While quantum measurements have been shown to constitute a resource for operating quantum thermal machines, the nature of the energy exchanges involved in the interaction between system and measurement apparatus is still under debate. In this work, we show that a microscopic model of the apparatus is necessary to unambiguously determine whether quantum measurements provide energy in the form of heat or work. We illustrate this result by considering a measurement-based refrigerator, made of a double quantum dot embedded in a two-terminal device, with the charge of one of the dots being continuously monitored. Tuning the parameters of the measurement device interpolates between a heat- and a work-fueled regimes with very different thermodynamic efficiency. Notably, we demonstrate a trade-off between a maximal thermodynamic efficiency quantified by the signal-to-noise ratio in the work-fueled regime. Our analysis offers a new perspective on the nature of the energy exchanges occurring during a quantum measurement, paving the way for energy optimization in quantum protocols and quantum machines.

In the quantum world, quantum measurements change the state of the measured system. This measurementinduced dynamics can exhibit entropy and energy transfers between the measuring apparatus and the system [1], which in turn are witnesses of the nontrivial thermodynamic balance behind the measurement process. On the one hand, the minimum work cost of measurement has been shown to strongly depend on measurement performance [2, 3], leading to a diverging resource cost for ideal (i.e. projective) measurements [4]. On the other hand, while a measurement can be shown to be a source of work under ideal conditions [5, 6], the stochasticity of the measurement-induced dynamics in the general case is reminiscent of the action of a thermal bath [1], and can even induce thermalization [7]. Moreover, several theories attempting to describe the emergence of the non-unitary measurement-induced dynamics have emphasized the key role of the inaccessible degrees of freedom of the measuring apparatus [8, 9], which in thermodynamic language constitute a heat bath [3, 10], and are responsible for irreversibility and heat transfers occurring during the measurement.

Elucidating the thermodynamic nature of the energy provided by a quantum measurement is a prerequisite to quantifying the efficiency of engine cycles incorporating quantum measurements such as quantum Maxwell demons [11–13], and measurement-powered machines [6, 14–20]. It is also a necessary step towards systematic energetic optimization of protocols involving a large number of quantum measurements such as fault-tolerant quantum algorithms [21]. Here, we address this question and show that the nature of the energy transfer occurring during a quantum measurement is controlled by micro-

FIG. 1. Principle of the continuous measurement-powered refrigerator. The charge in the right quantum dot is continuously monitored by an apparatus at rate γ_M . As this measurement does not commute with the dot Hamiltonians, it results in an energy flow \dot{E}_M , which in turn powers heat transfer from the cold (left) to the hot (right) lead, that is $J_L < 0 < J_S$. On general grounds, the measuring apparatus can be powered either by a source of work providing power P_M and/or a source of heat at temperature T_M providing heat flow J_M .

scopic parameters of the measuring apparatus, and can be tuned from a regime where the measurement is mostly fueled by heat, to a regime where it is mostly fueled by work. When the measurement is incorporated into an engine cycle, these regimes correspond to very different values of the thermodynamic efficiency for the machine, even if the average measurement-induced dynamics appears to be the same. We illustrate this on an example of measurementpowered refrigerator based on two single-electron quantum-dots (QDs) coupled to electron reservoirs at different temperatures. Unlike a previous proposal of a twoqubit measurement-based refrigerator [16], our machine involves a measurement that is local (rather then occurring in an entangled basis) and is in competition with an always-on tunnel coupling between the QDs. Moreover, instead of using a discrete projective measurement as a stroke of our machine cycle (which would correspond to infinite work cost [4]), we consider a weak continuous measurement [22] which results in a machine producing steady-state cooling power.

Conducting a thermodynamic analysis of the device, we show that its efficiency depends on the nature of its fuel, heat, work or a mixture of both. It is only by considering a microscopic model of the measurement apparatus that we can distinguish between work-fueled and heat-fueled regimes, and investigate without ambiguity the performances of this measurement-based refrigerator. As realistic charge measurement apparatus, we consider a biased electronic tunnel junction, - a quantum point contact (QPC)-, capacitively coupled to one of the QD. Remarkably, we highlight a trade-off between the efficiency of the machine, which is maximized in the heat-fueled regime, and the signal-to-noise ratio which becomes maximal when the QPC is powered by work input only. The work performed to operate the machine is then mostly dissipated into the reservoirs connected to the QPC, leading to poor cooling efficiency. Our results show that determining the nature of energy exchanges do require a microscopic knowledge of the device, and that work-fueled devices do not necessarily correspond to the best thermodynamic efficiency.

Model. – We consider as working body a system composed of two tunnel-coupled single energy-level QDs, coupled to an electron reservoir. In addition, we assume a continuous measurement of the number of electrons in the right-hand dot. This setup is illustrated in Fig. 1. In this work, we investigate the steady-state dynamics of this system under the assumption of weak system-bath coupling which allows us to use a master equation (ME) approach. Explicit calculations detailed in the Supp. Mat. show that a valid regime for operating this device as a measurement-fueled refrigerator corresponds to a strong inter-dot coupling q with respect to the systembath couplings, captured by a global ME. The latter involves the global energy eigenstates of the QDs system, denoted hereafter $\{|00\rangle, |-\rangle, |+\rangle, |11\rangle\}$. Our analysis focuses on the dynamics of the single-electron Hilbert subspace spanned by states $\{|00\rangle, |\pm\rangle\}$, a description valid for high enough Coulomb repulsion between and within the dots. The ME for the reduced density operator ρ of the QDs takes the form:

$$\dot{\rho} = -i[H_{\rm QD}, \rho] + \left(\mathcal{L}_L + \mathcal{L}_R + \mathcal{L}_{\mathcal{M}}\right)\rho,\tag{1}$$

with the system Hamiltonian $H_{\rm QD} = \frac{\Omega}{2} \left(c^{\dagger}_{+} c_{+} - c^{\dagger}_{-} c_{-} \right) + \epsilon \left(c^{\dagger}_{+} c_{+} + c^{\dagger}_{-} c_{-} \right)$. We denote by ϵ the average charging energy and $\Omega \equiv \sqrt{\Delta^{2} + g^{2}}$ the energy difference between the two hybridized eigenstates $|\pm\rangle$, with Δ the energy detuning between the bare QDs and g the inter-dot tunnel coupling strength. The fermionic operators $c_{\pm} = |00\rangle \langle \pm|$ are associated with eigenenergies $\epsilon \pm \frac{\Omega}{2}$ of the system. The dissipative part of the ME comprises three terms,

$$\mathcal{L}_{\alpha} = \sum_{l=\pm} \left(\Gamma_{\alpha l \downarrow} D[c_l] + \Gamma_{\alpha l \uparrow} \mathcal{D}[c_l^{\dagger}] \right), \quad \alpha = L, R, (2)$$

$$\mathcal{L}_{M} = \frac{1}{\Delta t} \int_{t}^{t+\Delta t} dt' \gamma_M \mathcal{D}[\hat{n}_R(t')] = \gamma_M \sum_{\omega=0,\pm\Omega} \mathcal{D}[\hat{n}_{\omega}], (3)$$

capturing respectively dissipation to the left and right reservoirs, and the measurement channel with $\mathcal{D}[X] \bullet \equiv X \bullet X^{\dagger} - \frac{1}{2}(X^{\dagger}X \bullet + \bullet X^{\dagger}X)$. Under weak system-bath coupling assumption, the exchanges of particles with the reservoirs are set by strengths $\Gamma_{\alpha l\uparrow} = \Gamma_{\alpha l}f_{\alpha l}$ and $\Gamma_{\alpha l,\downarrow} = \Gamma_{\alpha l}(1 - f_{\alpha l}))$, with $f_{\alpha l} = [e^{(\epsilon + l\Omega/2 - \mu_{\alpha})/kT_{\alpha}} + 1]^{-1}$ the Fermi function of lead α characterized by chemical potential μ_{α} and temperature T_{α} , and the bare rates $\Gamma_{\alpha l} = 2\pi \sum_{k} g_{\alpha,k}^2 \delta(\epsilon + l\Omega/2 - \omega_k) \ll \epsilon$. The local charge measurement operator is expressed in the energy eigenbasis, $\hat{n}_R(t) = e^{iH_{\text{QD}}t} \hat{n}_R e^{-iH_{\text{QD}}t} = \sum_{\omega=0,\pm\Omega} \hat{n}_\omega e^{i\omega t}$. We stress that, as any Lindblad equation, the deriva-

We stress that, as any Lindblad equation, the derivation of Eq. (1) from the Hamiltonian microscopic model involved a coarse-graining in time with time step Δt assuming $\Delta t \gg \Omega^{-1}$ [23], which also had to be taken into account when deriving the form of \mathcal{L}_M , see Eq. (3). This was done by assuming $\Delta t \gamma_M \ll 1$ [24]. We refer again to the Sup. Mat. for all technical details.

Thermodynamic balance.– We calculate steady-state energy and heat flows by solving the master equation Eq. (1) at long times where $\dot{\rho}_{ss} = 0$. We recall that steady-state heat flows provided by each reservoir $\alpha =$ L, R are defined as the difference between the energy flow from this reservoir and the electrical power carried by exchanged particles due to a finite chemical potential μ_{α} [25]:

$$J_{\alpha} = \dot{E}_{\alpha} - P_{\alpha} = \text{Tr}\{(H_{\text{QD}} - \mu_{\alpha} \sum_{l} c_{l}^{\dagger} c_{l}) \mathcal{L}_{\alpha} \rho_{ss}\}.$$
(4)

In the following, we focus on the case $\mu_L = \mu_R$ (no net electric work exchanged with the reservoirs). We also introduce the flow of energy \dot{E}_M provided by the measuring apparatus to the system, computed from:

$$\dot{E}_M = \text{Tr}\{H_{\text{QD}}\mathcal{L}_M\rho_{ss}\},\tag{5}$$

FIG. 2. a): Stationary cooling power J_L (blue), heat flow received from the hot lead J_R (orange) and energy flow provided by the measuring apparatus \dot{E}_M (green) in unit of γg as a function of the measurement strength γ_M . b) Cooling power J_L in units of γg as a function of the ratio of the hot over cold lead temperatures T_R/T_L and the measurement strength γ/g . c) Efficiency of conversion of measurement energy into cooling power $\eta_{\rm id} = J_L/\dot{E}_M$ as a function of the ratio of the hot over cold lead temperatures T_R/T_L and the measurement strength γ/g . In a) and b) and c), other parameters are set as follows: $\gamma/g = 0.01, \ \Delta/g = 4.3, \ \mu/g = 10, \ \epsilon/g = 5.4, \ \gamma_M/g = 1, \ T_L/g = 2$, and for a): $T_R/T_L = 2$. The red dots indicate the parameter values considered in the QPC model.

