## ABSTRACT

The Early Release Observations (ERO) from *Euclid* have detected several new galaxy-galaxy strong gravitational lenses, with the all-sky survey expected to find 170 000 new systems, greatly enhancing studies of dark matter, dark energy, and constraints on the cosmological parameters. As a first step, visual inspection of all galaxies in one of the ERO fields (Perseus) was carried out to identify candidate strong lensing systems and compared to the predictions from Convolutional Neural Networks (CNNs). However, the entire ERO data set is too large for expert visual inspection. In this paper, we therefore extend the CNN analysis to the whole ERO data set, using different CNN architectures and methodologies. Using five CNN architectures, we identified 8,469 strong gravitational lens candidates from  $I_E$ -band cutouts of 13 *Euclid* ERO fields, narrowing them to 97 through visual inspection, including 14 grade A and 31 grade B candidates. We present the spectroscopic confirmation of a strong gravitational lensing candidate, EUCL J081705.61+702348.8. The foreground lensing galaxy, an early-type system at  $z = 0.335$ , and the background source, a star-forming galaxy at  $z = 1.475$  with [O II] emission, are both identified. Lens modelling using the Euclid strong lens modelling pipeline reveals two distinct arcs in a lensing configuration, with an Einstein radius of  $1''18 \pm 0''.03$ , confirming the lensing nature of the system. These findings highlight the importance of a broad CNN search to efficiently reduce candidates, followed by visual inspection to eliminate false positives and achieve a high-purity sample of strong lenses in *Euclid*.

**Key words.** Gravitational lensing: strong; Methods: statistical; Surveys; Cosmology: observations; Techniques: image processing

## 1. Introduction

The deflection of light rays from a distant background source by a massive foreground object, a phenomenon known as strong gravitational lensing, produces multiple resolved images, arcs, or Einstein rings, depending upon relative positions and alignment of the source, lens, and observer. Strong lensing has many important applications, such as (i) mapping the mass distribution of galaxy (Broadhurst et al. 1995; Limousin et al. 2005; Koopmans 2004; Nightingale et al. 2019; Turyshev & Toth 2022), (ii) providing constraints on dark energy (Sarbu et al. 2001; Sereno 2002; Meneghetti et al. 2005; Biesiada 2006; Oguri et al. 2008; Shiralilou et al. 2020) and dark matter (Tortora et al. 2010; Gilman et al. 2019; Nadler et al. 2021; Vegetti et al. 2024), (iii) constraining the slope of inner mass density profile (e.g., Treu & Koopmans 2002; Zhang 2004; Gavazzi et al. 2007; Koopmans et al. 2009; Zitrin et al. 2012; Spinelli et al. 2015; Li et al. 2018; He et al. 2020; Şengül & Dvorkin 2022), and, (iv) measurement of the Hubble constant ( $H_0$ ) using time-delay cosmography between multiple imaged sources (Rhee 1991; Kochanek 2003; Grillo et al. 2018; Treu et al. 2022; Shajib et al. 2023; Birrer et al. 2024).

Gravitational lensing is sensitive to the presence of all foreground matter, regardless of whether this matter is in the form of visible baryonic matter or dark matter. To a very good approximation, dark matter appears to be collisionless, and lacking in detectable signatures of interactions via any of the fundamental forces except gravity. As such, gravitational lensing is one of the few probes of the dynamics and physical properties of dark matter particles that drive the growth of large-scale structures in the Universe and dominate the cosmic matter budget.

The *Euclid* mission (Euclid Collaboration: Mellier et al. 2024) is a 1.2 m space survey telescope with primary science objectives including measurements of cosmic shear from weak lensing, and galaxy clustering, from which cosmological parameter constraints follow. *Euclid* was successfully launched in July 2023 and is in the process of observing approximately one-third of the sky in its wide survey (Euclid Collaboration: Scaramella et al. 2022), and  $\sim 50$  deg $^2$  in its deep fields, about two magnitudes deeper than the wide survey. *Euclid*'s instruments consist of a visible imager (VIS), a near-infrared imager and a slitless spectrometer (NISP), and are described in more detail in Euclid Collaboration: Cropper et al. (2024) and Euclid Collaboration: Jahnke et al. (2024), respectively. The vast imaging and spectroscopic dataset from the *Euclid* survey enables a wide range of legacy science. Data sets such as these generally excel in their potential for discovering rare objects.

