— Abstract

We study computational aspects of first-order logic and its extensions in the semiring semantics developed by Grädel and Tannen. We characterize the complexity of model checking and data complexity of first-order logic both in terms of a generalization of BSS-machines and arithmetic circuits defined over K. In particular, we give a logical characterization of FAC⁰_K by an extension of first-order logic that holds for any K that is both commutative and positive.

1 Introduction

In the last decade, the use of semirings to study provenance has attracted more attention [21, 9, 15, 19, 20]. In this article, we study computational aspects of first-order logic in the semiring semantics originating from the study of provenance in databases [20].

Semirings are algebraic structures that generalize rings by relaxing the requirement for additive inverses. They have found numerous applications in computer science due to their versatility and modularity in modeling and analyzing computational problems [31, 30, 14, 25, 26, 11, 35]. In other words, specific semirings correspond to different computational paradigms or problem domains. Important examples of semirings include the *Boolean semiring* $\mathbb{B} = (\mathbb{B}, \lor, \land, 0, 1)$ as the simplest example of a semiring that is not a ring, the probability semiring $\mathbb{R}_{\geq 0} = (\mathbb{R}_{\geq 0}, +, \cdot, 0, 1)$ consisting of the non-negative reals with standard addition and multiplication, and the semiring of natural numbers $\mathbb{N} = (\mathbb{N}, +, \cdot, 0, 1)$ which consists of natural numbers with their usual operations. Yet, other examples include the semiring of multivariate polynomials $\mathbb{N}[X] = (\mathbb{N}[X], +, \cdot, 0, 1)$ which is the free commutative semiring generated by the indeterminates in X, the tropical semiring $\mathbb{T} = (\mathbb{R} \cup \{\infty\}, \min, +, \infty, 0)$ which consists of the reals expanded with infinity and has min and + respectively plugged in for addition and multiplication, and the Łukasiewicz semiring $\mathbb{L} = ([0, 1], \max, \cdot, 0, 1)$, used in multivalued logic, which endows the unit interval with max addition and multiplication $a \cdot b := \max(0, a + b - 1)$.

Most of the classical complexity theory lives in the domain of the Boolean semiring \mathbb{B} , whereas \mathbb{N} is the domain of problems related to counting, and $\mathbb{R}_{\geq 0}$ for problems with geometric or continuous features. On the other hand, tropical semirings have various applications in performance analysis [28] and reachability problems [14].

Several computation models can be generalized to various classes of semirings. For example, weighted automata and weighted Turing machines label the transitions of the machine with semiring elements representing quantities such as probabilities, costs, or capacities. Different semirings enable automata to model varied quantitative behaviours with a wide array of applications (see, e.g., [24, 1]). Furthermore, circuit complexity theory and algebraic algorithms readily generalize to various families of semirings (see [13] and the references therein).

Semirings have also found applications in database query evaluation. Semiring provenance is an approach to query evaluation in which the result of a query is something more than just mere one-bit true/false answer. The basic idea behind this approach is to annotate the atomic facts in a database by values from some semiring K, and to propagate these values through a query. Depending on the choice of the semiring, the provenance valuation gives information about a query, e.g., regarding its confidence, cost, or the number of assignments that make the query true [20]. Semiring semantics for query languages is currently an actively studied topic in database theory (see, e.g., [8, 22] for Datalog queries and [10, 27, 34] for conjunctive queries).

Semiring semantics has also been defined for first-order logic [19, 33]. In this context, it has particularly been explored via key themes in classical finite model theory, including Ehrenfeucht–Fraïssé games, locality, 0-1 laws, and definability up to isomorphisms [5, 7, 16, 18]. Recently, semiring semantics has been further extended to more expressive logical languages such as fixed-point logic [9] and team-based logics [3]. It is worth noting that the logics in these works differ from the logics studied in the context of weighted machines and logics [24, 1]. In fact, a natural computation model for our purposes is a generalization of the BSS-machine that we define in this article. The inputs of such a machine are finite sequences of the elements of the semiring K whereas the weighted machines operate with classical Boolean inputs.