Energy conservation for the working body takes then the form:

$$\frac{dU}{dt} = J_L + J_R + \dot{E}_M = 0, \qquad (6)$$

with $U = \text{Tr}\{H_{\text{QD}}\rho_{ss}\}$ the steady-state value of working body internal energy.

Assuming $T_R > T_L$ for the rest of this work, this device operates as a refrigerator whenever $J_L > 0$ (see Fig. 1 for the sign convention). In Fig. 2a), we show the heat flows J_L, J_R and energy flow \dot{E}_M as a function of the measurement strength γ_M . At $\gamma_M = 0$, the measurement apparatus is not active, and the device reduces to a simple double dot subject to a thermal bias. Consequently, the heat flows J_L and J_R have the same magnitude and opposite directions, defining a heat current from hot to cold, as expected. No cooling process takes place. At sufficiently large value of γ_M/g , and for a fixed temperature bias $\Delta T = T_R - T_L$ not exceeding a critical value $\Delta T_c > 0$, energy provided by the measuring apparatus $\dot{E}_M > 0$ (green curve) is used to continuously extract heat from the cold bath ($J_L > 0$, blue curve) and to dissipate it into the hot bath ($J_R < 0$, orange curve). The device then operates as a measurement-fueled refrigerator. Without any further prescription to analyze the nature of the energy flow from the apparatus in terms of heat or work, we can only compute an *apparent* efficiency of this process:

1

$$\eta_{\rm app} = \frac{J_L}{\dot{E}_M} \,, \tag{7}$$

plotted in Fig. 2c). This quantity is maximized for $\gamma_M > g$ and $T_R \gtrsim T_L$ where it reaches the value $\eta_{\rm app} \simeq \frac{\Delta(\mu-\epsilon)}{\Omega^2} - \frac{1}{2}$, setting a condition for refrigeration to happen on the dot parameters and the reservoir chemical potential: $\Delta(\mu - \epsilon) > \Omega^2/2$. While efficiency η_{app} brings some information about the process from the standpoint of the working body dynamics, the energy flows E_M does not reflect the actual resource cost of the measurement. The latter, has been shown to include other contributions on top of the energy transferred to the system, related to the amount of acquired information, and entropy produced during the measurement [3]. In particular, treating the measuring apparatus as a black box can hide an energy balance, where a work input of magnitude larger than E_M is partly dissipated as heat inside the apparatus. To gain further insights into the machine's efficiency, we introduce in the following a thermodynamic model of the measuring apparatus.

General thermodynamic model of the apparatus – In full generality, it is reasonable to assume that the measurement apparatus operates in contact with an environment at temperature T_M (for instance, constituted by its internal degrees of freedom), while being powered by a work source (see Fig. 1). The energy flow received by the working body therefore originates from a combination of heat J_M and work P_M :

$$E_M = J_M + P_M \,. \tag{8}$$

Under this generic description, the second law of thermodynamics imposes at steady state (see Fig. 1 for the sign convention):

$$-\frac{J_L}{T_L} - \frac{J_R}{T_R} - \frac{J_M}{T_M} \ge 0.$$
(9)

Using Eq. (6), we obtain:

$$J_L \le \frac{T_L}{T_R - T_L} \left(P_M + J_M \left(\frac{T_M - T_R}{T_M} \right) \right).$$
(10)

Two limiting operating regimes then emerge for the machine. First, when $T_M = T_R$, *i.e.* when the measurement apparatus operates at the hot bath, refrigeration $J_L \geq 0$ is possible only if $P_M > 0$. This regime corresponds to a conventional work-fueled refrigerator, whose coefficient of performance is limited by Carnot's bound $J_L/P_M \leq \eta_C = T_L/(T_R - T_L)$. In contrast, when $P_M = 0$ and $T_M > T_R$, refrigeration is possible provided $J_M \geq 0$, that is when the measuring apparatus provides heat to the working body. The device then behaves as an autonomous absorption refrigerator [26–29] with three reservoirs at different temperatures, characterized by the coefficient of performance $J_L/J_M \leq \frac{T_R^{-1} - T_M^{-1}}{T_L^{-1} - T_R^{-1}}$. In the general case, the refrigeration process can be fueled by a combination of heat (whenever $J_M \geq 0$) and work (whenever $P_M \geq 0$). The efficiency of conversion of this hybrid combination of resources into positive cooling power is quantified by [30]:

$$\eta = \frac{J_L}{P_M \Theta(P_M) + J_M \left(1 - \frac{T_R}{T_M}\right) \Theta(J_M)} \le \eta_C, \quad (11)$$

where Θ denotes Heaviside's step function. This general analysis shows that the regime of operation and the actual thermodynamic efficiency are controlled by the ratio $\xi = J_M/P_M$ between work and heat inputs of the apparatus, which in turn depends on its microscopic details. The measurement-induced dynamics of the working body (characterized by the measurement rate γ_M) only fixes the value of the total energy flow \dot{E}_M received by the dots. In the following, we analyze a microscopic model of the apparatus which allows us to vary the work versus heat parts of \dot{E}_M , while keeping the measurement-induced dynamics on the system fixed.

QPC as a continuous charge detector. – A QPC is an electronic tunnel junction whose energy-dependent transmission probability $\mathcal{T}(E)$, hence the charge current flowing through it, depends on the charge of a neighbor dot via capacitive coupling [31–34]. Current through the QPC is induced by coupling it to two electrically-biased leads, which we hereafter call source (S) and drain (D) to distinguish them from the L, R reservoirs coupled to the working body. They are characterized by Fermi distributions f_S and f_D , respectively. A schematic of this situation is shown in Fig. 3a. Due to electronic shot noise [35], the measurement takes a finite time to completely project the QD onto one of its charge state. Reciprocally, over a finite integration time Δt (corresponding to the coarse-graining time step of the Lindblad equation). the method provides a weak measurement [22]. The latter costs work associated with maintaining a voltage bias $\Delta V = \mu_M / e$ between source and drain of the QPC, leading to an electrical power consumption $P_M = \Delta V I_{QPC}$. The heat flow J_M equals the total heat current from the source and drain leads.

FIG. 3. a): Realistic measuring apparatus model based on a tunnel junction (QPC) capacitively coupled to the right QD. b): Cooling power $J_L/\gamma g$, c): Coefficient of performance η of the hybrid machine, defined in Eq. (11) and d): Signal-tonoise ratio, as a function of the measuring apparatus temperature T_M and electric bias μ_M . The dashed black line delimits the area $J_L \leq 0$ in which refrigeration is not possible. e): Ratio $\xi = J_M/P_M$ of the heat and power flows used to fuel the measuring apparatus as a function of the electric bias μ_M , for different values of the measuring apparatus temperature T_M . The other parameters are the same as in Fig.

From the microscopic model corresponding to the QPC [33], we derive the measurement-induced Lindbladian with all details provided in the Supp. Mat.:

$$\mathcal{L}_{\text{QPC}} = \sum_{\omega=0,\pm\Omega} \gamma_{\text{QPC}}(\omega) D[\hat{n}_{\omega}], \qquad (12)$$

with

$$\gamma_{\text{QPC}}(\omega) = \int dE \ \mathcal{T}_M(E) f_S(E) (1 - f_D(E - \omega)) + \int dE \ \mathcal{T}_M(E) (1 - f_S(E)) f_D(E + \omega)$$
(13)

In the above, we have defined $\mathcal{T}_M(E) = (\sqrt{\mathcal{T}_1(E)} - \sqrt{\mathcal{T}_0(E)})^2$, where $\mathcal{T}_{0/1}(E)$ is the transparency of the QPC at energy E when the right dot is empty/occupied. Importantly, the Lindbladian \mathcal{L}_{QPC} reduces to \mathcal{L}_M only when $\gamma_{\text{QPC}}(\omega)$ is energy-independent, *i.e.* $\gamma_{\text{QPC}}(\omega) =$

 $\gamma_{\text{QPC}}(\epsilon) \equiv \gamma_M$. This holds true either when $\mu_M \gg \Omega$ (the electric bias powering the measuring apparatus is much larger than the scale of transitions induced in the working body) or when $T_M \gg T_R$ (the apparatus operates at a temperature larger than the two other heat sources, the left and right reservoirs coupled to the QDs). When using \mathcal{L}_{QPC} instead of \mathcal{L}_M in the ME (1), we find that the refrigerator progressively stops working when we exit this ideal regime ($\gamma_{\text{QPC}}(\omega) = \gamma_M$). Figure 3 b) shows the cooling power density plot. J_L becomes negative within the region delimited by the dotted line, which corresponds to the regime where γ_{QPC} is strongly frequency-dependent.

From our microscopic model, we also compute the steady-state electric current through the QPC I_{QPC} , electric power P_M , and heat flow J_M (see Supp. Mat.) to assess the ratio $\xi = J_M/P_M$ as a function of the QPC parameters and the coefficient of performance η (see Eq. (11)). Results are shown in Fig. 3c) and d). We observe that our model can operate in both the work-fueled and heat fueled regime depending on the QPC parameters.

The first regime occurs when $\mu_M \ll \Omega$, and the ratio ξ diverges. It corresponds to the machine being mainly fueled by heat coming from the QPC leads. Refrigeration $(\xi > 0)$ then requires a sufficiently high QPC temperature $T_M > T_R$ and, as discussed earlier, the machine operates as an absorption fridge. The measurement apparatus transfers almost all the heat provided by its reservoirs to the working body $\dot{E}_M \simeq J_M$. Interestingly, this regime achieves high values of the coefficient of performance, almost reaching the apparent efficiency, $\eta \simeq \eta_{\rm app}$.

The second regime corresponds to $\mu_M \gtrsim \Omega$, when the ratio ξ goes to -1. In this case, electrical work is consumed by the apparatus, and is almost entirely dissipated as heat into the QPC reservoirs, $J_M \simeq -P_M$. Only a small fraction of it is transferred to the working body and fuels the refrigerator, $\dot{E}_M \ll P_M$. The machine then works as a conventional refrigerator, with low overall coefficient of performance (see Fig. 3 d).

