Abstract

T, p flash calculations determine the correct number of phases at phase equilibrium and their compositions for fixed temperature and pressure. They are essential for chemical process simulation and optimization. The convex envelope method (CEM) is an existing approach that employs the tangent plane criterion to determine liquid phase equilibria for chemical systems with an arbitrary number of components without providing the number of phases beforehand. This work extends the CEM to include also vapor and solid phases. Thus, any phase equilibrium of a given system with an arbitrary number of components and phases can be calculated over the whole composition space. The CEM results are presented for various vapor-liquid and solid-liquid phase equilibria examples of up to four components. We show how the CEM can be used for parameter fitting of g^E -models. As an outlook, we demonstrate how the CEM can be combined with a machine learning-based tool for property prediction to construct phase equilibria.

Keywords: Vapor-Liquid Equilibrium, Liquid-Liquid Equilibrium,

1. Introduction

T, p flash calculations are important in practice to determine all types of phase equilibria (Lucia et al., 2000). Calculation of phase equilibria, in turn, is crucial for chemical process simulation and optimization (Zhang et al., 2011).

Generally, the numerical calculation of phase equilibria is an optimization problem. For a T, p flash (i.e., the calculation of the phase equilibrium at constant temperature and pressure) the Gibbs free energy G of the system has to be minimized (Gibbs, 1873, 1876). Thus, a pre-requisite to do a T, p flash is a thermodynamic model of G or other potentials from which it can be derived. There are two main approaches for the respective thermodynamic models: equations of state such as Peng-Robinson (Peng and Robinson, 1976), Redlich–Kwong-Soave (Soave, 1972), SAFT (Chapman et al., 1989), or g^E models such NRTL and UNIQUAC (Prausnitz et al., 1999). While there are also hybrids and others, it is beyond the scope of the present work to dive into this. We will simply assume that such thermodynamic models are given. The calculations of the T, p flash are greatly simplified, if the type of coexisting phases in equilibrium are known. In this case, the solution of the minimization problem can be transformed into an algebraic equation problem, resulting in well known equations such as the (extended) Raoult’s law for the vapor-liquid equilibrium (VLE) or the iso-activity criterion for the liquid-liquid equilibrium (LLE). In the present work, we will consider however the general case, in which the type and number of phases is

not known *a priori* and the general optimization problem has to be solved.

We classify the approaches to solve the general optimization problem into two classes. On the one hand, there are mathematical programming approaches which are either deterministic (e.g., (Mitsos and Barton, 2007; Pereira et al., 2010; Perevoshchikova et al., 2012; Wasylkiewicz et al., 2013)) or stochastic (e.g., (Bonilla-Petriciolet et al., 2011)). For a more thorough review of such optimization algorithms for phase equilibrium we refer to (Zhang et al., 2011; Piro and Simunovic, 2016; Domanska, 2019). Such algorithms are in principle fallible and require good initial guesses to improve the success rate.

On the other hand, there are geometrically motivated approaches which find stable phases based on tangents (or more generally convex hulls in case of higher dimensions), on the G state surface (or graph of G) in the composition space, resulting in the tangent plane criterion (Baker et al., 1982). Examples for such approaches are given in (Sorensen et al., 1979; Swank and Mullins, 1986; Teh and Rangaiah, 2002).

Building on the tangent plane criterion (Baker et al., 1982), there are plenty approaches based on the convex envelope method (CEM) (Ryll, 2009; Ryll et al., 2012; Göttl et al., 2023), which is sometimes also referred to as the method of the convex hull (Lee et al., 1992; Hildebrandt and Glasser, 1994; Joseph et al., 2017). In the CEM, the graph of the Gibbs free energy G is computed for the whole discretized composition space of a given chemical system. By constructing the convex envelope (or convex hull) for this graph and employing the tangent plane criterion (Baker et al., 1982), an approximation (due to the discretization) of the phase equilibrium dia-

gram can be stored in a piecewise linear representation. Afterwards, T,p flash calculations can be done for any given feed composition. The CEM is a robust method for determining phase equilibria with an arbitrary number of phases, i.e., the number of phases is determined by the CEM. This concept has been employed in several works in the past for the calculation of binary and ternary VLE (Hildebrandt and Glasser, 1994; Afanasyev, 2012; Joseph et al., 2017). It was also shown that it is possible to calculate binary and ternary solid-liquid equilibria (SLEs) using the convex hull method (Lee et al., 1992). In (Ryll, 2009; Ryll et al., 2012), the CEM was shown to work for liquid phase equilibria for chemical systems with up to four components. A graphical evaluation scheme was implemented that distinguishes several cases for the number of existing phases and makes the decision on a case-by-case basis. This work was continued in (Göttl et al., 2023), where a general mathematical framework was provided that allows the application of the CEM to chemical systems with an arbitrary number of components and an arbitrary number of phases for liquid phase equilibria.