Contributions. In order to characterize the complexity of model checking, we generalize the well-known BSS-machines [6] to arbitrary semirings. We also give a logical characterisation of (non-uniform) FAC_K^0 by an extension of first-order logic that is true for any semiring K that is commutative and positive.

Organisation. In Section 2.1, we generalize the BSS-model from the reals to a wide variety of semirings and show how classical computations can be simulated on such a machine. In Section 2.2, we go through the basic definitions regarding arithmetic circuits over a semiring In Section 2.3, we define the semiring interpretation of first-order formulas. In Section 3, we characterize the complexity of model checking and the data complexity of first-order logic over a semiring K in terms of a generalization of BSS-machines and in Section 4 we give a characterization via arithmetic circuits defined over K.

2 Preliminaries

We assume familiarity with basic concepts in theoretical computer science, e.g., Turing machines [32]. We start with the fundamental definition of a semiring.

▶ **Definition 1.** A semiring is a tuple $K = (K, +, \cdot, 0, 1)$, where + and \cdot are binary operations on K, (K, +, 0) is a commutative monoid with identity element 0, $(K, \cdot, 1)$ is a monoid with identity element 1, \cdot left and right distributes over +, and $x \cdot 0 = 0 = 0 \cdot x$ for all $x \in K$. K is called commutative if $(K, \cdot, 1)$ is a commutative monoid. As usual, we often write ab instead of $a \cdot b$.

A semiring is ordered if there exists a partial order \leq such that for all $a, b, c \in K$ $a \leq b \implies a + c \leq b + c$ and $0 \leq a, 0 \leq b \implies 0 \leq ab$.

A semiring is positive if it has no divisors of 0, i. e. $ab \neq 0$ for all $a, b \in K$, where $a \neq 0 \neq b$ and if a + b = 0 implies that a = b = 0.

Throughout this paper, we only consider nontrivial semirings, i.e., semirings where $0 \neq 1$.

2.1 BSS_K Machines

▶ **Definition 2.** For a semiring K we define $K^* = \bigcup_{n\geq 0} K^n$ and denote by K_* the set of all x of the form $x = (..., x_{-2}, x_{-1}, x_0.x_1, x_2, ...)$, where $x_i \in K$ for all $i \in \mathbb{Z}$ and for some sufficiently large k, it holds that $x_j = 0$ for all j with $|j| \geq k$.

▶ **Definition 3.** We define two shift operations on K_* . Shift left σ_l , where $\sigma_l(x_i) = x_{i+1}$ and its inverse shift right σ_r , where $\sigma_r(x_i) = x_{i-1}$.

The following definition adapts BSS machines to arbitrary semirings K. The computation nodes of a BSS machine are usually formulated in terms of quotients of polynomial functions with real coefficients. Since semirings generally lack additive and multiplicative inverses, BSS_K machines have no operations corresponding to subtraction and division.

▶ Definition 4 (BSS_K machines). Let K be a semiring. A BSS_K machine consists of an input space $\mathcal{I} = K^*$, a state space $\mathcal{S} = K_*$ and an output space $\mathcal{O} = K^*$, together with a directed graph whose nodes are labelled by 1,..., N. The nodes are of five different types.

- Input node. The node labelled by 1 is the only input node. The node is associated with a next node $\beta(1)$ and the input mapping $g_I: \mathcal{I} \to \mathcal{S}$.
- Output node. The node labelled by N is the only output node. This node is not associated with any next node. Once this node is reached, the computation halts, and the result of the computation is placed on the output space by the output mapping $g_O: S \to O$.
- Computation nodes. A computation node m is associated with a next node $\beta(m)$ and a mapping $g_m: S \to S$ such that for some $c \in K$ and $i, j, k \in \mathbb{Z}$ the mapping g_m is identity on coordinates $l \neq i$ and on coordinate i one of the following holds:
 - $= g_m(x)_i = x_j + x_k \ (addition),$
 - $= g_m(x)_i = x_j \times x_k \quad (multiplication),$
 - $g_m(x)_i = c \ (constant \ assignment).$
- Branch nodes. A branch node m is associated with nodes $\beta^{-}(m)$ and $\beta^{+}(m)$. Given $x \in S$ the next node is $\beta^{-}(m)$ if $x_1 = x_2$ and $\beta^{+}(m)$, otherwise. If K is ordered, instead the next node is $\beta^{-}(m)$ if $x_1 \leq x_2$ and $\beta^{+}(m)$, otherwise.
- Shift nodes. A shift node m is associated either with shift left σ_l or shift right σ_r , and a next node $\beta(m)$.