Even when $\gamma_{\rm OPC}$ is frequency-independent, the measurement performed by the QPC remains nonideal. To relate the thermodynamic performance of the refrigerator to the efficiency of the measurement which fuels it. we compute the signal-to-noise ratio (SNR) of the QPC charge current $r = \Delta I_{OPC}^2 / S_{II}(0)$ (see Supp. Mat.). As shown in Fig. 3 e), higher SNRs, indicating more efficient charge measurements are only obtained in the second regime when $\mu_M \gtrsim \Omega$ (energetically wasteful regime). In contrast, the heat-fueled regime leads to a vanishing SNR. This observation is in full agreement with the analysis of [3] where (i) the work cost of measurement was shown to grow with the amount of extracted information, and (ii) the possibility for measurement-fueled engine to achieve better thermodynamic performance when using inefficient (noisy) measurements was predicted.

Our measurement-fueled refrigerator is a paradigmatic example verifying these predictions. We stress that an important property of the machine to be able to exploit inefficient measurements is the absence of any feedback stroke, unlike some other measurement-powered engines [6, 14, 20, 36, 37].

Conclusions. – We analyzed a measurement-based quantum refrigerator generating steady-state cooling power, whose fuel is brought by the continuous detection of a local electric charge in a double quantum dot system. By introducing a general thermodynamic model for the measuring apparatus, we have shown that the machine can be either fueled by heat (as an absorption fridge), fueled by work (as a conventional fridge), or be an hybrid of both. Without a microscopic model of the measurement apparatus, it is not possible to distinguish between the different operating modes. We have therefore considered a realistic implementation of such a measurement apparatus. in the form of a QPC. The machine can be tuned to be heat-fueled or work-fueled by changing the microscopic parameters of the model (potential bias and temperature). Our analysis shows a trade-off between the thermodynamic efficiency of the refrigerator, and the measurement efficiency, sheding a new light on the thermodynamic balance behind a quantum measurement, and revealing how microscopic parameters impact the nature of measurement-induced energy transfers. While ideal measurements mostly cost and provide work [5], and are extremely wasteful [4], realistic noisy measurements provide heat and can achieve better energy-conversion efficiency. Our results pave the roads towards energetic optimization of quantum measurement protocols, a crucial step in the development of quantum computing. An interesting follow-up would be to relate the heat content of the energy provided by the measurement to measures of the measurement efficiency accessible in the dot dynamics, in contrast with SNR. Candidates include the purity of the dot state conditioned to a given value of the QPC current, or the efficiency coefficient appearing in the dot stochastic master equation [24].

A. MICROSCOPIC DERIVATION OF THE MASTER EQUATION

Coarse-graining and secular approximation

The leads $\alpha = L, R$ are microscopically described by bare Hamiltonians H_{α} , and their coupling V_{α} to the dots:

$$H_{\alpha} = \sum_{k} \epsilon_{k} d^{\dagger}_{\alpha,k} d_{\alpha,k}, \qquad V_{\alpha} = \sum_{k} g_{\alpha,k} d_{\alpha,k} c^{\dagger}_{\alpha} + h.c.$$
(S1)

with $d_{\alpha,k}$ the fermionic annihilation operator for an electron in mode k of reservoir α , and $c_L = |00\rangle \langle 10|, c_R = |00\rangle |01\rangle$ anihilate an electron in the left and right dot, respectively. It is also useful to express the double dot Hamiltonian in terms of the local operators:

$$H_{\rm QD} = \epsilon \left(c_+^{\dagger} c_+ - c_-^{\dagger} c_- \right) + \frac{\Delta}{2} \left(c_L^{\dagger} c_L - c_R^{\dagger} c_R \right) + \frac{g}{2} \left(c_L^{\dagger} c_R + c_R^{\dagger} c_L \right).$$
(S2)

The Lindbladians \mathcal{L}_{α} induced by the leads can be derived from a time coarse-graining of the exact Liouville equation for the joint QDs-leads system with time step Δt , followed by a trace over the leads' degrees of freedom. Namely, assuming that lead α is initially in at thermal equilibrium, and after performing Born and Markov approximations [1, 2] we get:

$$\mathcal{L}_{\alpha}\rho = -\frac{1}{\Delta t} \operatorname{Tr}_{\alpha} \left\{ \int_{t}^{t+\Delta t} ds \int_{0}^{\infty} d\tau [V_{\alpha}^{I}(s), [V_{\alpha}^{I}(s-\tau), \rho(s) \otimes \rho_{\alpha}^{\mathrm{eq}}]] \right\}$$
(S3)

The superscript I refers to the interaction picture with respect to the Hamiltonian $H_{\rm QD} + \sum_{\alpha} H_{\alpha}$. The explicit form of the Lindbladian \mathcal{L}_{α} is then obtained from the decomposition of V_{α} in the basis of eigenoperators of $H_{\rm QD}$, and a crucial approximation called the secular approximation [1]. This approximation consists in neglecting in Eq.(S3) the terms oscillating in time s at frequency ω larger than Δt^{-1} . Indeed, these terms will have a smaller weight than the other terms by a factor $\operatorname{sinc}(\omega\Delta t/2) \ll 1$, with $\omega\Delta t \gg 1$. The approximation therefore requires a sufficiently long coarse-graining time, fulfilling:

$$\Gamma_{\alpha}, \omega_i^{\text{nonsec}} \ll \Delta t^{-1} \ll \omega_i^{\text{sec}}, \tau_c^{-1}, \tag{S4}$$

where τ_c is the memory time of the bath, Γ the magnitude of the lead-induced dissipation (see main text) and $\{\omega_j^{\text{nonsec}}, \omega_i^{\text{sec}}\}\$ are frequencies involved in the system's free dynamics. It is only when all the system's frequencies are much larger than Γ_{α} that the secular approximation is fully justified. The compliance of the dynamics with thermodynamic laws is then well-understood [3]. Here, we have

$$c_{\alpha}^{I}(t) = e^{-i\epsilon t} \sum_{l=\pm,n=0,1} e^{-il\Omega t/2} e^{-inUt} A_{\alpha,n,l} , \qquad (S5)$$

where

$$\begin{cases}
A_{L,0,+} = \cos(\theta)|00\rangle\langle +| \\
A_{L,0,-} = -\sin(\theta)|00\rangle\langle -| \\
A_{R,0,+} = \sin(\theta)|00\rangle\langle +| \\
A_{R,0,-} = \cos(\theta)|00\rangle\langle -|
\end{cases}
\begin{cases}
A_{L,1,+} = \cos(\theta)|-\rangle\langle 11| \\
A_{L,1,-} = \sin(\theta)|+\rangle\langle 11| \\
A_{R,1,+} = -\sin(\theta)|-\rangle\langle 11| \\
A_{R,1,-} = \cos(\theta)|+\rangle\langle 11|,
\end{cases}$$
(S6)

are eigenoperators of $H_{\rm QD}$, whose eigenstates fulfill:

$$|+\rangle = \cos(\theta)|10\rangle + \sin(\theta)|01\rangle,$$
 (S7)

$$|-\rangle = -\sin(\theta)|10\rangle + \cos(\theta)|01\rangle.$$
(S8)

Anticipating that we will assume $\epsilon \Delta t \gg 1$, we only keep in Eq. (S3) the terms oscillating as a function of s at frequencies lower than ϵ , i.e. involving one $c_{L,R}$ and one $c_{L,R}^{\dagger}$ only:

$$\mathcal{L}_{\alpha}\rho = -\frac{1}{\Delta t} \int_{t}^{t+\Delta t} ds \int_{0}^{\infty} d\tau \left\langle R_{\alpha}^{I} R_{\alpha}^{I\dagger}(-\tau) \right\rangle \left(c_{\alpha}^{I\dagger}(s) c_{\alpha}^{I}(s-\tau) \rho - c_{\alpha}^{I}(s-\tau) \rho c_{\alpha}^{I\dagger}(s) \right) -\frac{1}{\Delta t} \int_{t}^{t+\Delta t} ds \int_{0}^{\infty} d\tau \left\langle R_{\alpha}^{I\dagger} R_{\alpha}^{I}(-\tau) \right\rangle \left(c_{\alpha}^{I}(s) c_{\alpha}^{I\dagger}(s-\tau) \rho - c_{\alpha}^{I\dagger}(s-\tau) \rho c_{\alpha}^{I}(s) \right) + \text{h.c.}$$
(S9)

When introducing the exact form of $c_{\alpha}^{I}(s-\tau)$, we obtain constant operators multiplied by an exponential factor of the form $e^{i\omega\tau}e^{i\nu s}$. The integration over τ can then be performed yielding numerical factors involving the bath spectral densities, namely:

$$S_{\alpha}(\omega) = \int_{0}^{\infty} d\tau e^{i\omega\tau} \left\langle R_{\alpha}^{I} R_{\alpha}^{I\dagger}(-\tau) \right\rangle$$

$$= \sum_{k,k'} g_{\alpha,k} g_{\alpha,k'} \int_{0}^{\infty} d\tau e^{i(\omega-\omega_{k'})\tau} \left\langle d_{\alpha,k} d_{\alpha,k'}^{\dagger} \right\rangle$$

$$= \sum_{k} g_{\alpha,k}^{2} \left(\pi \delta(\omega-\omega_{k}) - i\mathcal{P} \frac{1}{\omega-\omega_{k}} \right) (1 - f_{\alpha}(\omega_{k}))$$

$$\equiv \frac{1}{2} \Gamma_{\alpha,\downarrow}(\omega) + i\Delta_{\alpha,\downarrow}(\omega)$$
(S10)

and

$$R_{\alpha}(\omega) = \int_{0}^{\infty} d\tau e^{i\omega\tau} \left\langle R_{\alpha}^{I\dagger} R_{\alpha}^{I}(-\tau) \right\rangle$$

$$= \sum_{k,k'} g_{\alpha,k} g_{\alpha,k'} \int_{0}^{\infty} d\tau e^{i(\omega+\omega_{k'})\tau} \left\langle d_{\alpha,k}^{\dagger} d_{\alpha,k'} \right\rangle$$

$$= \sum_{k} g_{\alpha,k}^{2} \left(\pi \delta(\omega+\omega_{k}) - i\mathcal{P}\frac{1}{\omega+\omega_{k}} \right) f_{\alpha}(\omega_{k})$$

$$\equiv \frac{1}{2} \Gamma_{\alpha,\uparrow}(-\omega) - i\Delta_{\alpha,\uparrow}(-\omega) .$$
(S11)

