measured yields, p_{\perp} spectra, and $v_2(p_{\perp})$ of ϕ -meson [14] and charged kaons [11] in Au+Au collisions at $\sqrt{s_{\text{NN}}} = 200$ GeV, respectively. We generate charged kaons and ϕ mesons with uniform η distributions within $|\eta| < 1.0$.

FIG. 1. The parameterized (a) angular and (b) momentum resolutions of Eq. (3) and Eq. (4), respectively, used in our toy-model simulation.

The kaon p_{\perp} is sampled in $0 < p_{\perp} < 10$ GeV/c according to the Boltzmann distribution with a temperature given by the kinetic freeze-out temperature and then boosted by a common flow velocity. The kinetic freeze-out temperature and flow velocity are taken from Ref. [11] according to the measurements in 40-50% centrality Au+Au collisions at 200 GeV. The kaon v_2 is taken to be $v_2 = 0.06 \times p_{\perp}/\text{GeV}/c$, up to $p_{\perp} = 2$ GeV/c and constant above this p_{\perp} value, according to the charged hadron measurement [15].

For ϕ mesons, p_{\perp} is sampled within $1.2 < p_{\perp} < 5.4$ GeV/c according to a fit to the p_{\perp} spectrum measured in 40-50% centrality Au+Au collisions [14]. The ϕ -meson v_2 is taken to be $v_2 = 0.064 \times p_{\perp}/\text{GeV}/c$, from fit to ϕ -meson 200 GeV data in the 10-40% centrality measured in [14] up to $p_{\perp} = 3$ GeV/c and constant above this p_{\perp} value.

The average multiplicity density for ϕ -mesons is taken to be $dN_{\phi}/dy = 1.44$ as measured in the 40-50% centrality [16]. The kaon multiplicity density $dN_{K^+}/dy = dN_{K^-}/dy = 9.35$ is used and taken to be the average of the measured K^+ and K^- multiplicities [11]. The event-by-event multiplicities are generated by Poisson distributions with twice these averages. The ϕ -meson's rapidity is uniformly sampled within $|y| < 1$, and the kaon pseudorapidity is uniformly sampled within $|\eta| < 1$; Pseudorapidity is used for kaons by choice to conform with data

analysis [8].

We decay the ϕ -mesons into kaons according to the angular distribution of Eq. (1) with an input ρ_{00}^{MC} value. We smear the direction of the momentum vectors of the kaons (both primordial and decay) by Gaussian distributions, with standard deviations according to the parameterization in Eq. (3). We smear the p_{\perp} of the kaons using a Gaussian distribution with standard deviation parameterized according to Eq. (4).

C. Analysis Methods of Spin Alignment

We require the kaon pairs (KK) included in the analysis to have kinematics of $1.2 < p_{\perp, KK} < 5.4$ GeV/ c and $|y_{KK}| < 1.0$ (where the ϕ -meson mass is used in calculating y_{KK}) as in the STAR results [8].

We examine two methods in analyzing ρ_{00} : the yield method and the invariant mass (m_{inv}) method. The yield method is conventional [7, 8]. It analyzes ϕ -meson yield vs. $\cos\theta^*$ and extracts ρ_{00} from a fit over $\cos\theta^*$ bins, as in Eq. (1). To extract the ϕ -meson yield, a mixed-event m_{inv} distribution of K^+K^- pairs is first subtracted from that of real events; this removes the majority of the combinatorial background. The resulting m_{inv} distribution is then fit with a Breit-Wigner (BW) function together with a certain function to model the residual background,

$$\frac{dN_{K^+K^-}}{dm_{\text{inv}}} = \frac{A\Gamma}{(m_{\text{inv}} - m_{\phi})^2 + (\Gamma/2)^2} + \left(\frac{dN_{K^+K^-}}{dm_{\text{inv}}} \right)_{\text{bkg}}, \quad (6)$$

where the BW amplitude A and width Γ are fit parameters, and m_{ϕ} is the mass of the ϕ -meson which can be treated as a fit parameter or fixed (in our analysis it is treated as a fit parameter). In the published STAR data [8] the residual background was assumed to be a first-order polynomial function. The ϕ -meson yield is obtained from the fit BW function. If the combinatorial background was precisely known and the ϕ -meson signal shape is precisely BW, then the ϕ -meson yield can be reliably obtained in each $\cos\theta^*$ bin and the ρ_{00} be reliably extracted. A major systematic uncertainty in such analyses is the background modeling in each $\cos\theta^*$ bin, and several other functional forms are assessed for the systematic uncertainty. Another systematic uncertainty comes from the BW assumption for the signal shape. This systematic uncertainty is not straightforward to assess, but may be important.