The input mapping $g_I : \mathcal{I} \to \mathcal{S}$ places an input (x_1, \ldots, x_n) in the state

$$(\ldots,0,\underbrace{1,\ldots,1}_{n},0.x_1,\ldots,x_n,0,\ldots)\in\mathcal{S},$$

where the size of the input n is encoded in unary in the n first negative coordinates. The output mapping $g_O: S \to O$ maps a state to the string consisting of its first l positive coordinates, where l is the number of consecutive ones stored in the negative coordinates starting from the first negative coordinate.

A configuration at any moment of computation consists of a node $m \in \{1, ..., N\}$ and a current state $x \in S$. The (sometimes partial) input-output function $f_M \colon K^* \to K^*$ of a machine M is now defined in the obvious manner. A function $f \colon K^* \to K^*$ is computable if $f = f_M$ for some machine M. A language $L \subseteq K^*$ is decided by a BSS_K machine M if its characteristic function $\chi_L \colon K^* \to K^*$ is f_M .

Example 5. For instance, g_O maps

 $(\ldots, 2, 1, 1, 1, 0.x_1, x_2, x_3, x_4, \ldots) \in \mathcal{S},$

to $(x_1, x_2, x_3) \in \mathcal{O}$.

▶ **Definition 6.** A machine M runs in (deterministic) time $t: \mathbb{N} \to \mathbb{N}$, if M reaches the output in t(|x|) steps for each input $x \in \mathcal{I}$. The machine M runs in polynomial time if t is a polynomial function. The complexity class P_K is defined as the set of all subsets of K^* that are decided by some machine M running in polynomial time.

▶ **Definition 7.** A machine M requires space $s: \mathbb{N} \to \mathbb{N}$, if M reaches the output using s(|x|) coordinates of the state space for each input $x \in \mathcal{I}$. The machine M requires polynomial space if s is a polynomial function. The complexity class PSPACE_K is defined as the set of all subsets of K^* that are decided by some machine M requiring polynomial space.

Arbitrary computations and comparisons need a way to remember intermediate values. To this end, we use $(\ldots, 0, x_1, 1, x_2, 1, \ldots, x_n, 1, 0, \ldots)$ as a more useful starting state of a BSS_K machine. The gap between two input values allows the machine to temporarily store values or move a value from one end of the state space to the other. The following result shows, that obtaining this gap normal form can be achieved with polynomial overhead as an initialization step of a BSS_K machine.

▶ **Proposition 8.** The initial state space $(..., 0, 1, ..., 1, 0.x_1, ..., x_n, 0, ...)$ can be converted into $(..., 0.x_1, 1, x_2, 1..., x_n, 1, 0...)$ with quadratic overhead. Similarly, the reverse direction can be achieved with quadratic overhead.

Proof. Figure 2 in Appendix A implements the subroutine Init, converting the initial configuration into $(\ldots, 0, x_1, 1, x_2, 1, \ldots, x_n, 1, 0, \ldots)$ in $\mathcal{O}(n^2)$ steps. Analogously, Figure 3 implements the reverse.

▶ Remark 9. Using the gap normal form allows easy simulation of branching nodes using $x_i = x_j$ or $x_i = c$ as branching condition.

Next we define a hybrid of a BSS_K -machine and a Turing machine that is technically more convenient for the proofs in other sections.