Recently, machine learning (ML) approaches, which treat the underlying thermodynamics as a black box, have gained attention for modeling of phase equilibria. For instance, in (Kunde et al., 2019), a support vector machine is employed to develop a surrogate model for LLEs. An artificial neural network is applied in (Sun et al., 2023) to predict binary VLEs. In (Mao et al., 2019), Flory-Huggins interaction theory was combined with elements from the CEM and ML. A convex hull is constructed around the Flory-Huggins free energy density to calculate LLEs for systems with up to five components. Here, the simplices within the convex hull are classified using the spectrum of

the Laplacian of the underlying adjacency matrices. The authors include a approach based on principal component analysis and clustering methods to determine the number of coexisting phases and a Cahn-Hilliard approach to model the separation kinetics. For a more comprehensive overview of surrogate models in chemical process engineering and ML approaches for phase equilibrium calculations, we refer to respective reviews (McBride and Sundmacher, 2019; Arroyave, 2022).

The present work extends the mathematical framework for the CEM that was provided in (Göttl et al., 2023). This allows to simultaneously include all possible phase equilibria between the aggregate states solid, liquid, and gaseous. Given a chemical system at pressure p and temperature T , the framework takes as input the thermodynamic model of G as a function of the composition for all conceivable phases. As output, our framework computes the resulting phase equilibria, i.e., for any given feed composition, it is determined if and which phase equilibrium is present (e.g., VLE, VLLE, LLE, SLE). The number of phases, their aggregate state, and their composition are also calculated. From a mathematical viewpoint, our method works with systems with an arbitrary number of components and an arbitrary number of phases. We show the capabilities of our framework with various VLE and SLE examples from the literature with up to four components. We publish the code used to generate all the results shown in this work. Furthermore, we show how the CEM can be utilized to fit g^E -model parameters. As an outlook on further usage of the CEM, we combine it with the HANNA-model (Specht et al., 2024), a machine learning model that predicts binary activity coefficients from SMILES-strings. Combining the CEM

with the HANNA-model, we constructed a complete T, x, y -diagram for a binary, heteroazeotropic mixture, ranging from SLE, over LLE, over VLLE, to VLE.

2. Methodology

2.1. General Idea of the CEM

The idea of the CEM (Ryll, 2009; Ryll et al., 2012; Göttl et al., 2023) for liquid phases is illustrated in Figure 1 a), where the Gibbs energy of mixing for a binary liquid mixture is computed across the entire discretized composition space, represented by blue squares in Figure 1 a). The convex envelope is then constructed around the graph to identify phase splits. Phase splits occur where the convex envelope connects points that are not direct neighbors in the discretization, as depicted in Figure 1 a) by the black dashed line (same procedure as described in (Göttl et al., 2023)). Here, one phase split is observed.

To include more aggregate states, the Gibbs energy of mixing for liquid, vapor (pink circles), and solid phases (green triangles) is computed, resulting in one graph for each investigated aggregate state. Convex envelopes are constructed for the combined graphs, as shown in Figure 1 b), c), and d). For systems with multiple aggregate states, phase splits occur in two types. The first type is the same as explained above. In the second type, a phase split is identified when two points connected by the convex envelope belong to different aggregate states, as the aggregate state of a point is determined by the minimum value among the three Gibbs energy of mixing graphs. Examples of this type are shown in Figure 1 b), c), and d) where one phase

split (black dashed line) between distinct aggregate states is identified, respectively. In Figure 1 a), b), and c), the Gibbs energy of mixing of some aggregate states were omitted for the sake of illustration, since they were not relevant for the construction of the convex envelope (similarly as the graph of the Gibbs energy of mixing of the solid aggregate state shown in Figure 1 d)).

2.2. CEM Workflow

The workflow of the extended CEM is adopted from (Ryll, 2009; Ryll et al., 2012; Göttl et al., 2023) and follows the same major steps as introduced in (Göttl et al., 2023), with modifications to accommodate the inclusion of vapor and solid aggregate states. In the following, the four steps of the CEM are introduced with a special focus on the modifications. For details of the steps, we refer to (Göttl et al., 2023).

Step I) **Discretization of the composition space**

The discretization is done in the same way as described in (Göttl et al., 2023). The composition space of an arbitrary chemical system containing N components can be represented by a simplex with N vertices. To discretize this composition space, we specify the distance $1/\delta$, $\delta \in \mathbb{N}$ between neighboring points. Following this procedure for a simple, binary example system ($N = 2$) with $\delta = 2$, we would obtain the following discretization (the elements of the set are the molar fractions of the points in the discretization): $\mathcal{D} = \{(1.0, 0.0), (0.5, 0.5), (0.0, 1.0)\}$.