*Euclid* is widely expected to be transformative in the field of strong gravitational lensing, with 170 000 galaxy-scale strong lenses predicted in its wide survey (e.g., Collett 2015), increasing the number of known strong lenses by about two orders of magnitude. This creates a new frontier of rare object discovery, such as the detection of highly magnified high-redshift (e.g.,  $z > 2$ ) background sources, or of “Jackpot” systems with two background galaxies magnified at different redshifts being magnified by the same foreground lens. Each of these opens the possibility of a range of new legacy science goals for *Euclid*, including the direct detection and statistical characterization of dark matter halo substructure (e.g., Vegetti & Vogelsberger 2014; Hezaveh et al. 2016; Li et al. 2016, 2017; Despali et al. 2018; O’Riordan et al. 2023), geometrical constraints on the dark energy equation of state (e.g., Gavazzi et al. 2008; Stern et al. 2010;

Shlivko & Steinhardt 2024), and calibration of initial mass function of early-type galaxies (Treu et al. 2010; Barnabè et al. 2013; Leier et al. 2016).

However, identifying these  $\sim 10^5$  strong lensing systems among the  $\sim 10^9$  *Euclid* galaxies is a non-trivial task. Driven by *Euclid* and other major sky surveys, many authors have developed machine learning methods for finding strong gravitational lensing systems (e.g., Petrillo et al. 2017, 2019a,b; Lanusse et al. 2018; Pourrahmani et al. 2018; Schaefer et al. 2018; Davies et al. 2019; Metcalf et al. 2019; Li et al. 2020, 2021; Christ et al. 2020; Cañameras et al. 2020; Christ et al. 2020; Huang et al. 2017; Rezaei et al. 2022; Andika et al. 2023; Gentile et al. 2021; Savary et al. 2022; Rojas et al. 2022; Wilde et al. 2022; Nagam et al. 2023, 2024).

The first data released from *Euclid* were the Early Release Observations (ERO) (Cuillandre et al. 2024; Martín et al. 2024; Massari et al. 2024; Hunt et al. 2024; Saifollahi et al. 2024; Cuillandre et al. 2024; Marleau et al. 2024; Kluge et al. 2024; Atek et al. 2024; Weaver et al. 2024). As a first test for the existence of a large population of strong gravitational lenses, Acevedo Barroso et al. (2024, hereafter AB24) inspected all galaxies in the Perseus ERO field (Cuillandre et al. 2024), finding three gravitational lensing systems (termed grade A candidates), 13 probable systems (grade B candidates), and 52 possible strong lenses (grade C candidates). These were compared to the results of 21 CNN architectures in Pearce-Casey et al. (2024, hereafter PC24), with the result that, at best, CNNs produce lens candidate lists that are only  $\sim 10\%$  pure. The best performing CNN was also one of the deepest networks, pre-trained on over a hundred million galaxy classifications from the Galaxy Zoo citizen science project (Lintott et al. 2008), with a final layer fine-tuned by re-training on strong lenses painted onto real galaxy images from the *Euclid* ERO data sets. However, some similarities were observed in the false positives, such as the presence of spiral arms in the target galaxy, suggesting that further improvements to the CNN architecture or training process are possible.

The entire *Euclid* ERO data set is too large for expert volunteers to conduct such an examination of every galaxy in a timely fashion. Therefore, in this paper, we present the results of our strong gravitational lens search in the remainder of the *Euclid* ERO data, using a CNN-based approach followed by visual inspection. In performing this analysis, we take an approach inspired by previous works (Jacobs et al. 2017, 2019; Andika et al. 2023; Nagam et al. 2023), by comparing the outputs of various CNN lens finders. Inevitably, the vast majority of *Euclid*'s strong gravitational lenses will first be identified through an initial CNN search, followed by visual inspection. However, this CNN search inevitably misses some strong lensing systems, resulting in a population of false negatives. Here, we attempt to mitigate this by considering a diversity of CNN approaches, searching for systems that are detected by one CNN and not another. This approach is particularly important for discovering rare lensing configurations that will contribute to *Euclid*'s legacy science goals.