The invariant mass method is newly developed. The idea is not new; similar methods have been used in hyperon polarization analysis and in anisotropic flow analysis of resonances. First, the $\cos\theta^*$ -inclusive m_{inv} distribution is fit by BW and a background function, typically polynomial, and the ϕ -meson signal-to-background ratio, $r(m_{\text{inv}})$, is obtained from the fit [17]. The $r(m_{\text{inv}})$ is then

used to fit a profile of the $\langle \cos^2\theta^* \rangle$ vs. m_{inv} by

$$\langle \cos^2\theta^* \rangle = \frac{r(m_{\text{inv}})(5\rho_{00} - 1)/2 + \langle \cos^2\theta^* \rangle_{\text{bkg}}}{r(m_{\text{inv}}} + 1}, \quad (7)$$

to extract the spin alignment ρ_{00} parameter. In Eq. (7) we have converted $\langle \cos^2\theta^* \rangle$ of the ϕ -meson decay Eq. (1) into ρ_{00} , $\langle \cos^2\theta^* \rangle = \frac{5}{2}(\rho_{00} - \frac{1}{3}) + \frac{1}{3}$, so ρ_{00} can be directly extracted from the fit. This method is expected to be less vulnerable than the yield method because it does not have to fit the signal and background of the m_{inv} distributions of several $\cos\theta^*$ bins, but only the inclusive m_{inv} distribution and the fit of $\langle \cos^2\theta^* \rangle$ vs. m_{inv} . The latter fit involves modeling the background $\langle \cos^2\theta^* \rangle_{\text{bkg}}$ as a function of m_{inv} , which depends on the kinematics of the background kaons. We use a first-order polynomial in m_{inv} for the background $\langle \cos^2\theta^* \rangle_{\text{bkg}}$.

The details of these two analysis methods will become clearer along the way when we present the results of our study. Angular and momentum resolutions can affect both methods in non-trivial ways, and this will also become clearer when we discuss their effects on the results.

III. SIMULATION RESULTS

A. Pure ϕ -meson Case

We first examine the impact of track resolutions on the reconstructed $\langle \cos^2\theta^* \rangle$ of the real ϕ -mesons (without including combinatorial background) as a function of m_{inv} . The input of ϕ -meson is given as $\rho_{00} = 1/3$ (that is, without spin alignment). Figure 2(a) shows the m_{inv} distributions of the ϕ -mesons before (black) and after (red) angular and momentum smearing. The curves are BW fits. As expected, the smeared case has a lower amplitude, larger width, and worse χ^2 goodness of fit for a pure BW signal, relative to the one before smearing. In other words, the signal is no longer a BW function, and this will be discussed further below. Figure 2(b) is the ϕ -meson $\langle \cos^2\theta^* \rangle$ vs. m_{inv} for the unsmeared (black) and smeared case (red). Without smearing, we see roughly uniform $\langle \cos^2\theta^* \rangle$ vs. m_{inv} ; with smearing, we see distortion near the ϕ -meson mass—there is a considerable peak at m_{ϕ} and dips at lower and higher m_{inv} . An example constant fit is shown in Fig. 2(b) demonstrating that the weighted average $\langle \cos^2\theta^* \rangle$ over the ϕ -meson mass region recovers the input $\rho_{00} = 1/3$, or $\langle \cos^2\theta^* \rangle = 1/3$, despite the momentum and angular smearing.

Figure 3 shows the individual effects of the θ and ϕ resolutions and the momentum resolution. The angular smearing has a much larger effect than the smearing in transverse momentum. A $\langle \cos^2\theta^* \rangle$ peaked region means that the large $\cos^2\theta^*$ bins have more KK pairs than its fair share, and the dipped region means the opposite. Therefore, the center-dipped and side-peaked $\langle \cos^2\theta^* \rangle$ vs. m_{inv} distribution from the ϕ -angle smearing implies that the m_{inv} distributions of the ϕ -mesons