Step II) **Determination of the Gibbs free energy graphs and the convex envelope**

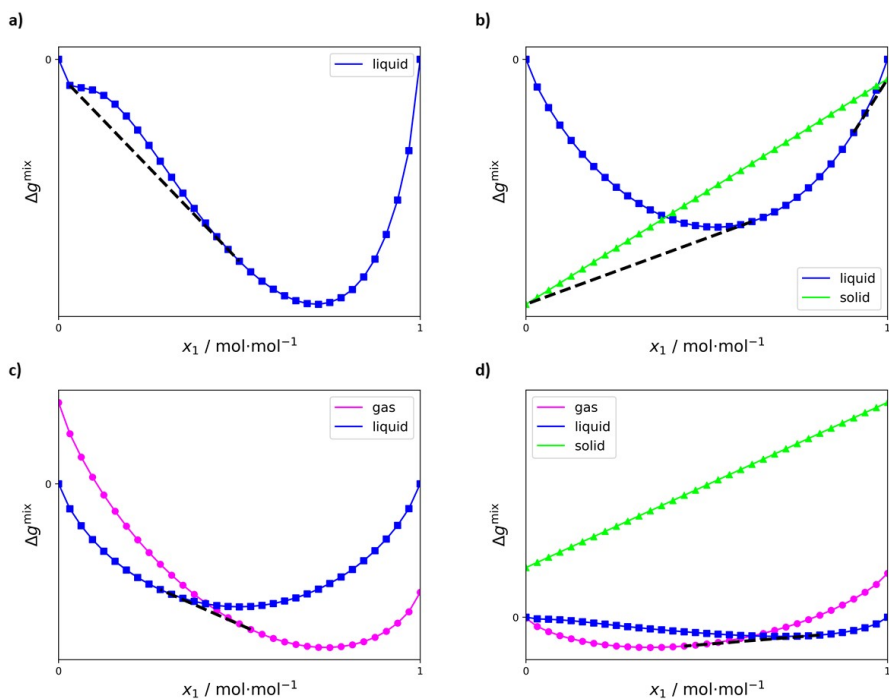

Figure 1: The concept of the convex envelope method is illustrated for an LLE in a), a SLE in b), a VLE in c), and d). The Gibbs energy of mixing is computed for the respective phases, and the convex envelope is constructed for the (combined) graphs to identify phase splits (black dashed line). Blue squares indicate liquid, green triangles solid and pink circles vapor phases. In a), b), and c), the Gibbs energy of mixing graphs of some aggregate states were omitted, since they were not relevant for the construction of the convex envelope (similarly as the Gibbs energy of mixing graph of the solid aggregate state shown in d))

In the present work, we focus on T, p flash calculations and thus the minimization of the Gibbs free energy G . Note that for other boundary conditions other potentials (e.g., Helmholtz free energy A for T, V flash calculations) can be used analogously.

Our method requires that we can calculate the molar Gibbs free energy g for any composition \boldsymbol{x} of any conceivable aggregate phase at given temperature T and pressure p : $g = g(T, p, \boldsymbol{x})$. For illustration purposes, we chose a commonly used approach based on g^E models. Independent of considered phase J , we use pure liquids at T and p as a reference state ("Raoult"):

$$g(T, p, \boldsymbol{x}) = \sum_{i=1}^N x_i g_i^{\text{pure liquid}}(T, p) + \Delta g^{\text{mix}, J}(T, p, \boldsymbol{x}). \quad (1)$$

The sum term of reference states is constant and can thus be omitted for the minimization of Gibbs free energy (Ryll, 2009; Ryll et al., 2012). The mixture term $\Delta g^{\text{mix}, J}$ contains changes of g related to ideal and non-ideal mixing as well as changes related to phase change if J is not a liquid phase. Under typical assumptions (ideal vapor phase, negligible pressure dependence of non-gaseous properties), one arrives at the following expressions for the liquid and vapor phase (Rowlinson and Swinton, 1982; Olaya et al., 2010):

$$\Delta g^{\text{mix, liquid}}(T, p, \boldsymbol{x}) = \mathcal{R}T \sum_{i=1}^N x_i \ln(x_i \gamma_i), \quad (2)$$

$$\Delta g^{\text{mix, vapor}}(T, p, \boldsymbol{x}) = \mathcal{R}T \sum_{i=1}^N x_i (\ln(x_i) + \ln(\frac{p}{p_i^*})). \quad (3)$$

For the solid phase, we assume that the difference between c_p for liquid and solid can be neglected. Additionally, in this work, we only consider systems where a pure component can form a solid phase. $\Delta g^{\text{mix,solid}}$ for such a phase consisting only of component i is given by (Reyes et al., 2001):

$$\Delta g^{\text{mix,solid}}(T, p) = \frac{T \Delta h_i^f}{T_i^m} \left(1 - \frac{T_i^m}{T}\right). \quad (4)$$

This expression is only defined for pure components, e.g., for $\mathbf{x} = (1.0, 0.0)$ and $\mathbf{x} = (0.0, 1.0)$ in a binary system. As discussed above, we need an expression for $\Delta g^{\text{mix,solid}}$ that is defined everywhere in the whole composition space. To achieve this, we will use the following expression, which is linear in x_i , as can also be seen in Figure 1 b) and d):

$$\Delta g^{\text{mix,solid}}(T, p, \mathbf{x}) = \mathcal{R}T \sum_{i=1}^N x_i \frac{\Delta h_i^f}{\mathcal{R}T_i^m} \left(1 - \frac{T_i^m}{T}\right). \quad (5)$$

The linearity in x_i ensures that the construction of the convex envelope allows solid phases only at the locations of the pure components inside the composition space, e.g., as shown in Figure 1 b).