This paper is structured as follows. In Sect. 2, we summarise the *Euclid* ERO data characteristics and the processing applied to them for the detection of strong gravitational lenses with CNNs. Section 3 presents the methodology used. The results are presented in Sect. 4, and the results of recent spectroscopic follow-up are presented in Sect. 5. The summary and the conclusions are discussed in Sect. 6.

## 2. *Euclid* Early Release Observation data

The *Euclid* ERO data release covers 17 galactic and extragalactic fields. The objective was to acquire scientific observations for communication and early scientific results before the start of the nominal mission ([Euclid Early Release Observations 2024; Cuillandre et al. 2024](#)).

In this work, we focus on all the ERO fields except for the Perseus cluster, which has already been mined for lenses in AB24 and PC24. All ERO fields are covered by both the VIS and NISP instruments. However, in Table B.1, we present only the VIS statistics for brevity. We refer the reader to [Cuillandre et al. \(2024\)](#) for a more complete overview.

Given the  $O(10^6)$  sources in the whole ERO catalogues, we narrow our selection to extended sources brighter than 23 magnitudes in VIS  $I_E$ -band. This is in agreement with the selection used in AB24 and PC24. Thus, the selection corresponds to  $MAG\_AUTO < 23$  and  $CLASS\_STAR < 0.5$  in the VIS catalogues, for a total of 377 472 sources. This classification is conservative and includes a significant fraction of stars.

We create postage stamps for every selected source. Each stamp covers  $9\farcs9 \times 9\farcs9$ , corresponding to  $99 \times 99$  pixels in VIS and  $33 \times 33$  pixels in the NISP bands. The stamp size is kept large enough to include any galaxy-scale lensing effects, given that the typical Einstein radius is rarely larger than  $3''$ , but also small enough to keep only the relevant information, without contamination from nearby sources.

## 3. Methodology

### 3.1. Candidate selection

We employed the following CNN models: 4-Layer CNN ([Manjón-García 2021](#)), DenseLens ([Nagam et al. 2023](#)), Lens-CLR (Andika et al. in prep.), MRC-95 ([Wilde 2023](#)), and Naberrie ([Wilde 2023](#)). For a detailed overview of these models and their application to the *Euclid* ERO Perseus field, see PC24. We applied each of these CNN models to the 377 472 extracted VIS cutouts, obtaining five scores per source. To mitigate the impact of noise in individual classifications, we clipped scores below 0.1 and computed the geometric mean as the final score. The arbitrary clipping step helps to prevent the removal of good candidates due to noisy classifications.

Each CNN model was trained on different data sets and used different architectures, thereby capturing a wide variety of lensing and non-lensing features (see PC24 for more details). This aggregating method allowed for a more robust and consistent identification of lens candidates. From the initial 16 ERO fields, three fields (Horsehead, IC 342, and NGC 6254) were excluded from our final analysis since they did not contain any viable candidates. The cutouts were then ranked based on the geometric mean values, and the top 650 cutouts from each of the remaining 13 fields were selected, resulting in a total of 8450 cutouts chosen by the CNNs for further inspection. We adopt the same approach as AB24 and PC24, utilizing both the VIS and NISP bands for visual inspection, because the human eye is good at detecting subtle colour variations ([Marshall et al. 2009](#)). However, we exclude the NISP cutouts from the CNN inference process to focus on a single band, which is effective at capturing morphological features ([Petrillo et al. 2019a](#)), while acknowledging that incorporating additional bands could provide additional information and may improve classification performance.

### 3.2. Visual inspection of candidates

During the visual analysis of the results of individual models, 19 additional notable candidates were identified and included in the selection. This brought the total number of candidates to 8469, which were then subjected to a first round of visual inspection by 12 experts, in which the experts rejected obvious non-lenses. The voting results from this stage of visual inspection are illustrated in Fig. 1, showing the distribution of votes each candidate received. Based on the voting, 183 candidates that received three or more votes were selected for further inspection.