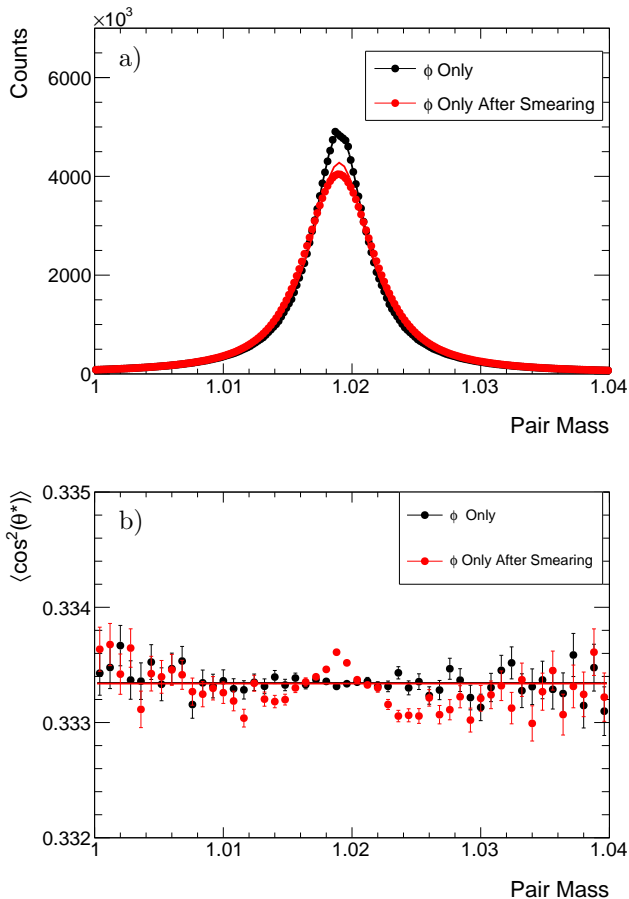

FIG. 2. (Color online) Resolution effects on true ϕ -mesons in the invariant mass method. (a) ϕ -meson m_{inv} distributions, and (b) $\langle \cos^2 \theta^* \rangle$ as a function m_{inv} , before (black markers) and after (red markers) angular and momentum smearing by Eqs. (3–5). Only those real ϕ -mesons (no combinatorial K^+K^- pairs) are used in these plots and the input $\rho_{00} = 1/3$. The BW fits by Eq. (6) (with no background) are superimposed on (a); The horizontal lines in (b) are constant fit to the data points of corresponding color.

are broadened from small to large $\cos^2 \theta^*$ bins. The opposite behavior from the θ -angle smearing implies that the ϕ -meson m_{inv} distributions are narrowed from small to large $\cos^2 \theta^*$ bins. These opposite behaviors are presumably due to non-trivial interplays of the different Jacobians involving the θ and ϕ angles and the kinematic boost to the pair rest frame. Note that we have used the same resolution parameters as in Eq. (5) for the smearing of the angles θ and ϕ . The opposite effects of polar- and azimuthal-angle smearing largely cancel each other out. Asymmetric polar- and azimuthal-angle resolutions would make the overall effect larger.

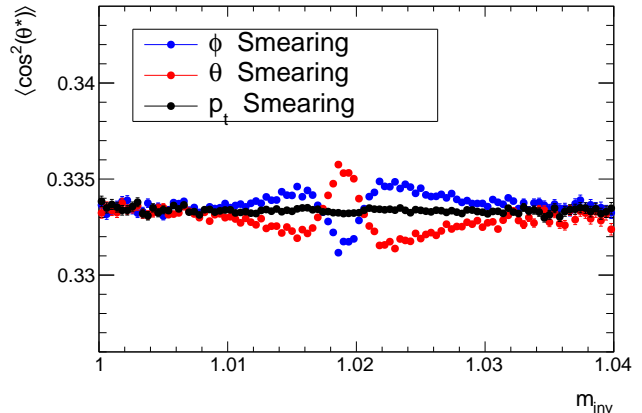

FIG. 3. (Color online) Effects of smearing for θ (red markers), ϕ (blue markers), and p_{\perp} (black markers), separately, on $\langle \cos^2 \theta^* \rangle$ for true ϕ -mesons. The effect of momentum smearing is insignificant compared to those of angular smearing. Equal θ - and ϕ -angle resolutions are used as in Eq. (5).

B. ϕ -meson with Combinatorial Background

We now perform a “data-like” analysis with the m_{inv} method and the yield method with input $\rho_{00} = 1/3$.