In Equations 2 - 5, \mathcal{R} is the ideal gas constant, γ_i is the activity coefficient, T_i^m is the melting temperature, h_i^f is the melting heat in J/mol, and p_i^* is the vapor pressure of component i . Note that our method also works for more complex thermodynamics, e.g., non-ideal vapor phases or solid complexes as long as $g = g(T, p, \mathbf{x})$ can be calculated.

For every point in the discretization \mathcal{D} , we compute the Gibbs energy of mixing Δg^{mix} for the liquid, gaseous, and solid aggregate states according to Equations 2, 3, and 5.

Combining these three graphs yields a plot as for example shown in Figure 1 d). The molar fractions \boldsymbol{x} are transformed to cartesian coordinates $\boldsymbol{a} \in \mathbb{R}^n$, $n = N - 1$ (for details on this transformation, we refer to (Göttl et al., 2023)). The transformed molar fractions are combined with the obtained values for Δg^{mix} to obtain the following graph:

$$\mathcal{G} = \{(\boldsymbol{a}, \Delta g^{\text{mix},s}(\boldsymbol{x})) | \boldsymbol{x} \in \mathcal{D}, s \in \{\text{solid, liquid, vapor}\}\} \subseteq \mathbb{R}^{n+1}.$$

Subsequently, the convex envelope is constructed around the elements of the graph \mathcal{G} .

Step III) **Classification of the simplices of the convex envelope**

The convex envelope constructed in Step II) consists of several simplices, each corresponding to structures of different dimensions depending on the number of components in the chemical system. In binary systems, for example, these simplices are straight line segments; for ternary systems, they are triangles; for quaternary systems, they are tetrahedra; and so on. Each simplex within the convex envelope must be examined to determine whether it represents a phase split by a linearized model.

As described in (Göttl et al., 2023), this examination consists of two distinct checks for each simplex. The first check involves determining whether the simplex contains at least one heterogeneous line segment. A heterogeneous line segment is defined as a straight line connecting two points with different phases. In (Göttl et al., 2023), a line segment was classified as heterogeneous if it connects two points that are not neighboring inside the discretization, e.g., as visualized in Figure 1 a):

the black dashed line is a heterogeneous line segment (and also a simplex of the convex envelope since $N = 2$ for this example), since it is part of the convex envelope and connects two points that are not neighboring inside the discretization. In this work, we additionally classify also line segments as heterogeneous that connect points with different aggregate states, e.g., the black dashed line in Figure 1 c) that connects a point from the liquid and a point from the vapor phase. If the simplex contains at least one such a line segment, it is called a heterogeneous simplex and the second check of the procedure is initiated.

In the second check, it is evaluated if the simplex models a unique phase split in a linearized phase separator model. As mentioned in (Ryll, 2009; Göttl et al., 2023), simplices that fail the second check occur rarely and only at the boundary of the multiphase regions, e.g., close to the critical point. Usually, they nearly vanish, when enough points within the discretization are specified. The second check follows the exact same procedure as outlined in (Göttl et al., 2023) and is therefore omitted here.

The simplices that fulfill both criteria are called feasible, heterogeneous simplices.

Steps I)-III) have to be executed to yield the phase equilibrium for the given chemical system at specified T and p . To store the phase equilibrium, it is sufficient to store the feasible, heterogeneous simplices that model a phase split found in Step III).

Step IV) **Computation of phase splits**

For any given feed composition, one has to check if the feed lies within one of the feasible, heterogeneous simplices that model a phase split (from Step III)). If such a simplex is found, the resulting phase split can be calculated in the same way as described in (Göttl et al., 2023).

2.3. g^E -model parameter fitting using the CEM

This section describes how the CEM can be used for fitting parameters of a g^E -model to given experimental data. The method is explained alongside the NRTL model (Prausnitz et al., 1999), but can also be applied to other models.