However, during the subsequent analysis, 32 of these 183 candidates were identified as duplicates, which were removed from the sample. These duplicates arose from the VIS source catalogue itself containing multiple entries for the same physical source, with slight positional shifts within  $1''$  between the duplicate entries. This left 151 unique candidates, which then underwent a second, more rigorous round of visual inspection. This stage involved 15 experts who graded each candidate based on the presence of lensing features, using a grading scheme (see AB24) that categorized the candidates into four grades: A, B, C, and X. In short, the grading scheme implies the following:

- Grade A represents definite lenses with clear lensing features;
- Grade B suggests the presence of lensing features, though confirmation requires additional data;
- Grade C indicates lensing features that could also be attributed to other physical phenomena;
- Grade X refers to objects that are definitively not lenses.

**Fig. 1.** The voting results for stage 1 of the visual inspection process, which involved 12 people, were based on 8469 candidates selected by CNNs.

## 4. Results

We present here an overview of the grade A, B, and C candidates found in our search of the ERO fields. Our search methodology combined multiple CNN models with visual classification to ensure robust candidate identification.

### 4.1. CNNs with visual classification

We identified a total of 97 lens candidates, distributed as 14 grade A candidates, 31 grade B candidates, and 52 grade C candidates with visual classification. We also identified 54 objects as

grade X (non-lenses) during our visual inspection process. The catalogue of all these candidates is shown in Table A.1.

The 14 grade A candidates, representing definite lenses, are shown in Fig. 2. The 31 grade B candidates, which exhibit strong lensing features but require further confirmation, are presented in Fig. 3. Due to the larger number of grade C candidates, we have divided their presentation across Figs. 4 and 5, collectively displaying all 52 grade C objects that show potential lensing characteristics but necessitate additional investigation.

#### 4.2. Prediction

We compare our findings with predictions made by Collett (2015), who estimated that the *Euclid* mission would discover approximately 170 000 strong gravitational lenses over its planned survey area of 15 000 square degrees. Given that the 13 *Euclid* ERO fields we analysed cover a total area of  $8.12 \text{ deg}^2$ , we would naively expect  $\sim 90$  strong lenses in the ERO area, although this reduces to  $\sim 70$  after applying our  $I_E < 23$  pre-selection. Our study has identified 97 grade A, B, and C lens candidates, a number that aligns closely with the theoretical expectations. However, experience suggests that most grade C candidates are unlikely to be lenses. Taking Collett (2015) as truth and pessimistically assuming only our grade A candidates are lenses, we would conclude that our search is  $\sim 15\%$  complete. If the grade B candidates are also all lenses we have found  $\sim 60\%$  of all the lenses with  $I_E < 23$  that are in the ERO fields.

#### 5. Palomar spectroscopy

We obtained optical spectroscopic follow-up of several of the grade A and grade B candidates using the Double Spectrograph (DBSP; Oke & Gunn 1982) on the 5m Hale telescope at Palomar Observatory between June and October 2024. Table 1 presents the targets for which we were able to measure at least one redshift in the candidate strong lens system. All nights had typical  $\sim 1''.2$  Palomar seeing. The June and July nights were photometric, while the October night had some clouds at the start, and end of the night, but was relatively clear at the time of the reported observation. For each observation, we obtained two or three exposures of 1200 s using the  $1''.5$  slit, the 600 lines blue grating (blazed at  $4000 \text{ \AA}$ ), the  $5500 \text{ \AA}$  dichroic, and the 316 lines red grating (blazed at  $7500 \text{ \AA}$ ). The slits were aligned on the candidate lensing galaxy at a position angle to cover the putative lens feature. The data were reduced using standard techniques within the Image Reduction and Analysis Facility (IRAF).