▶ **Definition 10** (K-TMs). Let K be an arbitrary (ordered) semiring. A K-Turing machine is a tuple $M = (Q, q_0, R, O, P, \Gamma, b, \Sigma, \delta)$ such that

- \blacksquare Q is a finite set of states,
- $q_0 \in Q$ is the initial state,
- \blacksquare R is a finite set of K-valued registers, which are always initialized to 0,
- $\bigcirc O \subseteq \{=, \leq\}, if K is ordered, and otherwise <math>O \subseteq \{=\},$
- $\blacksquare P: Q \to O \times R \text{ is the branch predicate function},$
- \square Γ is a finite set of tape alphabet symbols such that $\Gamma \cap K = \emptyset$,
- $\bullet b \in \Gamma \text{ is the blank symbol,}$
- $\Sigma \subseteq (\Gamma \setminus \{b\}) \cup K \text{ is the set of input symbols,}$
- **—** the partial transition function

 $\delta \colon Q \times (\Gamma \cup \{\top, \bot\}) \to Q \times (\Gamma \cup K \cup \{\mathrm{id}\} \cup (\{+, \cdot\} \times R)) \times \mathcal{P}(R) \times \{\sigma_l, \mathrm{id}, \sigma_r\}$

determines the type of the next transition of the machine. If the value of the function δ is not defined, the machine halts.

The transitions of the machine are defined in the following manner. Let q be the current state and let a be the current tape symbol. If $a \in \Gamma$, the type of the transition is given by $\delta(q, a)$. Otherwise, δ is applied to (q, v), where $v \in \{\top, \bot\}$ is the truth value of the comparison $a \circ x$, where $P(q) = (\circ, r)$ and x is the current value in register r. Then, the value (q', z, s, σ) given by δ is applied as follows:

- = q' is the next state of the machine,
- z determines the symbol to be written on the tape under the head of the machine so that if $z \in \Gamma \cup K$, the symbol z is written, if z = id, the symbol a is not changed, and if both $z = (\star, r)$ and $a \in K$ are true, then the value of the operation $a \star x$ is written on the tape, where x is the current value of the register r, and otherwise the machine halts,
- if $a \in K$, the values of the registers in the set $s \subseteq R$ are set to a, and in the case that both $a \in \Gamma$ and $s \neq \emptyset$ are true, the machine halts,

• the tape is shifted according to the shift operation $\sigma \in \{\sigma_l, \sigma_r\}$ or kept in place ($\sigma = id$). The input mapping g_I maps an input (x_1, \ldots, x_n) into the form $(\ldots, b. x_1, \ldots, x_n, b, \ldots)$. Once the machine halts, the output mapping g_O extracts the string consisting of the first positive coordinates until the first blank symbol with a positive coordinate. The input-output function $f_M: \Sigma^* \to \Sigma^*$ is defined in the obvious manner.

We define a function $f: \Sigma^* \to \Sigma^*$ to be computable by a K-Turing machine, if $f = f_M$ for some K-TM M. The use of time and space are defined in the same manner as for an ordinary Turing machine.

▶ Lemma 11. Let K be a semiring and let $f: K^* \to K^*$ be a function that is computed by a K-Turing machine M that runs in time t and space s. Then there is a BSS_K machine M' computing f and a constant c such that for each $x \in K^*$, the machine M' runs on input x in time $c(t(|x|) + |x|^2 + |f(x)|^2 + 1)$ and in space cs(|x|) + c.

Proof. See Appendix B.

2.2 Arithmetic Circuits

In the upcoming section we will introduce relevant concepts for arithmetic circuits over semirings. For ease of definition, we require the semiring to be commutative, but we note that the definitions would also make sense for non-commutative semirings. One would merely need to add an order to the inputs of any particular gate.

Definition 12. Let K be a commutative semiring. An arithmetic circuit C over K is a connected, directed acyclic graph. Its nodes (also called gates) can be one of the following types:

Input gates are ordered, have indegree 0 and contain the respective input values of the circuit. **Constant gates** have indegree 0 and are labelled with elements of K.

Arithmetic gates can have an arbitrary indegree only bounded by the number of gates in the circuit. They can be labelled with either + or \times .

Output gates are ordered, have outdegree 1 and contain the output values of the circuit after the computation.