We therefore have

$$\mathcal{L}_{\alpha}\rho = -\frac{1}{\Delta t} \int_{t}^{t+\Delta t} ds \sum_{l,l'=\pm} \sum_{n,n'=0,1} \left(A^{\dagger}_{\alpha,n,l}A_{\alpha,n',l'}\rho - A_{\alpha,n',l'}\rho A^{\dagger}_{\alpha,n,l} \right) S_{\alpha}(\epsilon + l'\Omega/2 + n'U) e^{i(l-l')\Omega s/2} e^{i(n-n')Us}$$
$$-\frac{1}{\Delta t} \int_{t}^{t+\Delta t} ds \sum_{l,l'=\pm} \sum_{n,n'=0,1} \left(A_{\alpha,n,l}A^{\dagger}_{\alpha,n',l'}\rho - A^{\dagger}_{\alpha,n',l'} \right) \rho A_{\alpha,n,l} R_{\alpha}(-\epsilon - l'\Omega/2 - n'U) e^{-i(l-l')\Omega s/2} e^{-i(n-n')Us}$$
$$+ \text{h.c.}$$
(S12)

The integration over s yields numerical coefficients of the form

$$\int_{t}^{t+\Delta t} ds e^{i\omega_{l,l',n,n'}s} = \Delta t e^{i\omega_{l,l',n,n'}(t+\Delta t/2)} \operatorname{sinc}(\omega_{l,l',n,n'}\Delta t/2),$$
(S13)

where $\omega_{l,l',n,n'} = (l-l')\Omega/2 + (n-n')U$ and $\operatorname{sinc}(x) = \sin(x)/x$ (or the complex conjugate of the above expression). Now, we see that depending on the relationship between Δt , Ω and U, the sinc function will be either of the order of unity $\omega_{l,l',n,n'}\Delta t \gtrsim 1$ or vanishingly small $\omega_{l,l',n,n'}\Delta t \gg 1$, and the master equation will involve terms sensitive to different subsets of the frequencies $\{\omega_{l,l',n,n'}\}$, which are nothing but the Bohr frequencies of the two dot system (minus the charging energy ϵ assumed to be big). Finally, the inequality $\Delta tU \gg 1$ (resp. $\Delta t\Omega \gg 1$) imposes that only the terms n = n' (resp. l = l') of Eq. (S3) must be kept in the final master equation. An even more general treatment would add another index $k = \pm$ for the dependence in ϵ , define frequencies $\omega_{l,l',n,n',k,k'} = \omega_{l,l',n,n'} + (k-k')\epsilon$ allowing to study the case $\epsilon \Delta t \ll 1$ that we have ruled out from the beginning. We distinguish four cases from the most "secular" (all transition frequencies are resolved separately by the bath, the Lindblad operators appearing in the Lindbladian act on the total dot system, that is, are "global") to the most "local" (only ϵ is resolved, the Lindblad operators are local):

- 1. If $\epsilon, U, \Omega \gg \Delta t^{-1} \gg \Gamma$, only the terms l = l' and n = n' survive.
- 2. If $\epsilon, U \gg \Delta t^{-1} \gg \Omega, \Gamma$, only the terms n = n' survive.
- 3. If $\epsilon, \Omega \gg \Delta t^{-1} \gg U, \Gamma$, only the terms l = l' survive.
- 4. If $\epsilon \gg \Delta t^{-1} \gg U, \Omega, \Gamma$, all the terms survive.

After the corresponding terms have been suppressed, the final master equation is obtained by going back to the Schrödinger picture, removing any remaining time dependence. The regime suitable for the measurement-based refrigerator corresponds to case 1, which we focus on in the rest of the Appendix.

Global regime $\epsilon, U, \Omega \gg \Gamma$

In this case we only keep the terms n = n' and l = l', leading to:

$$\mathcal{L}_{\alpha}\rho = -\sum_{l=\pm}\sum_{n=0,1} \left(A_{\alpha,n,l}^{\dagger}A_{\alpha,n,l}\rho - A_{\alpha,n,l}\rho A_{\alpha,n,l}^{\dagger} \right) S_{\alpha}(\epsilon + l\Omega/2 + nU) -\sum_{l=\pm}\sum_{n=0,1} \left(A_{\alpha,n,l}A_{\alpha,n,l}^{\dagger}\rho - A_{\alpha,n,l}^{\dagger}\rho A_{\alpha,n,l} \right) R_{\alpha}(-\epsilon - l\Omega/2 - nU) + \text{h.c.} = -i[H_{\alpha}^{(LS)}, \rho] + \sum_{l=\pm}\sum_{n=0,1} (\Gamma_{\alpha,\downarrow}(\epsilon + l\Omega/2 + nU)D[A_{\alpha,n,l}] + \Gamma_{\alpha,\uparrow}(-\epsilon - l\Omega/2 - nU)D[A_{\alpha,n,l}^{\dagger}]), \quad (S14)$$

where

$$H_{\alpha}^{(LS)} = \sum_{l=\pm} \sum_{n=0,1} \lambda_l^2 \left[\Delta_{\alpha,\downarrow} (\epsilon + \frac{l\Omega}{2} + nU) A_{\alpha,n,l}^{\dagger} A_{\alpha,n,l} + \Delta_{\alpha,\uparrow} (-\epsilon - \frac{l\Omega}{2} - nU) A_{\alpha,n,l} A_{\alpha,n,l}^{\dagger} \right]$$
(S15)

is a small renormalization of the dot energy transition due to the coupling to the reservoirs (Lamb shift) [38]. Finally, we assume that $U \gg T_{\alpha}$ such that the two-electron state $|11\rangle$ is negligibly populated (single-electron regime). This means we keep only the terms n = 0 in Eq. (S14), leading to Eq. (2) of the main text.

B. LOCAL REGIME

1. Master equation

We have also investigated the machine in case 2 defined above, where only the $n \neq n'$ can be neglected, while all the terms in the sum over l, l' must be kept. After writing the result of this procedure back in the Schrödinger picture, we obtain:

$$\mathcal{L}_{\alpha}\rho = -\sum_{n=0,1}\sum_{l,l'=\pm} \left(A_{\alpha,n,l}^{\dagger}A_{\alpha,n,l'}\rho - A_{\alpha,n,l'}\rho A_{\alpha,n,l}^{\dagger} \right) S_{\alpha}(\epsilon + l'\Omega/2 + nU) -\sum_{n=0,1}\sum_{l,l'=\pm} \left(A_{\alpha,n,l}A_{\alpha,n,l'}^{\dagger}\rho - A_{\alpha,n,l'}^{\dagger}\rho A_{\alpha,n,l} \right) R_{\alpha}(-\epsilon - l'\Omega/2 - nU) + \text{h.c.}$$
(S16)

Note that we have performed the integration over s whose only effect is to cancel the $1/\Delta t$ factor. We now apply the assumption that the reservoir's spectral density is flat over the frequency scale Ω , *i.e.* we assume the following substitutions are valid:

$$S_{\alpha}(\epsilon + (l - l')\Omega/2 + nU) \rightarrow S_{\alpha}(\epsilon + nU)$$
 (S17)

$$R_{\alpha}(-\epsilon - (l - l')\Omega/2 - nU) \rightarrow R_{\alpha}(-\epsilon - nU).$$
(S18)

This approximation is expected to be valid in the regime $\Omega \ll T_{\alpha}$, and for a sufficiently slow-varying spectral density of the leads. We also use the identity:

$$\sum_{l} A_{\alpha,n,l} e^{-il\Omega s/2} = |0\rangle_{\alpha} \langle 1| \otimes |n\rangle_{\bar{\alpha}} \langle n|, \qquad (S19)$$

and, as before, apply the single-electron approximation (neglecting population of state $|11\rangle$), and neglect a Hamiltonian's correction to H_{QD} analogous to $H_{\alpha}^{(LS)}$. We obtain:

$$\mathcal{L}_{\alpha}^{(\mathrm{loc})}\rho = \Gamma_{\alpha,\downarrow}(\epsilon)D[c_{\alpha}] + \Gamma_{\alpha,\uparrow}(\epsilon)D[c_{\alpha}^{\dagger}].$$
(S20)

We can see that each lead L now induces a "local" Lindbladian, acting only onto the dot it is coupled to, as in the absence of inter-dot coupling. In the same regime, the coarse-graining time is much shorter than the evolution time-scale Ω^{-1} of $\hat{n}_R(t)$, such that the phenomenological measurement-induced Lindbladian takes the form:

$$\mathcal{L}_M = \gamma_M D[\hat{n}_R]. \tag{S21}$$

2. Error due to the local approximation

To test the stability of the local approximation in our system, we introduce the difference between Eq. (S16) (before the approximation) and Eq. (S16) (after), in the single-electron regime:

$$\delta \mathcal{L}_{\alpha} = \mathcal{L}_{\alpha} - \mathcal{L}_{\alpha}^{(\text{loc})} = -\sum_{l,l'=\pm} \left(A_{\alpha,0,l}^{\dagger} A_{\alpha,0,l'} \rho - A_{\alpha,0,l'} \rho A_{\alpha,0,l}^{\dagger} \right) \delta S_{\alpha,l'} - \sum_{l,l'=\pm} \left(A_{\alpha,0,l} A_{\alpha,0,l'}^{\dagger} \rho - A_{\alpha,0,l'}^{\dagger} \rho A_{\alpha,0,l} \right) \delta R_{\alpha,l'} + \text{h.c.}, \qquad (S22)$$

with $\delta S_{\alpha,l'} = S_{\alpha}(\epsilon + l'\Omega/2 + nU) - S_{\alpha}(\epsilon + nU)$ and $\delta R_{\alpha,l'} = R_{\alpha}(-\epsilon - l'\Omega/2 - nU) - R_{\alpha}(-\epsilon - nU)$. Neglecting the Hamiltonian part, we obtain:

$$\delta \mathcal{L}_{\alpha} = \sum_{l,l'=\pm} \left(A^{\dagger}_{\alpha,0,l} A_{\alpha,0,l'} \rho - A_{\alpha,0,l'} \rho A^{\dagger}_{\alpha,0,l} \right) \Gamma_{\alpha} \delta f_{\alpha,l'} - \sum_{l,l'=\pm} \left(A_{\alpha,0,l} A^{\dagger}_{\alpha,0,l'} \rho - A^{\dagger}_{\alpha,0,l'} \rho A_{\alpha,0,l} \right) \Gamma_{\alpha} \delta f_{\alpha,l'} + \text{h.c.}, \qquad (S23)$$

with $\delta f_{\alpha,l'} = f_{\alpha} \left(\epsilon + l' \frac{\Omega}{2} \right) - f_{\alpha} \left(\epsilon \right) = -\frac{l'\Omega}{2kT_{\alpha}} f_{\alpha} \left(\epsilon \right) \left(1 - f_{\alpha} \left(\epsilon \right) \right) + \mathcal{O}(\frac{\Omega}{kT_{\alpha}})^2.$