According to the NRTL model, the activity coefficient γ_i of component i is defined as:

$$\ln \gamma_i = \frac{\sum_{j=1}^N \tau_{ji} G_{ji} x_j}{\sum_{l=1}^N G_{li} x_l} + \sum_{j=1}^N \frac{x_j G_{ij}}{\sum_{l=1}^N G_{lj} x_l} \left(\tau_{ij} - \frac{\sum_{r=1}^N x_r \tau_{rj} G_{rj}}{\sum_{l=1}^N G_{lj} x_l} \right). \quad (6)$$

In Equation 6, the interactions between components i and j are defined by (we assume for the non-randomness parameter $\alpha_{ij} = \alpha_{ji} = \alpha$):

$$\tau_{ij} = \frac{A_{ij}}{RT}, \quad (7)$$

$$G_{ij} = \exp(-\alpha \tau_{ij}). \quad (8)$$

We consider a binary chemical system and a set of experimental data points \mathcal{E} that describe the respective phase equilibrium. An optimization procedure that searches for parameters (A_{12}, A_{21}, α) is defined with respect to the following criteria (in case of a system with N components, one searches (A_{ij}, A_{ji}, α) for every binary subsystem (i, j)):

1. For every data point in \mathcal{E} (i.e., p , T , molar fractions of the feed, molar fractions and aggregate states of the respective phases at equilibrium),

the CEM calculates the correct number of phases and the respective correct aggregate states.

2. The mean deviation (MD) of the calculated molar fractions for all data points $\mathcal{T} \subseteq \mathcal{E}$ that fulfill the first criterion is minimal:

$$\min_{(A_{12}, A_{21}, \alpha)} \sum_{t \in \mathcal{T}} \sum_{\text{phases } p \text{ in } t} \|\mathbf{x}_p^{\text{exp}} - \mathbf{x}_p^{\text{CEM}}\|_1. \quad (9)$$

Herein, $\|\cdot\|_1$ is the l^1 -norm (i.e., the sum of absolute values of the vector entries).

One possible approach to handle those criteria is to interpret the first criterion as a discrete constraint (it is either fulfilled or not fulfilled) and to apply some gradient-based optimization approach to find the minimum in Equation 9. Since such approaches usually require an initial solution that already fulfills the constraint (which we do not have at hand), we will define an alternative optimization approach as described in the following.

We will utilize a genetic algorithm based on differential evolution (Das and Suganthan, 2011) that works as follows (for the details, we refer to our implementation and to (Das and Suganthan, 2011)):

1. A random population of solutions is initialized (every solution is of the form (A_{12}, A_{21}, α)).
2. For a fixed number of generations, the current population is used to generate new candidate solutions using differential evolution (Das and Suganthan, 2011). The candidate solutions are compared to randomly chosen members of the population and replace those if they are superior.

3. The best solution is returned.

This procedure only requires a comparison-function as input that decides for two given solutions which solution is superior (for the second step, when the candidate solutions are pitched against the population members). We define this function as follows for two given solutions $S_1 = (A_{12}^1, A_{21}^1, \alpha^1)$ and $S_2 = (A_{12}^2, A_{21}^2, \alpha^2)$ as a 2-step comparison with respect to the previously defined criteria:

1. For both solutions, S_1 and S_2 , it is compared for how many points contained in \mathcal{E} the CEM calculates the correct number of phases and the respective correct aggregate states. If one solution is superior to the other with respect to that criterion, this solution is rated as the better solution and returned. If for both solutions the CEM calculates the correct number of phases and the respective correct aggregate states for the same number of points in \mathcal{E} , the solutions are also compared regarding the second criterion.
2. Both solutions are compared with respect to Equation 9. The solution with the lower value is returned as the better solution.

Using this comparison function in combination with the genetic algorithm based on differential evolution (Das and Suganthan, 2011), we can find solutions that provide a good prediction score for most of the available experimental data points. As will be shown in Section 3.3, the found parameter sets yield similar results as the provided parameter sets from the literature.

2.4. Implementation

The whole framework was implemented with the programming language Python (version 3.11.7). The convex envelope is found by usage of the QuickHull-algorithm (Barber et al., 1996), which is provided by the Qhull library within the package `scipy` (Virtanen et al., 2020). An implementation of the CEM for arbitrary aggregate states is published via GitHub: <https://github.com/quiringoettl/cem4all>.

3. Results

3.1. Qualitative Evaluation

It has already been shown that the CEM can be used for T, p flash calculations for LLEs (Ryll, 2009; Ryll et al., 2012; Göttl et al., 2023). In the present work, we show that the CEM also works for VLEs and SLEs. For a qualitative evaluation of VLEs and SLEs, the phase equilibria of respective binary and ternary system are constructed using parameters provided in the literature and are qualitatively compared to the source diagrams.

For VLEs, the CEM takes NRTL parameters and Antoine parameters for the pure components as input. In Figure 2 a), we show a p, x, y -diagram for the binary system methanol – benzene at 313.15 K (Oh et al., 2003). Figure 2 b) shows the T, x, y -diagram for methyl acetate – isopropyl acetate at 1.013 bar (Xiao et al., 2013). Figure 2 c) and d) show the VLE of the ternary system methyl *tert*-butyl ether (MTBE) – methanol – benzene at 313.50 K and 0.6108 bar (Figure 2 c)) and 0.3854 bar (Figure 2 d)). All plots in Figure 2 are generated using the CEM and show the expected phase split behavior.