We call the number of gates in a circuit C the *size* of C and the longest path from an input gate to an output gate the *depth* of C. We also write size(C) and depth(C) to denote the respective values.

The function $f_C \colon K^n \to K^m$ computed by an arithmetic circuit C with n input gates and m output gates is defined in the obvious way: Initially, the constant gates are associated with their respective constant values and the input $\overline{x} = x_1, \ldots, x_n$ is placed in the input gates. Then, whenever all predecessor gates of an arithmetic gate g have values, g computes the function it is labelled with, taking the values of its predecessors as arguments. Finally, once all arithmetic gates have values, the output gates take the values of their respective single predecessors and the values of the output gates $\overline{y} = y_1, \ldots, y_m$ are the output of the computation, i.e., $f_C(\overline{x}) = \overline{y}$.

A single circuit can only compute a function with a fixed number of arguments, which is why we call arithmetic circuits a *non-uniform* model of computation. In order to talk about arbitrary functions, we need to consider circuit families, i.e., sequences of circuits which contain one circuit for every input length $n \in \mathbb{N}$.

▶ **Definition 13.** Let K be a commutative semiring. A K-circuit family is a sequence of K-circuits $C = (C_n)_{n \in \mathbb{N}}$. The function computed by a circuit family $C = (C_n)_{n \in \mathbb{N}}$ is the function computed by the respective circuit, i.e.,

$$f_{\mathcal{C}}(x) = f_{C_{|x|}}(x).$$
(1)

For a function $f: \mathbb{N} \to \mathbb{N}$, we say that a circuit family \mathcal{C} is of size f (depth f) if the size (depth) of C_n is bounded by f(n) for all $n \in \mathbb{N}$. We also write size(\mathcal{C}) and depth(\mathcal{C}) to denote the respective values.

These notions allow us to define complexity classes with respect to arithmetic circuits.

g	input	$\operatorname{constant}$	+	×	output	=	¥	\leq	Z
type	1	2	3	4	5	6	7	8	9

Table 1 Type associations.

▶ **Definition 14.** Let K be a commutative semiring. Then the class FAC_K^0 consists of all functions $f: K^* \to K$ computable by K-circuit families C such that $size(\mathcal{C}) \in \mathcal{O}(n^{\mathcal{O}(1)})$ and $depth(\mathcal{C}) \in \mathcal{O}(1)$.

These circuits of the previously defined class compute only polynomials. If we want them to mimic branching behaviour akin to BSS_K machines, we need additional control structures. For this reason, we add binary relations to branch on in the following way.

▶ **Definition 15.** Let K be a commutative semiring, let $R \subseteq K^2$ be a relation and let $f_R: K^2 \to \{0, 1\}$ be the characteristic function of R. Then the class $FAC_K^0[R]$ consists of all functions $f: K^* \to K$ computable by K-circuit families C such that $size(\mathcal{C}) \in \mathcal{O}(n^{\mathcal{O}(1)})$ and $depth(\mathcal{C}) \in \mathcal{O}(1)$, where the circuits in C have an additional gate type which computes the function f_R .

Of particular interest for us will be the class $\operatorname{FAC}_{K}^{0}[O]$ for $O \subseteq \{=, \neq, \leq, \leq\}$. (Whenever we extend a logic or a computational model with an O, where $\leq \in O$ or $\not\leq \in O$, we assume the underlying semiring to be ordered.) In order to characterize these classes logically, we mention another useful property thereof: any function in $\operatorname{FAC}_{K}^{0}$ or the aforementioned extensions can be computed by circuits that are essentially trees.

▶ Lemma 16. Let $O \subseteq \{=, \neq, \leq, \neq\}$, let K be a commutative semiring and let $f: K^* \to K \in FAC_K^0[O]$. Then there exists a family of circuits $\mathcal{C} = (C_n)_{n \in \mathbb{N}}$ of size $\mathcal{O}(n^{\mathcal{O}(1)})$ and depth $\mathcal{O}(1)$ computing f such that for each circuit $C \in \mathcal{C}$, each non-input gate has fan-out 1 and for each gate g in C, each input-g path has the same length.