Figure 4 shows the K^+K^- pair m_{inv} distribution in the upper panel and the $\langle \cos^2 \theta^* \rangle$ vs. m_{inv} in the lower panel, similar to Fig. 2 but including a combinatorial background. The unsmeared data are shown in black, and the smeared data are shown in red. We see that angular and momentum smearing broadens the decay mass distribution in Fig. 4(a). Unlike the uniform distribution of $\langle \cos^2 \theta^* \rangle$ for the unsmeared pure ϕ -meson case in Fig. 2(b), the $\langle \cos^2 \theta^* \rangle$ distribution for the realistic case in Fig. 4(b) before smearing is peaked atop a decreasing pedestal. The pedestal is from the background KK pairs and their $\langle \cos^2 \theta^* \rangle$ is not $1/3$, dictated by the single kaon kinematic distributions. The ϕ -mesons with $\rho_{00} = 1/3$, therefore, appear as a peak in the plot in Fig. 4(b). The $\langle \cos^2 \theta^* \rangle$ vs. m_{inv} for the smeared case is similar, with subtle differences from the unsmeared case. For illustration, we fit the m_{inv} distributions in Fig. 4(a) with a BW function for the ϕ -meson signal and a linear function for the combinatorial background; We obtain the signal-to-background ratio from the fit. We then fit the $\langle \cos^2 \theta^* \rangle$ vs. m_{inv} plot in Fig. 4(b) with Eq. (7) with the background function also being linear in m_{inv} . We choose a linear function for the background in both fits, which is a good approximation within our limited fit range of $1 < m_{\text{inv}} < 1.04$ GeV/ c^2 . One could open up the fit range and use more elaborate functions to study background systematics; however, this is outside the scope of the present study.

Next, we perform an example yield method ρ_{00} extraction. For each $\cos^2 \theta^*$ bin, we take the real event m_{inv} distribution of K^+K^- pairs and subtract a “mixed event”

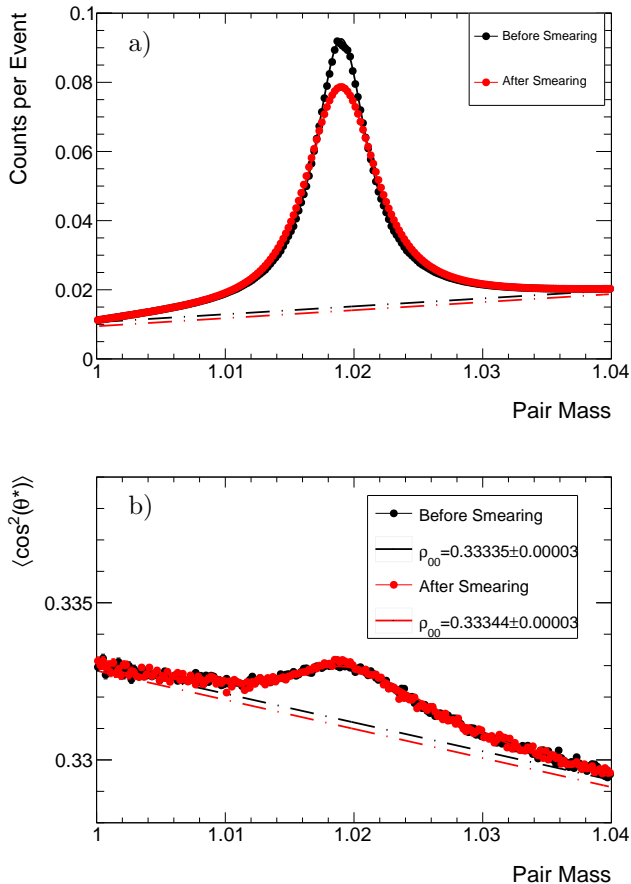

FIG. 4. (Color online) Resolution effects in the invariant mass method. (a) K^+K^- m_{inv} distributions, and (b) $\langle \cos^2 \theta^* \rangle$ as a function m_{inv} , before (black markers) and after (red markers) angular and momentum smearing by Eqs. (3–5). The kinematics of the ϕ -mesons and the background kaons, including v_2 , are taken from Refs. [11, 18] according to the 40–50% centrality Au+Au collisions. The input ϕ -meson $\rho_{00} = 1/3$. The BW and linear background fits by Eq. (6) are superimposed on (a); The fits in (b) are by Eq. (7) with a linear background.