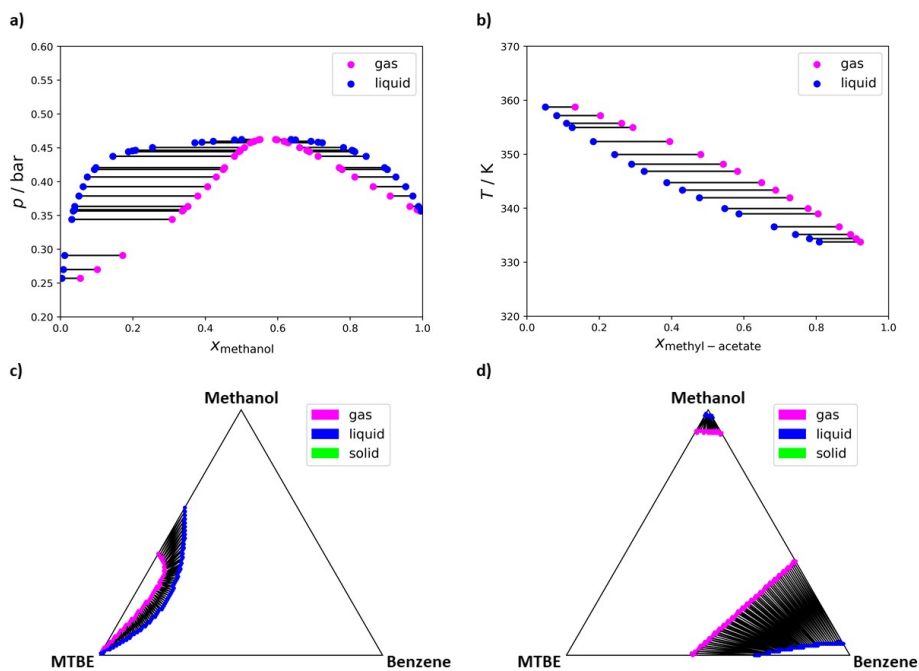

Figure 2: Binary and ternary VLEs of a) methanol – benzene (313.15 K) b) methyl acetate – isopropyl acetate (1.013 bar), and methyl *MTBE* – methanol – benzene (313.50 K) c) 0.6108 bar d) 0.3854 bar.

For SLEs, the CEM takes NRTL parameters, melting temperatures, and melting heats for the pure components as input. In Figure 3 a), a T, x, y -diagram for the binary system chloroform – acetylacetone at 1.0133 bar (Kim et al., 2011) is shown. Figure 3 b) depicts the SLE of the ternary system 3,4-dichloronitrobenzene – 2,3-dichloronitrobenzene – ethanol at 303.15 K and 1.0133 bar (Li et al., 2016). The yellow area marks a split into three phases: two (pure) solid phases and one liquid phase. In Figure 3 c) and d), the SLE of the system 3,4-dichloronitrobenzene – 2,3-dichloronitrobenzene – n-propanol at 1.0133 bar and at temperatures of 283.15 K in is given in c) and at 303.15 K in d). Once again, the yellow area marks a split into three phases. When comparing those plots to the literature (Kim et al., 2011; Li et al., 2016) one can see that the CEM is able to calculate the respective SLEs qualitatively.

When no NRTL model parameters (and also no other g^E -model parameters) are available, one can combine the CEM with models that directly predict the activity coefficients for a mixture given its components’ SMILES-strings, such as the HANNA-model (Specht et al., 2024). In Figure 3.1, we show a T, x, y -diagram for the heteroazeotropic, binary system butanol – water generated by the CEM, based on activity coefficients from the HANNA-model (Antoine parameters, melting temperatures, and melting heats were taken from (Linstrom and Mallard, 2024)). As can be seen, the whole range of phase equilibria, ranging from SLE, over LLE, over VLLE, to VLE is contained in the T, x, y -diagram.