All the lensing galaxies proved to be early-type galaxies with Ca H & K absorption and strong  $4000 \text{ \AA}$  breaks. One grade A system, EUCL J081705.61+702348.8, revealed redshifts for both the foreground lensing galaxy and the background source galaxy, where the latter had a slightly ( $\sim 1''.7$ ) offset emission line at  $9222.8 \text{ \AA}$  (Fig. 6). If the emission feature was associated with the primary target galaxy at  $z = 0.335$ , the implied rest-frame wavelength would be  $6908 \text{ \AA}$ , which does not correspond to any strong spectral features in galaxies, particularly early-type galaxies. Instead, the most plausible identification is [O II] emission from a lensed star-forming galaxy at  $z = 1.475$ .

To further confirm the lensing nature of EUCL J081705.61+702348.8, we modelled the system using the Euclid strong lens modelling pipeline implemented in PyAutoLens (Nightingale et al. 2018, 2021). A full description of the pipeline and application to a larger sample of lenses will be provided in the Q1 data release papers (Rojas et al. 2025,

Walmsley et al. 2025). Figure 7 presents the results for the VIS optical image. The foreground lens galaxy light is subtracted by fitting it with a multi-Gaussian expansion composed of 60 Gaussians (He et al. 2024). This reveals two distinct arcs in locations that are consistent with a singular isothermal ellipsoid (SIE) mass model configuration. PyAutoLens fits the SIE lens model, which the right panel of Figure 7 shows accurately ray-traces both arcs to the same region of the source-plane. The source reconstruction reveals two separate doubly imaged emission components, which lie outside the tangential caustic but within the radial caustic, consistent with the tangential and radial critical curves predicted by our SIE mass model for this lens system. The SIE lens mass model includes an external shear, and the inferred Einstein radius is  $1''.18 \pm 0''.03$ .

#### 6. Discussion and conclusions

We have presented a catalogue of strong gravitational lens candidates identified in the *Euclid* Early Release Observations, covering 13 fields with a total area of  $8.12 \text{ deg}^2$ . Our search methodology, combining multiple CNN models with visual classification, has yielded 97 lens candidates: 14 grade A, 31 grade B, and 52 grade C candidates. This multi-stage approach, using CNNs for initial candidate selection followed by careful visual inspection, has proven effective in producing a high-purity sample, particularly for grade A and B candidates.

The spectroscopic follow-up of our highest-quality candidates, notably EUCL J081705.61+702348.8, demonstrates the robustness of our classification system. Our spectroscopic analysis reveals an emission line at  $9222.8 \text{ \AA}$  that is most plausibly identified as [O II] from a lensed star-forming galaxy at  $z = 1.475$ , measuring the redshifts for both the foreground lensing galaxy ( $z = 0.335$ ) and the background source galaxy. The lens model implemented in PyAutoLens fits the two distinct arcs, revealing a source reconstruction with two doubly imaged emission components located outside the tangential caustic but within the radial caustic, thus confirming the strong lensing configuration. The lens modelling measured an Einstein radius of  $1''.18 \pm 0''.03$ .

We compare our findings with theoretical predictions, indicating that the discovery of 97 candidates (across all grades) in  $8.12 \text{ deg}^2$  is consistent with previous estimates of  $\sim 70$  strong lenses in this area (after applying our  $I_E < 23$  pre-selection). Taking a conservative approach where only grade A candidates are considered confirmed lenses, our search achieves  $\sim 15\%$  completeness, rising to  $\sim 60\%$  if grade B candidates are included. Our lower completeness rate compared to Zoobot1 (Walmsley et al. 2023), which identified 61 out of 68 known lenses (90% completeness) in RP24, may be attributed to the fact that in our study the true number of lenses is unknown, making it more challenging than studies where the ground truth was known. Furthermore, our selection of only the top 650 candidates based on geometric mean scores for each field, while chosen to maintain a reasonable balance between completeness and false positive rate, may have excluded some genuine lens candidates that received lower CNN scores.