3. Energy flows in the local regime

After solving the master equation in the local regime in the steady state, we inject the solution into the definitions of the heat provided by the leads and the energy flow from the measuring apparatus, and we get:

$$J_L = A^{-1}(f_R - f_L)g^2 j_+, \qquad J_R = A^{-1}(f_R - f_L)g^2 j_-, \qquad \dot{E}_M = A^{-1}(f_R - f_L)g^2 \gamma_M \Delta, \qquad (S24)$$

where we have defined a positive constant A verifying

$$A = \frac{g^2(\gamma_M + \Gamma_{\downarrow})(\Gamma_{\downarrow} + 2\Gamma_{\uparrow})}{\Gamma_L \Gamma_R} + (1 - f_L f_R)((\gamma_M + \Gamma_{\downarrow})^2 + 4\Delta^2)$$
(S25)

and energy currents

$$j_{\pm} = \pm \gamma_M(\epsilon_{\pm} - \mu) \pm \left(\Gamma_{L,\downarrow}(\epsilon_{-} - \mu) + \Gamma_{R,\downarrow}(\epsilon_{+} - \mu) \right),$$
(S26)

where $\epsilon_{\pm} = \epsilon \pm \Delta/2$ are the local energies of the left and right dots respectively. We have introduced the short-hand notation $\sum_{\alpha=L,R} \Gamma_{\alpha,\uparrow} = \Gamma_{\uparrow}$ (and similarly for Γ_{\downarrow}). These expressions verify as expected: $J_L + J_R + J_M = 0 = dU/dt$.

We can see that all the flows are proportional to g^2 , which means that they vanish in the absence of inter-dot coupling. They can be tracked back to the contribution of the dot internal energy associated with the inter-dot coupling $V_{L-R} = \frac{g}{2} \left(c_L^{\dagger} c_R + c_R^{\dagger} c_L \right)$. This scaling makes these steady-state energy flows of the same order of magnitude or smaller than the errors due to the local approximation, which we confirmed by a numerical analysis.

4. Conditions for refrigeration

Refrigeration occurs when $J_L \ge 0$, i.e. when $(f_R - f_L)j_+ > 0$, which implies a sufficiently large measurement rate:

$$\gamma_M \ge \frac{\Delta(\Gamma_R f_R - \Gamma_L f_L) - 2(\epsilon - \mu)\Gamma_\downarrow}{\Delta + 2(\epsilon - \mu)}.$$
(S27)

In addition, Δ and $(\epsilon - \mu)$ must have opposite signs. When this holds, we find that the energy flow exchanged with the measuring apparatus has the sign of $\Delta(f_R - f_L)$, which is negative. This is surprising at it implies that the measurement process takes away energy while both the hot and cold reservoirs are cooled down. This seems to be in contradiction with the fact that continuous unread measurements of a quantum system always increase its entropy. This results casts additional doubts on the validity of the heat flows predicted by the local Lindblad equation for this problem.

The results of the last two sections suggest that, in the weak lead-QDs coupling regime, the machine can generate significant cooling power only in the global regime where $\Omega = \sqrt{g^2 + \Delta^2} \gg \Gamma_{L,R}$.

C. MEASUREMENT WITH A QUANTUM POINT CONTACT

1. Microscopic model of the QPC

We use the model presented in [33]. The total Hamiltonian is $H = H_0 + V$ with $H_0 = H_{QD} + H_S + H_D$ and:

$$H_S = \sum_{q} \omega_q^S s_q^{\dagger} s_q, \qquad H_D = \sum_{p} \omega_p^S d_p^{\dagger} d_p \qquad V = \sum_{qp} (g_{qp} + \chi_{qp} \hat{n}_R) (s_q^{\dagger} d_p + d_p^{\dagger} s_q) = \Upsilon + \Xi \hat{n}_R + \text{H.c.}$$
(S28)

Here s_q and d_p are fermionic annihilation operators associated with QPC source and drain electron reservoirs. We have introduced the projectors Π_{\pm} acting onto the dot eigenstates $|\pm\rangle$, such that the occupation of the right dot verifies $\hat{n}_R = |01\rangle\langle 01| = \sin(\theta)^2 \Pi_+ + \cos(\theta)^2 \Pi_- + \cos(\theta)\sin(\theta)(|+\rangle\langle -|+|-\rangle\langle +|)$. In the interaction picture with respect to Hamiltonian H_0 , the density operator ρ_{tot}^I of the QDs and QPC evolves according to:

$$\dot{\rho}_{\text{tot}}^{I} = -i[V^{I}(t), \rho_{\text{tot}}^{I}], \qquad (S29)$$

where the interaction-picture coupling Hamiltonian takes the form $V^{I}(t) = \Upsilon(t) + \Xi(t)\hat{n}_{R}(t)$ with

$$\Upsilon(t) = \sum_{qp} g_{qp} s_q^{\dagger} d_p e^{i(\omega_q^S - \omega_p^D)t} + \text{h.c.}, \qquad \Xi(t) = \sum_{qp} \chi_{qp} s_q^{\dagger} d_p e^{i(\omega_q^S - \omega_p^D)t} + \text{h.c.}, \qquad \hat{n}_R(t) = \sum_{\omega = 0, \pm \Omega} n_\omega e^{i\omega t} .(S30)$$

Here, we have introduced the operators $\hat{n}_0 = \cos(\theta)^2 \Pi_+ + \sin(\theta)^2 \Pi_-$, $\hat{n}_\Omega = \cos(\theta) \sin(\theta) |+\rangle \langle -|$ and $\hat{n}_{-\Omega} = \cos(\theta) \sin(\theta) |-\rangle \langle +|$. By coarse-graining the evolution equation over a time Δt , we obtain:

$$\Delta \rho_{\text{tot}}^{I} = -i \int_{t}^{t+\Delta t} dt' [V^{I}(t'), \rho_{\text{tot}}^{I}(t)] - \int_{t}^{t+\Delta t} dt' \int_{t}^{t'} dt'' [V^{I}(t'), [V^{I}(t''), \rho_{\text{tot}}^{I}(t'')].$$
(S31)

6

To express the final expressions as integrals over the energy, it is convenient to take the continuous limit of the spectra of the source and drain reservoirs. We therefore define:

$$\mathcal{T}_{0}(E) = 2 \sum_{qk} g_{qk}^{2} \delta(\omega_{q}^{S} - E)$$

$$\mathcal{T}_{1}(E) = 2 \sum_{qk} (g_{qk} + \chi_{qk})^{2} \delta(\omega_{q}^{S} - E)$$

$$\mathcal{T}_{M}(E) = 2 \sum_{qk} \chi_{qk}^{2} \delta(\omega_{q}^{S} - E) = \left(\sqrt{\mathcal{T}_{0}(E)} - \sqrt{\mathcal{T}_{1}(E)}\right)^{2},$$
(S32)

with $\chi_{qk} \leq 0$ (see also [33]).

2. QPC-induced dynamics

Taking the partial trace over the source and drain spaces of Eq. (S31), we obtain:

$$\begin{aligned} \mathcal{L}_{\text{QPC}}\rho &= \frac{1}{\Delta t} \text{Tr}_{\text{S},\text{D}} \{ \Delta \rho_{\text{tot}}^{I}(t) \} \\ &= -\frac{1}{\Delta t} \int_{t}^{t+\Delta t} dt' \int_{t}^{t'} dt'' \text{Tr}_{\text{S},\text{D}} \{ [V^{I}(t'), [V^{I}(t''), \rho_{\text{tot}}^{I}(t'')] \} \\ &= -\frac{1}{\Delta t} \int_{t}^{t+\Delta t} dt' \int_{0}^{t'-t} d\tau \sum_{\omega,\omega'0,\pm\Omega} \text{Tr}_{\text{S},\text{D}} \{ [\Upsilon + \Xi \hat{n}_{\omega}^{\dagger} e^{-i\omega t'}, [\Upsilon(-\tau) + \Xi(-\tau) \hat{n}_{\omega'} e^{i\omega'(t'-\tau)}, \rho_{\text{qd}}^{I}(t) \otimes \rho_{\text{S},\text{D}}^{\text{eq}}] \}$$
(S33)

We now apply the secular approximation, assuming $\Omega \gg \Delta t^{-1} \gg \gamma_M$, similar to the procedure we followed to derive the reservoir-induced dynamics in the global regime. We therefore only keep the terms $\omega = \omega'$:

$$\begin{aligned} \mathcal{L}_{\rm QPC}\rho &= -\frac{1}{\Delta t} \int_{t}^{t+\Delta t} dt' \int_{0}^{t'-t} d\tau \operatorname{Tr}_{\rm S,D} \{ [\Upsilon + \Xi \hat{n}_{0}, [\Upsilon(-\tau) + \Xi(-\tau)\hat{n}_{0}, \rho_{\rm qd}^{I}(t) \otimes \rho_{\rm S,D}^{\rm eq}] \} \\ &- \sum_{\omega = \pm \Omega} \frac{1}{\Delta t} \int_{t}^{t+\Delta t} dt' \int_{0}^{t'-t} d\tau \operatorname{Tr}_{\rm S,D} \{ [\Xi \hat{n}_{\omega}^{\dagger}, [\Xi(-\tau)\hat{n}_{\omega}e^{-i\omega\tau}, \rho_{\rm qd}^{I}(t) \otimes \rho_{\rm S,D}^{\rm eq}] \} \\ &= \frac{1}{\Delta t} \int_{t}^{t+\Delta t} dt' \int_{0}^{t'-t} d\tau \operatorname{Tr}_{\rm S,D} \{ [(\Upsilon(-\tau) + \Xi(-\tau)\hat{n}_{0})\rho_{\rm qd}^{I}(t) \otimes \rho_{\rm S,D}^{\rm eq}, (\Upsilon + \Xi \hat{n}_{0})] \} + \text{h.c.} \\ &+ \sum_{\omega = \pm \Omega} \frac{1}{\Delta t} \int_{t}^{t+\Delta t} dt' \int_{0}^{t'-t} d\tau e^{-i\omega\tau} \operatorname{Tr}_{\rm S,D} \{ [\Xi(-\tau)\hat{n}_{\omega}\rho_{\rm qd}^{I}(t) \otimes \rho_{\rm S,D}^{\rm eq}, \Xi \hat{n}_{\omega}^{\dagger}] \} + \text{h.c.} \\ &= \frac{1}{\Delta t} \int_{t}^{t+\Delta t} dt' \int_{0}^{t'-t} d\tau \Big(\langle \Xi\Xi(-\tau) \rangle [\hat{n}_{0}\rho_{\rm qd}^{I}(t), n_{0}] + \langle \Upsilon\Xi(-\tau) \rangle [\hat{n}_{0}, \rho_{\rm qd}^{I}(t)] \Big) + \text{h.c.} \\ &+ \sum_{\omega = \pm \Omega} \frac{1}{\Delta t} \int_{t}^{t+\Delta t} dt' \int_{0}^{t'-t} d\tau \langle \Xi\Xi(-\tau) \rangle e^{-i\omega\tau} [\hat{n}_{\omega}\rho_{\rm qd}^{I}(t), \hat{n}_{\omega}^{\dagger}] + \text{h.c.} \end{aligned}$$
(S34)