background. We then fit the resulting m_{inv} distribution with a BW signal and a linear residual background, Eq. (6), to extract the yield in each $\cos \theta^*$ bin. In this case, we use a fixed BW width Γ in each bin, where this width is obtained from fitting the $\cos \theta^*$ -inclusive pair distribution by Eq. (6). Alternatively, the BW width can be allowed to vary from bin to bin, which we examine later. Regardless of how the yields are extracted ρ_{00} is obtained from a fit to these yields using Eq. (1). Figure 5 shows the extracted ϕ -meson yield as a function of $|\cos \theta^*|$ for the unsmeared (black) and smeared (red) data, superimposed by the fit curves of Eq. (1). The unsmeared data are consistent with $\rho_{00} = 1/3$, while the smeared data show a slight increase in the yield with $|\cos \theta^*|$, thus a ρ_{00} larger than $1/3$.

Our toy-model simulations demonstrate an effect of track resolutions on ρ_{00} . Such an effect can be experimen-

FIG. 5. (Color online) Yield vs. $|\cos \theta^*|$ bin. The ϕ -meson yield is obtained from fitting to the mixed-event subtracted m_{inv} distributions by Eq. (6) with a linear residual background; the BW width is fixed to that obtained from the fit to the $\cos \theta^*$ -inclusive data for demonstration purpose. Simulated data before and after tracking smearing are shown in black and red markers, respectively.

tally verified by comparing tracks of differing qualities. For example, in the STAR experiment, tracks are reconstructed from TPC hits (called global tracks), and then refitted by including the primary vertex position (called primary tracks). Primary tracks are more precise than global tracks; the differences in their track parameters can be considered as reflections of tracking resolutions. It would be interesting to compare the ρ_{00} values measured with global tracks and with primary tracks.

C. Strategy to Extract ϕ -meson ρ_{00}

As we have seen in the previous subsections, the angular and momentum smearing can distort the $\langle \cos^2 \theta^* \rangle$ vs. m_{inv} shape in non-trivial ways. These complicated behaviors are presumably caused by the interplay of many factors, each of which is affected by resolution smearing. These factors include the m_{inv} calculated from smeared K^+K^- pairs, the boost to the rest frame of the smeared pair, and the fact that θ^* is defined as the angle of a daughter in the pair rest frame with respect to the OAM direction in the lab frame (perpendicular to the reaction plane).

As mentioned above, the $\langle \cos^2 \theta^* \rangle$ peak at the ϕ -meson central mass value, such as that in Fig. 2(b), means that relatively more particles are found at the ϕ -meson mass position in large $\cos^2 \theta^*$ bins. This in turn means that the large $\cos^2 \theta^*$ bins will have a narrower m_{inv} peak than the small $\cos^2 \theta^*$ bins. In other words, the m_{inv} peak width decreases with increasing $\cos^2 \theta^*$. This shuffling of K^+K^- pairs across $\cos^2 \theta^*$ bins and across m_{inv} bins also renders that the signal shape is no longer BW. The extraction of ρ_{00} with the assumed BW signal is there-

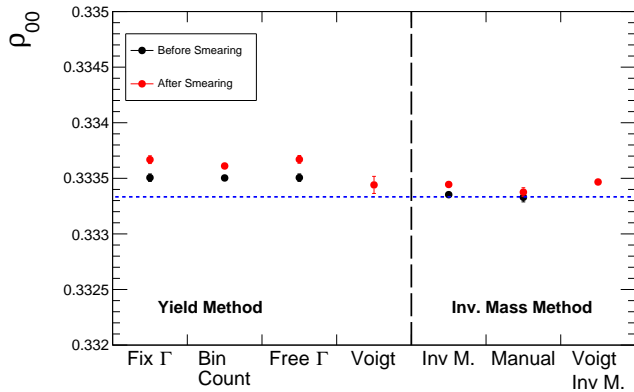

FIG. 6. (Color online) Extracted ρ_{00} by various methods from simulation data before (black markers) and after (red markers) track smearing. The methods used are from left to right: the yield method by Breit-Wigner fit of Eq. (6) with fixed width (fit yield and bin counting within twice widths both sides), by Breit-Wigner fit with free width, and by Voigt fit with free width; the invariant mass method by Breit-Wigner fit of Eq. (6) and then a fit to $\langle \cos^2 \theta^* \rangle$ vs. m_{inv} by Eq. (7), by manual calculation (bin counting) subtracting the fitted backgrounds, and by Voigt fit and then the $\langle \cos^2 \theta^* \rangle$ fit of Eq. (7). See text for details.

fore questionable. Furthermore, the width is often fixed across all $\cos^2 \theta^*$ bins in order to have better controlled systematics. However, resolution smearing narrows the mass peak with increasing $\cos^2 \theta^*$; This makes the extracted yields more questionable.