This work serves as a guide for future *Euclid* lens searches, demonstrating that a broad initial CNN search followed by careful visual inspection is essential to build high-purity lens samples. Although our current analysis focuses on single-band ( $I_E$ ) detections, the full potential of *Euclid* lens searches will be realized through multi-band analysis, refined CNN architectures, and expanded spectroscopic follow-up campaigns. The lens modelling pipeline demonstrated here for

**Fig. 2.** Mosaic of the grade A lens candidates from the second round of visual inspection. For each candidate, we show the high-resolution  $I_E$ -band cutout on the left and the lower-resolution  $H_E$ ,  $Y_E$ ,  $I_E$  composite on the right. The IAU name and field name are displayed at the top and bottom of the  $I_E$ -band cutout, respectively, and the final joint grade is shown in red at the bottom of the composite cutout. Each cutout is  $9.^{\circ}9 \times 9.^{\circ}9$  in size.

**Table 1.** Palomar spectroscopy of strong lens candidates.

IAU Name	Grade	Obs Date (UT)	PA (deg)	$z(\text{lens})$	$z(\text{source})$
EUCL J081705.61+702348.8	A	2024 Oct 03	-35	0.335	1.475

**Fig. 6.** Spectrum of the grade A strong lens candidate EUCL J081705.61+702348.8 obtained at Palomar Observatory. The spectrum reveals an early-type galaxy at  $z = 0.335$  with several characteristic absorption lines in addition to a strong 4000 Å break. There is a strong additional line at 9222.8 Å, which we associate with [O II] emission from the lensed source galaxy at  $z = 1.475$ .

**Fig. 7.** Lens model of the grade A system EUCL J081705.61+702348.8, created using the *Euclid* strong lens modelling pipeline implemented with PyAutoLens (Nightingale et al. 2018, 2021). The panels show: (i) the observed VIS optical image; (ii) the lens-subtracted image; (iii) the lens model reconstruction of the lensed source; and (iv) the source galaxy’s reconstructed unlensed emission in the source plane. The system is accurately modelled, providing strong evidence of its lensing nature. The mass model is a singular isothermal ellipsoid with external shear, the lens light is modelled using a multi-Gaussian expansion (He et al. 2024), and the source is reconstructed on an adaptive Delaunay mesh. The inferred Einstein radius is  $1.^{\prime\prime}18 \pm 0.^{\prime\prime}03$ .

## Appendix A: Lens candidates

We show the details of 97 lens candidates which are distributed as 14 grade A candidates, 31 grade B candidates, and 52 grade C candidates.

**Table A.1.** Probable lens candidates discovered with CNN classifiers. ID, IAU Name, Fields, RA, DEC, Classification prediction scores for five different networks (P1, P2, P3, P4 and P5), Geometric Mean (GM) of the five prediction scores and visual inspection grade are shown. Here, P1 refers to the Lens-CLR network, P2 refers to the Denselens, P3 refers to the 4-Layer CNN, P4 refers to the Naberrerie and P5 refers to the MRC95.

## Appendix B: Summary of the ERO fields

We present here the summary of the 16 *Euclid* ERO fields (except Perseus). The *Euclid* VIS instrument provides high-quality optical imaging through a single broad optical band (550-900 nm). The VIS camera features a pixel scale of  $0''.1$  per pixel. The point spread function (PSF) of VIS has a full width at half maximum (FWHM) of  $\lesssim 0''.18$  across the entire field of view (Cropper et al. 2016). For the ERO fields, each pointing consists of four dithered exposures of 565 seconds each, resulting in a total exposure time of 2260 seconds. This yields a typical  $5\sigma$  point-source depth of  $I_E \approx 26.2$  mag (Euclid Collaboration: Scaramella et al. 2022). The VIS images demonstrate excellent depth and resolution, with a median signal-to-noise ratio (S/N) of  $\sim 10\sigma$  for objects at  $I_E = 24.5$  mag.

**Table B.1.** Summary of all the 16 *Euclid* ERO Fields (except Perseus) including their corresponding area, and their corresponding catalogue size, which represents the number of sources in each field.

Field name	Area (deg $^2$ )	Catalogue size
Abell 2390	0.75	469 056
Abell 2764	0.75	542 729
Barnard 30	0.6	163 063
Dorado	0.6	518 445
Fornax	0.57	369 315
Holmberg II	0.6	466 276
Horsehead Nebula	0.58	157 264
IC 10	0.62	1 403 807