We now use that

$$\operatorname{Tr}\left\{\Xi\Xi(-\tau)\rho_{S,D}^{\mathrm{eq}}\right\} = \sum_{jk} \sum_{lm} \chi_{jk} \chi_{lm} \left(\left\langle s_{j}^{\dagger} d_{k} s_{l} d_{m}^{\dagger} \right\rangle e^{i(\omega_{l}^{S} - \omega_{m}^{D})\tau} + \left\langle s_{j} d_{k}^{\dagger} s_{l}^{\dagger} d_{m} \right\rangle e^{-i(\omega_{l}^{S} - \omega_{m}^{D})\tau} \right)$$
$$= \sum_{jk} \sum_{lm} \chi_{jk} \chi_{lm} \left(\delta_{jl} \delta_{km} \left\langle s_{l}^{\dagger} s_{l} \right\rangle \left\langle d_{k} d_{k}^{\dagger} \right\rangle e^{i(\omega_{l}^{S} - \omega_{m}^{D})\tau} + \delta_{jl} \delta_{km} \left\langle s_{l} s_{l}^{\dagger} \right\rangle \left\langle d_{k}^{\dagger} d_{k} \right\rangle e^{-i(\omega_{l}^{S} - \omega_{m}^{D})\tau} \right)$$
$$= \sum_{kl} \chi_{lk}^{2} \left(f_{l}^{S} (1 - f_{k}^{D}) e^{i(\omega_{l}^{S} - \omega_{k}^{D})\tau} + (1 - f_{l}^{S}) f_{k}^{D} e^{-i(\omega_{l}^{S} - \omega_{k}^{D})\tau} \right)$$
(S35)

and similarly for Υ and cross-correlations between Ξ and Υ , and define

$$A_{\Delta t}(u) = \frac{1}{u^2 \Delta t} (1 + iu\Delta t - e^{iu\Delta t})$$
(S36)

$$G_{\Delta t}(u) = \operatorname{Re}A_{\Delta t}(u) = \frac{1}{u^2 \Delta t} (1 - \cos(u\Delta t))$$
(S37)

$$F_{\Delta t}(u) = \operatorname{Im} A_{\Delta t}(u) = \frac{1}{u} \left(1 - \frac{\sin(u\Delta t)}{u\Delta t} \right) .$$
(S38)

We obtain:

$$\mathcal{L}_{\text{QPC}}\rho = \sum_{\omega=0,\pm\Omega} \sum_{kl} \chi_{kl}^2 \left(A_{\Delta t} (\omega_l^S - \omega_k^D - \omega) f_l^S (1 - f_k^D) + A_{\Delta t} (\omega_k^D - \omega_l^S - \omega) (1 - f_l^S) f_k^D) \right) [\hat{n}_{\omega} \rho_{\text{qd}}^I(t), \hat{n}_{\omega}^{\dagger}] + \text{h.c.} \\ + \sum_{kl} \chi_{kl} g_{kl} \left(A_{\Delta t} (\omega_l^S - \omega_k^D) f_l^S (1 - f_k^D) + A_{\Delta t} (\omega_k^D - \omega_l^S) (1 - f_l^S) f_k^D) \right) [\hat{n}_0, \rho_{\text{qd}}^I(t)] + \text{h.c.}$$
(S39)

We now assume that the width of the function $G_{\Delta t}(u)$, which is given by $1/\Delta t$, is negligible with respect to the typical variation scale of f_l^S and f_k^D , which is a valid approximation when $\Delta t \gg \beta_S, \beta_D$. The regime we consider is then:

$$\Delta t \gg \Omega^{-1}, T_S^{-1}, T_D^{-1}.$$
 (S40)

In this regime, we can replace the function $G_{\Delta t}$ by a Dirac distribution. Introducing:

$$\gamma_{\rm QPC}(\omega) = 2\sum_{kl} \chi_{kl}^2 (f_l^S (1 - f_k^D) \delta(\omega_l^S - \omega_k^D - \omega) + (1 - f_l^S) f_k^D \delta(\omega_l^S - \omega_k^D + \omega)), \tag{S41}$$

which takes the expression given in the main text in the continuous limit of the reservoirs' spectra, we finally obtain:

$$\mathcal{L}_{\text{QPC}}\rho = -i[H'_{LS},\rho] + \sum_{\omega=0,\pm\Omega} \gamma_{\text{QPC}}(\omega)D[\hat{n}_{\omega}]\rho, \qquad (S42)$$

where

$$H_{LS}' = \sum_{\omega=0,\pm\Omega} \sum_{kl} \chi_{kl}^2 \left(f_l^S (1 - f_k^D) F_{\Delta t} (\omega_l^S - \omega_k^D - \omega) - (1 - f_l^S) f_k^D F_{\Delta t} (\omega_l^S - \omega_k^D + \omega) \right) \hat{n}_{\omega}^{\dagger} \hat{n}_{\omega}$$

+2 $\sum_{kl} \chi_{kl} g_{kl} \left(f_l^S (1 - f_k^D) - (1 - f_l^S) f_k^D \right) F_{\Delta t} (\omega_l^S - \omega_k^D) \hat{n}_0$ (S43)

is a small correction to the double-dot energy transitions due to the coupling to the QPC, which is omitted in the main text as it can be included as a re-normalization of Ω .

3. Energy exchanges within the QPC

We assume that the source has a chemical potential $\mu_M > 0$ while the drain Fermi energy is used as the energy reference. We can define power P_M^{in} injected to fuel the QPC, and the heat flows exchanged with the source J_S and drain J_D as:

$$P_M = -\mu_M \frac{d}{dt} \left\langle \sum_q s_q^{\dagger} s_q \right\rangle \tag{S44}$$

$$J_S = -\frac{d}{dt} \left\langle \sum_{q} (\omega_q^S - \mu_M) s_q^{\dagger} s_q \right\rangle \tag{S45}$$

$$J_D = -\frac{d}{dt} \left\langle \sum_p \omega_p^D d_p^{\dagger} d_p \right\rangle \tag{S46}$$

3.1 Work flow

$$P_{M} = -\mu_{M} \operatorname{Tr}_{S,D,qd} \left\{ \sum_{q} s_{q}^{\dagger} s_{q} \frac{\Delta \rho_{\text{tot}}^{I}}{\Delta t} \right\}$$

$$= \mu_{M} \sum_{q} \frac{1}{\Delta t} \int_{t}^{t+\Delta t} dt' \int_{t}^{t'} dt'' \operatorname{Tr} \left\{ s_{q}^{\dagger} s_{q} [\Upsilon(t') + \Xi(t') \hat{n}_{R}(t'), [\Upsilon(t'') + \Xi(t'') \hat{n}_{R}(t''), \rho_{\text{tot}}^{I}(t'')] \right\}$$

$$= \mu_{M} \sum_{q} \frac{1}{\Delta t} \int_{t}^{t+\Delta t} dt' \int_{0}^{t'-\tau} d\tau \left[\left\langle [s_{q}^{\dagger} s_{q}, \Upsilon(t') + \hat{n}_{R}(t') \Xi(t')] (\Upsilon(t'-\tau) + \hat{n}_{R}(t'-\tau) \Xi(t'-\tau)) \right\rangle + \operatorname{H.c.} \right] (S47)$$

We now expand $\hat{n}_R(t) = \sum_{\omega} \hat{n}_{\omega}^{\dagger} e^{-i\omega t}$ and apply as before the secular approximation, keeping terms which do not oscillate as a function of t'. Indeed, those terms all oscillate at a frequency much larger than $\Delta t^{-1} \ll \Omega$. We define

$$j_{qk}(\omega) = \frac{1}{\Delta t} \operatorname{Re} \int_{t}^{t+\Delta t} dt' \int_{0}^{t'-\tau} d\tau \left[f_{q}^{S} (1-f_{k}^{D}) e^{i(\omega_{q}^{S}-\omega_{k}^{D})\tau} - (1-f_{q}^{S}) f_{k}^{D} e^{-i(\omega_{q}^{S}-\omega_{k}^{D})\tau} \right] e^{-i\omega\tau} = G_{\Delta t} (\omega_{q}^{S}-\omega_{k}^{D}-\omega) f_{q}^{S} (1-f_{k}^{D}) - G_{\Delta t} (\omega_{k}^{D}-\omega_{q}^{S}-\omega) (1-f_{q}^{S}) f_{k}^{D}$$
(S48)

to express the non-zero contributions:

$$\frac{1}{\Delta t} \operatorname{Re} \int_{t}^{t+\Delta t} dt' \int_{0}^{t'-\tau} d\tau \operatorname{Tr} \left\{ [s_{q}^{\dagger} s_{q}, \Upsilon] \Upsilon(-\tau) \rho(t) \otimes \rho_{S,D}^{\operatorname{eq}} \right\} = \sum_{k} g_{qk}^{2} j_{qk}(0)$$

$$\frac{1}{\Delta t} \operatorname{Re} \int_{t}^{t+\Delta t} dt' \int_{0}^{t'-\tau} d\tau \operatorname{Tr} \left\{ [s_{q}^{\dagger} s_{q}, \Xi] \Xi(-\tau) \hat{n}_{\omega}^{\dagger} \hat{n}_{\omega} e^{-i\omega\tau} \rho(t) \otimes \rho_{S,D}^{\operatorname{eq}} \right\} = \sum_{k} \chi_{qk}^{2} j_{qk}(\omega) \left\langle \hat{n}_{\omega}^{\dagger} \hat{n}_{\omega} \right\rangle$$

$$\frac{1}{\Delta t} \operatorname{Re} \int_{t}^{t+\Delta t} dt' \int_{0}^{t'-\tau} d\tau \operatorname{Tr} \left\{ [s_{q}^{\dagger} s_{q}, \Xi] \Upsilon(-\tau) \hat{n}_{0} \rho(t) \otimes \rho_{S,D}^{\operatorname{eq}} \right\} = \sum_{k} \chi_{qk} g_{qk} j_{qk}(0) \left\langle \hat{n}_{0} \right\rangle$$

$$\frac{1}{\Delta t} \operatorname{Re} \int_{t}^{t+\Delta t} dt' \int_{0}^{t'-\tau} d\tau \operatorname{Tr} \left\{ [s_{q}^{\dagger} s_{q}, \Upsilon] \Upsilon(-\tau) \hat{n}_{0} \rho(t) \otimes \rho_{S,D}^{\operatorname{eq}} \right\} = \sum_{k} \chi_{qk} g_{qk} j_{qk}(0) \left\langle \hat{n}_{0} \right\rangle$$
(S49)