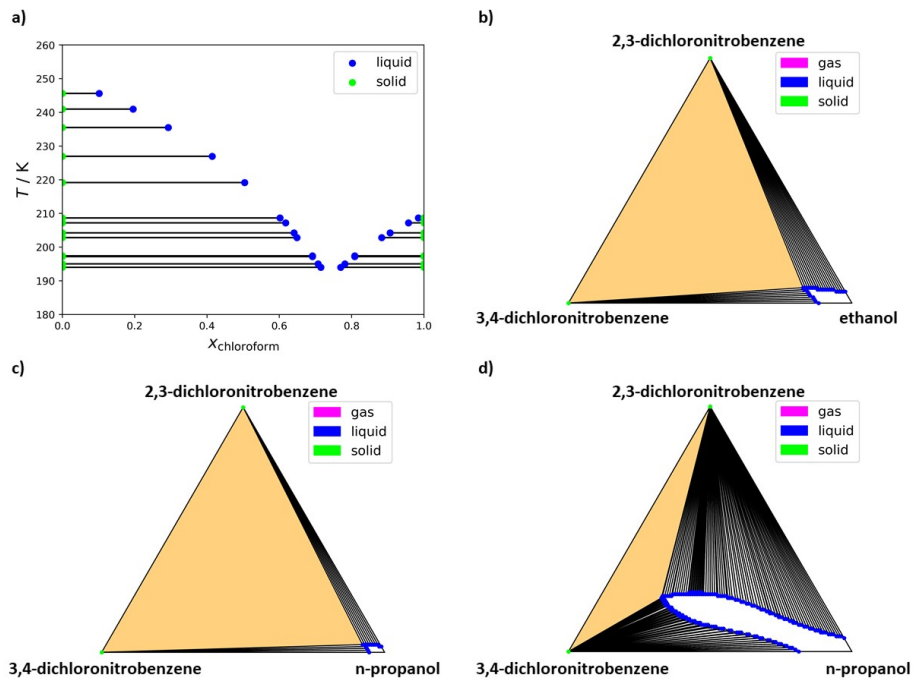

Figure 3: Binary and ternary SLEs of a) chloroform – acetylacetone (1.0133 bar), b) 3,4-dichloronitrobenzene – 2,3-dichloronitrobenzene – ethanol (303.15 K and 1.0133 bar) and 3,4-dichloronitrobenzene – 2,3-dichloronitrobenzene – n-propanol (1.0133 bar) c) 283.15 K d) 303.15 K. The yellow area marks a split into three phases.

Figure 4: T, x, y -diagram for the binary system butanol – water ranging from SLE, over LLE, over VLLE, to VLE. The activity coefficients were predicted using the HANNA-model (Specht et al., 2024). Antoine parameters, melting temperatures, and melting heats were taken from (Linstrom and Mallard, 2024).

3.2. Quantitative Evaluation

To provide a quantitative evaluation of our framework, we use the CEM to calculate phase equilibria for various systems and compare our results to experimental data from the literature (Oh et al., 2003; Kim et al., 2011; Xiao et al., 2013; Li et al., 2016, 2017; Gao et al., 2018). We measure the accuracy of the generalized CEM by MD to given data:

$$\text{MD} = \frac{\sum_{i=1}^N \sum_{j=1}^M \sum_{k=1}^P |x_{ijk}^{\text{source}} - x_{ijk}^{\text{CEM}}|}{NMP}, \quad (10)$$

where N is the number of components, M the number of examined feed streams, P the number of phases and x^{source} refers to the molar fraction reported in the literature.

As in (Göttl et al., 2023), we set the discretization parameter δ to 256 for binary systems, to 128 for ternary systems, and to 64 for quaternary systems. If the CEM fails to calculate the correct number of phases or the correct aggregate states of the phases, we will note this data point as a missing feed (MF). These occur only rarely, for example, if the feed composition is very close to an azeotrope.

Tables 1, 2, and 3 show the results for binary VLEs and SLEs, respectively. The value of the mean deviation is below 0.015 for all systems, deducing a high accuracy of the calculated phase splits. Furthermore, there are no missing feeds for SLEs. The missing feeds for the VLEs occur exclusively close to the boundary of the two-phase regions, e.g., close to an azeotrope.

The results for the ternary VLEs and SLEs are reported in Tables 4 and 5. Again, there are no missing feeds in case of the SLEs. For the VLE systems, the single missing feed is close to the boundary of the multiphase

Table 1: Results for binary VLEs from (Oh et al., 2003) at 313.15 K (p, x, y -data). M describes the number of feed streams, which were examined for the calculation of the mean deviation MD and MF is the number of missing feed streams.

System	$p \setminus \text{bar}$	M	MF	MD
methanol–benzene	0.20–0.60	23	1	0.006
methanol–toluene	0.05–0.60	23	3	0.014
MTBE–benzene	0.20–0.70	23	2	0.006
MTBE–methanol	0.30–0.75	24	4	0.004
MTBE–toluene	298.15	20	0	0.005

Table 2: Results for binary VLE from (Xiao et al., 2013) at 1.013 bar (T, x, y -data). M describes the number of feed streams, which were examined for the calculation of the mean deviation MD and MF is the number of missing feed streams.

models deviate from the experimental data. Additional deviations come from the discretization procedure of the CEM. We only report the combined deviations.

3.3. g^E -model parameter fitting using the CEM

As explained beforehand, the CEM can be used to fit parameters of a g^E -model to given experimental data. In Table 8, we show results for carrying out the parameter fit for the NRTL model using the genetic algorithm explained in Section 2.3. We set the number of generations and the population size for the genetic algorithm both to 50.

Table 7: Results for quaternary SLEs from (Li et al., 2017). M describes the number of feed streams, which were examined for the calculation of the mean deviation MD and MF is the number of missing feed streams.