Figure 6 shows the extracted ρ_{00} in Section III B assuming the BW function for the ϕ -meson signal (with both fixed and varying widths) and a linear function for the residual combinatorial background. We also show the ρ_{00} value obtained with yields from bin counting within a mass range of $\pm 2\Gamma$ about the peak mass from the fixed-width fit. The extracted ρ_{00} without resolution smearing (black points) is slightly above the input value of $1/3$, presumably because of systematics in the yield extraction, e.g., the imperfect linear background assumption. The extracted ρ_{00} values with resolution smearing (red points) differ from those without, indicating the effect of track resolutions on ρ_{00} . However, the effect is small, less than 0.0005 , well within the typical experimental uncertainties of the order of 0.001 [8]. We note, as mentioned in Sect. III A, that we used the same angular resolution for polar and azimuthal angles and unequal resolutions between them would likely increase the effect of resolution smearing on ρ_{00} .

We may improve the yield method in several ways. For example, after momentum smearing, the signal peak is no longer BW and may be better modeled by the Voigt function (a convolution of BW with Gaussian mass res-

olution). The slight difference in the extraction of the yield from a Voigt function compared to the BW across $\cos \theta^*$ bins can have an effect on the extracted ρ_{00} , as shown in Fig. 6.

In the invariant mass method, we fit the m_{inv} histogram within $1.0 < m_{\text{inv}} < 1.04$ GeV/ c^2 using BW and a linear background function to extract the signal-to-noise ratio, and then fit the $\langle \cos^2 \theta^* \rangle$ vs. m_{inv} using the signal-to-noise ratio and a linear $\langle \cos^2 \theta^* \rangle_{\text{bkg}}$ function. The results are shown in Fig. 6. The effect of track smearing in the invariant mass method is similar to that in the yield method. We can improve the extraction of the signal-to-noise ratio by fitting the m_{inv} histogram using a Voigt signal function. The ρ_{00} using the new signal-to-noise ratio is also shown in Fig. 6; no significant change is observed.

Lastly, due to the shuffle of pairs across $\cos \theta^*$ bins and across m_{inv} bins, the ρ_{00} quantity is no longer a constant over m_{inv} for the signal ϕ -mesons. The ρ_{00} value, treated as a fit parameter and extracted from fitting to Eq. (7), may be biased. To circumvent this, we calculate ρ_{00} “by hand,” analogous to bin counting. To do this, we multiply the pair count by $\langle \cos^2 \theta^* \rangle$ for each bin of m_{inv} within $[1.01, 1.03]$ GeV/ c^2 , subtract the corresponding background quantity, and divide by the total number of signal pairs. The background pair count and the background $\langle \cos^2 \theta^* \rangle_{\text{bkg}}$ are obtained from respective fits by Eq. (6) and Eq. (7) as before. The obtained signal $\langle \cos^2 \theta^* \rangle$ can be readily converted to ρ_{00} . This “manual” (bin count) calculation of ρ_{00} does not use a signal shape and is therefore not affected by the distortion of the signal shape caused by the momentum and angular smearing. The results are shown in Fig. 6. Again, no qualitative differences are observed from all other methods, presumably because the track-smearing effect is small.

IV. SUMMARY

In this work we have investigated the effect of tracking resolutions on ϕ -meson spin alignment by toy-model simulations. We examine the yield method and the invariant mass method in extracting the spin alignment observable ρ_{00} . Using typical values of tracking angular and momentum resolutions (see Eq. (5)), we find the effects on the extracted ρ_{00} from both methods to be small (< 0.0005), well within typical experimental uncertainties (~ 0.001) on the measured ρ_{00} .

- [17] One can also subtract the mixed-event background first, and then do a fit with BW and a residual background to obtain the signal-to-noise ratio with the subtracted mixed-event background added back. Since the purpose of this fit is to obtain the signal-to-noise ratio of ϕ -meson, not the yield vs. $\cos \theta^*$ as in the yield method, the different ways of fit do not cause significant systematics.