We obtain:

$$P_M \simeq 2\mu_M \sum_{qk} \left[\left\langle (g_{qk} + \chi_{qk} \hat{n}_0)^2 \right\rangle j_{qk}(0) + \chi^2_{qk} \sum_{\omega = \pm \Omega} \left\langle \hat{n}^{\dagger}_{\omega} \hat{n}_{\omega} \right\rangle j_{qk}(\omega) \right]$$
(S50)

As before, we use that $G_{\Delta t}(u) = \operatorname{Re} A_{\Delta t}(u)$ is much narrower than $f_k^{S,D}(u)$ in the considered regime, which allows us to take the continuous limit of the source and drain spectra:

$$P_M \simeq \mu_M I_{\rm QPC}, \qquad I_{\rm QPC} = \sum_{\omega=0,\pm\Omega} I_{\omega}$$
 (S51)

where:

$$I_{0} = \int dE \mathcal{F}_{0}(E) \left\langle \left(\sqrt{\mathcal{T}_{0}(E)} - \sqrt{\mathcal{T}_{M}(E)} \hat{n}_{0} \right) \left(\sqrt{\mathcal{T}_{0}(E)} - \sqrt{\mathcal{T}_{M}(E)} \hat{n}_{0} \right) \right\rangle,$$

$$I_{\pm\Omega} = \int dE \mathcal{T}_{M}(E) \mathcal{F}_{\omega}(E) \left\langle \hat{n}_{\pm\Omega}^{\dagger} \hat{n}_{\pm\Omega} \right\rangle,$$
(S52)

and

$$\mathcal{F}_{\omega}(E) = f_{S}(E)(1 - f_{D}(E - \omega)) - (1 - f_{S}(E))f_{D}(E + \omega),$$
(S53)

and the QPC transparencies (see Eq.(S32)). We have assumed that $\mathcal{T}_1 \leq \mathcal{T}_0$, such that $\sqrt{\mathcal{T}_M} = \sqrt{\mathcal{T}_0} - \sqrt{\mathcal{T}_1}$ [33].

With the same approach and approximations, we find:

$$J_{S} = -\operatorname{Tr}_{SD,qd} \left\{ \sum_{q} (\omega_{q}^{S} - \mu_{M}) s_{q}^{\dagger} s_{q} \frac{\Delta \rho_{\text{tot}}^{I}}{\Delta t} \right\}$$
$$= \sum_{q} (\omega_{q}^{S} - \mu_{M}) \frac{1}{\Delta t} \int_{t}^{t+\Delta t} dt' \int_{t}^{t'} dt'' \operatorname{Tr} \left\{ s_{q}^{\dagger} s_{q} [\Upsilon(t') + \Xi(t') \hat{n}_{R}(t'), [\Upsilon(t'') + \Xi(t'') \hat{n}_{R}(t''), \rho_{\text{tot}}^{I}(t'')] \right\}$$
$$= 2 \sum_{qk} (\omega_{q}^{S} - \mu_{M}) \left[\left\langle (g_{qk} + \chi_{qk} n_{0})^{2} \right\rangle j_{qk}(0) + \chi_{qk}^{2} \sum_{\omega = \pm \Omega} \left\langle n_{\omega}^{\dagger} n_{\omega} \right\rangle j_{qk}(\omega) \right],$$
(S54)

and

$$J_{D} = -\operatorname{Tr}_{SD,qd} \left\{ \sum_{p} \omega_{p}^{D} d_{p}^{\dagger} d_{p} \frac{\Delta \rho_{\text{tot}}^{I}}{\Delta t} \right\}$$
$$= \sum_{p} \omega_{p}^{D} \frac{1}{\Delta t} \int_{t}^{t+\Delta t} dt' \int_{t}^{t'} dt'' \operatorname{Tr} \left\{ d_{p}^{\dagger} d_{p} [\Upsilon(t') + \Xi(t') \hat{n}_{R}(t'), [\Upsilon(t'') + \Xi(t'') \hat{n}_{R}(t''), \rho_{\text{tot}}^{I}(t'')] \right\}$$
$$= -2 \sum_{qk} \omega_{k}^{D} \left[\left\langle (g_{qk} + \chi_{qk} n_{0})^{2} \right\rangle j_{qk}(0) + \chi_{qk}^{2} \sum_{\omega = \pm \Omega} \left\langle n_{\omega}^{\dagger} n_{\omega} \right\rangle j_{qk}(\omega) \right]$$
(S55)

The total heat flow dissipated by the measuring apparatus then corresponds to

$$J_M = J_S + J_D \,. \tag{S56}$$

3.3 Measurement-induced energy flow

The total energy provided by the QPC reservoirs is therefore:

$$J_M + P_M = 2\sum_{qk} (\omega_q^S - \omega_k^D) \left[\left\langle (g_{qk} + \chi_{qk} n_0)^2 \right\rangle j_{qk}(0) + \chi_{qk}^2 \sum_{\omega = \pm \Omega} \left\langle n_\omega^\dagger n_\omega \right\rangle j_{qk}(\omega) \right]$$
(S57)

As before, we use that $G_{\Delta t}(u) = \operatorname{Re} A_{\Delta t}(u)$ is much narrower than $f_k^{S,D}(u)$ to replace it with a Dirac delta function. As a consequence, the factor $(\omega_k^S - \omega_q^D)j_{qk}(0)$ vanishes:

$$J_{M} + P_{M} = 2 \sum_{qk} \chi_{qk}^{2} \sum_{\omega=0,\pm\Omega} \omega \left\langle n_{\omega}^{\dagger} n_{\omega} \right\rangle \left[f_{q}^{S} (1 - f_{k}^{D}) \delta(\omega_{q}^{S} - \omega_{k}^{D} - \omega) + (1 - f_{q}^{S}) f_{k}^{D} \delta(\omega_{k}^{S} - \omega_{q}^{D} - \omega) \right]$$

$$= \sum_{\omega=0,\pm\Omega} \omega \gamma_{\text{QPC}}(\omega) \left\langle n_{\omega}^{\dagger} n_{\omega} \right\rangle$$

$$= Tr[H_{\text{QD}} \mathcal{L}_{M} \rho_{\text{qd}}]$$

$$= \dot{E}_{M}.$$
(S58)

4. QPC shot noise and signal to noise ratio

4.1 QPC current and activity

As a starting point to evaluate the electric current noise in the QPC, we decompose the evolution of the total system during Δt in terms of jump events between the source and drain reservoirs (which contribute to the QPC current and shot noise), and evolution between such jumps events [39, 40]. Because of the coupling to the double-dot system, each

$$\mathcal{L}^{+}[\rho] = \frac{1}{\Delta t} \operatorname{Tr}_{S,D} \left\{ \int_{t}^{t+\Delta t} dt' \int_{t}^{t'} dt'' V_{+}^{I}(t') \rho_{\text{tot}}^{I}(t'') V_{+}^{I\dagger}(t'') \right\} + \text{H.c.}$$
(S59)
$$\mathcal{L}^{-}[\rho] = \frac{1}{\Delta t} \operatorname{Tr}_{S,D} \left\{ \int_{t}^{t+\Delta t} dt' \int_{t}^{t'} dt'' V_{-}^{I}(t') \rho_{\text{tot}}^{I}(t'') V_{-}^{I\dagger}(t'') \right\} + \text{H.c.}$$
(S59)
$$\mathcal{L}^{\text{nj}}[\rho] = \frac{\Delta \rho_{\text{tot}}^{I}}{\Delta t} - \mathcal{L}^{+}[\rho_{\text{tot}}] - \mathcal{L}^{-}[\rho_{\text{tot}}].$$
(S60)

where

$$V_{+}^{I}(t) = \sum_{qp} \left(g_{qp} + \hat{n}_{R}(t)\chi_{qp} \right) s_{q}^{\dagger} d_{p} e^{i(\omega_{q}^{S} - \omega_{p}^{D})t}$$
(S61)

$$V_{-}^{I}(t) = \sum_{qp} \left(g_{qp} + \hat{n}_{R}(t) \chi_{qp} \right) d_{p}^{\dagger} s_{q} e^{-i(\omega_{q}^{S} - \omega_{p}^{D})t},$$
(S62)

are the terms of the coupling operator $V^{I}(t)$ associated with an electron transfer from the source to the drain (+) and from the drain to the source (-), which verifies $V^{I}_{+}(t) + V^{I}_{-}(t) = V^{I}(t)$.