System	$T \setminus \text{bar}$	$p \setminus \text{bar}$	M	MF	MD
adipic acid–glutaric acid–succinic acid–ethanol	283.15	1.012	21	2	0.001
adipic acid–glutaric acid–succinic acid–ethanol	303.15	1.012	24	1	0.004
adipic acid–glutaric acid–succinic acid–ethanol	313.15	1.012	22	0	0.008

Table 8: Results of parameter fit for binary VLEs and SLEs from (Kim et al., 2011), (Oh et al., 2003), (Xiao et al., 2013). The tuple (A_{12}, A_{21}, α) refers to the found NRTL parameters (A_{12}, A_{21} are defined as in Equation 7), MD is the mean deviation and MF is the number of missing feed streams using those parameters for the calculation of the respective phase equilibria. The parameter α was constrained to the range $(0.1, 1)$.

System	$T \setminus K$	$p \setminus \text{bar}$	A_{12}	A_{21}	α	MF	MD
chloroform–acetylacetone	180.0–260.0	1.0133	9.6023×10^2	-2.8627×10^3	2.6205×10^{-1}	0	0.002
methanol–benzene	313.15	0.2–0.6	1.6776×10^3	4.2855×10^3	3.2696×10^{-1}	0	0.010
methanol–toluene	313.15	0.05–0.6	3.348×10^3	6.3418×10^3	4.8615×10^{-1}	0	0.028
MTBE–benzene	313.15	0.2–0.7	-5.3803×10^3	8.2421×10^3	1.4228×10^{-1}	0	0.012
MTBE–methanol	313.15	0.3–0.75	1.9560×10^3	9.1785×10^2	1.5389×10^{-1}	2	0.003

4. Discussion

The present work demonstrates a generalization of the CEM (Ryll, 2009; Ryll et al., 2012; Göttl et al., 2023) that allows to do T, p flash calculations for chemical systems involving solid, liquid, and gaseous aggregate states. This approach enables the determination of arbitrary phase equilibria through a systematic discretization of the entire composition space and the subsequent construction of the convex envelope for the Gibbs energy. Building upon the mathematical framework proposed by (Göttl et al., 2023), the method is designed to handle systems with an arbitrary number of components and phases. Quantitative validation was achieved for VLEs and SLEs involving up to four components (LLEs were already addressed in (Göttl et al., 2023)). Regardless of the number of components, the VLEs and SLEs could be calculated reliably and with a high degree of accuracy. In rare cases and only close to the boundaries of the multiphase regions, e.g., close to azeotropes, the CEM sometimes has problems with calculating the correct phase splits.

Additionally, it is shown how to use the CEM for fitting parameters of g^E -models, such as NRTL, using experimental data. The methodology, detailed in Section 2.3, can also be applied to systems with more than two components, although computational complexity poses a limitation. For instance, a T, p flash over the entire composition space for a ternary system requires approximately one second. However, since experimental data often spans varying T and p , completing a full cycle over the dataset becomes time-intensive. This challenge is further amplified by the computational demands of the utilized genetic algorithm, which requires numerous full cycles to converge (e.g., $50 \times 50 = 2500$ for the shown results from Section 3.3).

While in theory (as proven mathematically in (Göttl et al., 2023)), the CEM can be applied to systems of an arbitrary number of components, computational complexity becomes also a limiting factor, when systems with more than six components are examined. Particularly the construction of the convex envelope is a challenging task. This also applies for the generalized framework presented in this work and therefore, we refer to (Göttl et al., 2023) for a thorough discussion of the implications of that matter.

A potential direction for future research lies in incorporating more advanced models for calculating the Gibbs energy of mixing. Additionally, the framework could be expanded to include the chemical equilibria of reactive systems, a concept previously described and implemented for binary and ternary systems by (Hildebrandt and Glasser, 1994).

As demonstrated, the CEM can be effectively combined with predictive tools such as the HANNA model (Specht et al., 2024) to perform qualitative analyses of chemical systems and their phase equilibria. This approach could be further developed by integrating additional models that predict pure component properties, such as melting temperature, melting enthalpy, or vapor pressure, as proposed in (Lansford et al., 2023) and (Santana et al., 2024). Moreover, future research could explore combining CEM-based simulations with conceptual process evaluation methods, as previously shown in (Ryll, 2009; Göttl et al., 2021, 2024). Such an integration could unify approaches for solvent and process design by predicting thermodynamic properties from SMILES-strings, simulating the resulting phase equilibria, and modeling apparatuses, e.g., for decantation or distillation, using the CEM.

5. Conclusion

This work generalizes the CEM to encompass systems with solid, liquid, and gaseous aggregate states, enabling the determination of arbitrary phase equilibria without prior knowledge about the number of occurring phases. By leveraging a robust mathematical framework, the methodology is shown to be applicable to multi-component systems. It has been quantitatively validated for VLEs and SLEs involving up to four components, demonstrating high accuracy of the phase splits. Additionally, the present work demonstrates how the CEM can be utilized to fit parameters for g^E models using experimental data. In summary, the CEM offers a robust method for T, p flash calculations, without requiring any *a priori* knowledge about the phase splits, e.g., the number of phases or respective aggregate states. Looking ahead, the combination of the CEM with a machine learning model for activity coefficient prediction illustrates its potential for integration into simulations, paving the way for unifying solvent and process design in future research.