Using the Fourier decomposition of $\hat{n}_R(t)$, one can further decompose the superoperators \mathcal{L}^{\pm} into components associated with a transition of energy $\hbar\omega \in \{0, \pm\hbar\Omega\}$ in the double-dot system:

$$\mathcal{L}^{\pm} = \sum_{\omega=0,\pm\Omega} \mathcal{L}^{\pm}_{\omega} \quad \text{with} \quad \mathcal{L}^{\pm}_{\omega}[\rho] = \int dE \ \mathcal{F}^{\pm}_{\omega}(E) \ \hat{K}_{\omega}(E)\rho \hat{K}^{\dagger}_{\omega}(E).$$
(S63)

They are defined in terms of the Kraus operators:

$$\hat{K}_0 = \sqrt{\mathcal{T}_0(E)} - \sqrt{\mathcal{T}_M(E)}\hat{n}_0, \qquad \hat{K}_\Omega = \sqrt{\mathcal{T}_M(E)}\hat{n}_\Omega, \qquad \hat{K}_{-\Omega} = \sqrt{\mathcal{T}_M(E)}\hat{n}_{-\Omega}, \qquad (S64)$$

and the functions

$$\mathcal{F}^{+}_{\omega}(E) = f_{S}(E)(1 - f_{D}(E - \omega)), \qquad \mathcal{F}^{-}_{\omega}(E) = (1 - f_{S}(E))f_{D}(E + \omega)$$
 (S65)

We can now express the superoperators measuring the current \mathcal{I} , and the activity \mathcal{A} in the QPC:

$$\mathcal{I} = \mathcal{L}^+ - \mathcal{L}^-$$
 and $\mathcal{A} = \mathcal{L}^+ + \mathcal{L}^-$. (S66)

They are related to the average current and activity, given that the dots are in the state ρ via $I_{\text{QPC}}(\rho) = \text{Tr}\{\mathcal{I}[\rho]\}, A_{\text{QPC}}(\rho) = \text{Tr}\{\mathcal{A}[\rho]\}.$

4.2 Quantum regression approach

The zero-frequency current noise at steady state is defined as:

$$s_{II}(\nu=0) = \int_{-\infty}^{\infty} d\tau S_{II}(\tau), \qquad (S67)$$

where $S_{II}(\tau)$ is the steady-state auto-correlation function of the QPC current. The latter is related to the current and activity operators via [39]:

$$S_{II}(\tau) = \delta(\tau)A_{\rm ss} + \underbrace{\operatorname{Tr}\left\{\mathcal{I}e^{\mathcal{L}_{\rm tot}|\tau|}\mathcal{I}[\rho_{\rm ss}]\right\} - I_{QPC}^2}_{C_{II}(\tau)}.$$
(S68)

To compute the term $C_{II}(\tau)$, we resort to the Quantum Regression formula [41].

$$\forall i \in \{+, -\}, \qquad \left\langle \dot{\Pi}_i(t) \right\rangle = \sum_{j=\pm} A_{ij} \left\langle \Pi_j(t) \right\rangle + B_i, \tag{S69}$$

where $\Pi_{\pm} = |\pm\rangle\langle\pm|$. The matrix **A** and the vector are determined by the master equation (1), using the closure relation $|00\rangle\langle 00| + \Pi_{+} + \Pi_{-} = 1$ to eliminate the population of state $|00\rangle$. The Quantum Regression Theorem then states that the steady-state correlation functions $C_{\mathcal{O}}^{(j)}(\tau) = \text{Tr}\{\Pi_j e^{\mathcal{L}_{qd}\tau} \mathcal{O}[\rho_{ss}]\}$, for any superoperator \mathcal{O} , obey the coupled set of differential equations:

$$\forall i \in \{+, -\}, \qquad \frac{d}{d\tau} C_{\mathcal{O}}^{(i)}(\tau) = \sum_{j=0,\pm} A_{ij} C_{\mathcal{O}}^{(j)}(\tau) + \langle \mathcal{O} \rangle_{\rm ss} B_i, \qquad (S70)$$

with $\langle \mathcal{O} \rangle_{\rm ss} = {\rm Tr} \{ \mathcal{O}[\rho_{\rm ss}] \}$. Introducing the column vector $\vec{C}_{\mathcal{O}}(\tau) = \left(C_{\mathcal{O}}^{(+)}(\tau), C_{\mathcal{O}}^{(-)}(\tau) \right)^T$, one then has:

$$\vec{C}_{\mathcal{O}}(\tau) = \left\langle \mathcal{O} \right\rangle_{\rm ss} \left(e^{A\tau} \left(\frac{\vec{C}_{\mathcal{O}}(0)}{\left\langle \mathcal{O} \right\rangle_{\rm ss}} - \vec{P}_{\rm ss} \right) + \vec{P}_{\rm ss} \right), \tag{S71}$$

where $\vec{P}_{ss} = -\mathbf{A}^{-1}\vec{B} = (p_{+,ss}, p_{-,ss})^T$ is the vector of steady-state populations. Moreover, we note that for any operator $X = \sum_i x_i \Pi_i$, we have $\operatorname{Tr}\{\mathcal{I}X\} = \sum_{k=0,\pm} i_k \operatorname{Tr}\{\Pi_k X\}$, with:

$$i_0 = \int dE \left(\mathcal{F}_0^+(E) - \mathcal{F}_0^-(E) \right) \mathcal{T}_0(E),$$
(S72)

$$i_{+} = \int dE \left[\left(\mathcal{F}_{0}^{+}(E) - \mathcal{F}_{0}^{-}(E) \right) \left(\sqrt{\mathcal{T}_{0}(E)}c^{2} + \sqrt{\mathcal{T}_{1}(E)}s^{2} \right)^{2} + \left(\mathcal{F}_{-\Omega}^{+}(E) - \mathcal{F}_{-\Omega}^{-}(E) \right) \mathcal{T}_{M}(E)c^{2}s^{2} \right]$$
(S73)

$$i_{-} = \int dE \left[\left(\mathcal{F}_{0}^{+}(E) - \mathcal{F}_{0}^{-}(E) \right) \left(\sqrt{\mathcal{T}_{0}(E)} s^{2} + \sqrt{\mathcal{T}_{1}(E)} c^{2} \right)^{2} + \left(\mathcal{F}_{\Omega}^{+}(E) - \mathcal{F}_{\Omega}^{-}(E) \right) \mathcal{T}_{M}(E) c^{2} s^{2} \right].$$
(S74)

Consequently, we can express the QPC current auto-correlation function in terms of $\vec{C}_{\mathcal{I}}(\tau)$ (using once more the closure relation):

$$C_{II}(\tau) = I_{QPC}\left(i_0 + \vec{i} \cdot \frac{\vec{C}_{\mathcal{I}}(\tau)}{\langle I \rangle_{\rm ss}}\right) - I_{QPC}^2 = I_{QPC}\left(i_0 + \vec{i} \cdot \left[e^{\mathbf{A}\tau} \left(\frac{\vec{C}_{\mathcal{I}}(0)}{\langle I \rangle_{\rm ss}} - \vec{P}_{\rm ss}\right) + \vec{P}_{\rm ss}\right] - I_{QPC}\right).$$
(S75)

where $\vec{i} = (i_0 - i_+, i_0 - i_-)$. We finally use that $i_0 + \vec{i} \cdot \vec{P}_{ss} = I_{QPC}$ to deduce the expression of the QPC shot noise:

$$s_{II}(\nu = 0) = A_{\rm QPC} - I_{\rm QPC} \vec{i} \cdot \mathbf{A}^{-1} \left(\frac{\vec{C}_{\mathcal{I}}(0)}{\langle I \rangle_{\rm ss}} - \vec{P}_{\rm ss} \right)$$
$$= \left(a_0 + \vec{a} \cdot \vec{P}_{\rm ss} \right) - \vec{i} \cdot \mathbf{A}^{-1} \left(\begin{array}{c} \left((i_+ - i_0) - \langle I \rangle_{\rm ss} \right) p_{+,ss} \\ \left((i_- - i_0) - \langle I \rangle_{\rm ss} \right) p_{-,ss}. \end{array} \right)$$
(S76)

In the last line, we have introduced the vector $\vec{a} = (a_+ - a_0, a_- - a_0)^T$ and the scalars a_0, a_{\pm} built on the same model as \vec{i}, i_0 and i_{\pm} to evaluate the activity:

$$a_0 = \int dE \left(\mathcal{F}_0^+(E) + \mathcal{F}_0^-(E) \right) \mathcal{T}_0(E),$$
(S77)

$$a_{+} = \int dE \left[\left(\mathcal{F}_{0}^{+}(E) + \mathcal{F}_{0}^{-}(E) \right) \left(\mathcal{T}_{0}(E)c^{2} + \mathcal{T}_{1}(E)s^{2} \right)^{2} + \left(\mathcal{F}_{-\Omega}^{+}(E) + \mathcal{F}_{-\Omega}^{-}(E) \right) \mathcal{T}_{M}(E)c^{2}s^{2} \right]$$
(S78)

$$a_{-} = \int dE \left[\left(\mathcal{F}_{0}^{+}(E) + \mathcal{F}_{0}^{-}(E) \right) \left(\mathcal{T}_{0}(E)s^{2} + \mathcal{T}_{1}(E)c^{2} \right)^{2} + \left(\mathcal{F}_{\Omega}^{+}(E) + \mathcal{F}_{\Omega}^{-}(E) \right) \mathcal{T}_{M}(E)c^{2}s^{2} \right].$$
(S79)

4.3 Signal-to-noise ratio

We evaluate the signal-to-noise ratio by dividing the difference between the two values of the signal ΔI_{QPC} (the electric current through the QPC) and the associated noise $S_{II}(0)$. Precisely:

$$\Delta I_{\rm QPC} = I_{\rm QPC}^0 - I_{\rm QPC}^1$$

where I_{QPC}^0 and I_{QPC}^1 are the values of the current associated with the right dot being empty or occupied, respectively. Those values are obtained from Eqs. (S51)-(S52), by noting that when the right dot is occupied, we have:

$$\langle +|\rho|+\rangle = \cos^2\theta, \qquad \langle -|\rho|-\rangle = \sin^2\theta, \qquad (\langle \hat{n}_R \rangle = 0)$$
 (S80)

$$\langle \hat{n}_0 \rangle = 2\cos^2\theta \sin^2\theta, \qquad \left\langle \hat{n}_{\Omega}^{\dagger}\hat{n}_{\Omega} \right\rangle = \cos^4\theta \sin^2\theta, \qquad \left\langle \hat{n}_{-\Omega}^{\dagger}\hat{n}_{-\Omega} \right\rangle = \cos^2\theta \sin^4\theta$$
(S81)

In contrast, when the right dot is empty, the state of the double dot system is not completely determined and can be parametrized by the population p_{00} of the state $|00\rangle$:

$$\langle +|\rho|+\rangle = \sin^2 \theta (1-p_{00}), \qquad \langle -|\rho|-\rangle = \cos^2 \theta (1-p_{00}), \qquad (\langle \hat{n}_R \rangle = 1)$$
 (S82)

$$\left\langle \hat{n}_{0} \right\rangle = 1 - p_{00}, \qquad \left\langle \hat{n}_{\Omega}^{\dagger} \hat{n}_{\Omega} \right\rangle = \cos^{2} \theta \sin^{4} \theta (1 - p_{00}), \qquad \left\langle \hat{n}_{-\Omega}^{\dagger} \hat{n}_{-\Omega} \right\rangle = \cos^{4} \theta \sin 2\theta (1 - p_{00}). \tag{S83}$$

To evaluate the worst-case signal-to-noise ratio, we select the value of p_{00} corresponding to the smallest signal variation ΔI_{QPC} , which turns out to be $p_{00} = 0$.