Proof. This is a slight modification of a result about circuit over the reals [4, Lemma 26]. Essentially, for each gate g with more than one successor, we copy the subcircuit that has g on top once for each successor and pad the paths to all have the same length.

In the sequel, when characterizing circuit classes logically, it will be necessary, to be able to refer to properties of individual gates. For this reason, we follow the type associations defined in Tab. 1.

2.3 First-Order Logic under Semiring Interpretations

In this section, we consider first-order logic with semiring semantics from [3] that extends the logic introduced in [21] by adding formula (in)equality that compares the semiring values of first-order formulas. This allows us to express different dependencies logically in the semiring context [3]. In the following, we denote by ar(R) (resp., ar(f)) the *arity* of a relational (resp., functional) symbol R (resp., f).

▶ Definition 17 (First-order logic over semirings). The syntax for the first-order logic (of vocabulary τ) with formula (in)equality over a commutative (ordered) semiring K for a set $O \subseteq \{=, \neq, \leq, \leq\}$, denoted by FO(O), is defined as follows:

 $\phi ::= \alpha \mid \alpha \circ \alpha \mid (\phi \land \phi) \mid (\phi \lor \phi) \mid \exists x \phi \mid \forall x \phi,$

Figure 1 Flight network as a *K*-interpretation.

where $\circ \in O$, x is a variable, and α is defined as below

$$\alpha \mathrel{\mathop:}= x = y \mid x \neq y \mid R(\bar{x}) \mid \neg R(\bar{x}) \mid (\alpha \land \alpha) \mid (\alpha \lor \alpha) \mid \exists x \alpha \mid \forall x \alpha,$$

where x and y are variables, \bar{x} is a tuple of variables such that $\operatorname{ar}(R) = |\bar{x}|$.

If $O = \emptyset$, we write FO instead of FO(\emptyset). Note that any $\alpha \in$ FO is a usual first-order formula in negation normal form. The assumption that K is ordered is required if $\leq \in O$ or $\leq \in O$. The definition of a set of *free variables* FV(ϕ) of a formula $\phi \in$ FO(O) extends from FO in the obvious way: FV($\phi \circ \psi$) = FV(ϕ) \cup FV(ψ), for $\circ \in O$. If ϕ contains no free variables, i.e., FV(ϕ) = \emptyset , it is called a *sentence*.

Let A be a finite set, $\tau = \{R_1, \ldots, R_n\}$ a finite vocabulary, and K a semiring. Define $Lit_{A,\tau}$ as the set of *literals* over A, i.e., the set of facts and negated facts $Lit_{A,\tau} = \{R(\bar{a}) \mid \bar{a} \in A^{\operatorname{ar}(R)}, R \in \tau\} \cup \{\neg R(\bar{a}) \mid \bar{a} \in A^{\operatorname{ar}(R)}, R \in \tau\}$. A K-interpretation is a mapping $\pi: Lit_{A,\tau} \to K$.

▶ **Definition 18.** Let $K = (K, +, \cdot, 0, 1)$ be a commutative (ordered) semiring, and π : Lit_{A, τ} → K a K-interpretation. Let $O \subseteq \{=, \neq, \leq, \not\leq\}$. The π -interpretation of a FO(O)-formula θ under assignment s is denoted by $\llbracket \theta \rrbracket_{\pi,s}$ and defined as follows:

$$\begin{split} \llbracket x \star y \rrbracket_{\pi,s} &= \begin{cases} 1 & \text{if } s(x) \star s(y), \\ 0 & \text{otherwise,} \end{cases} & \text{where } \star \in \{=, \neq\}, \\ \llbracket R(\bar{x}) \rrbracket_{\pi,s} &= \pi(R(s(\bar{x}))), \\ \llbracket \phi \wedge \psi \rrbracket_{\pi,s} &= \llbracket \phi \rrbracket_{\pi,s} \cdot \llbracket \psi \rrbracket_{\pi,s}, \\ \llbracket \exists x \phi \rrbracket_{\pi,s} &= \llbracket \phi \rrbracket_{\pi,s} \cdot \llbracket \psi \rrbracket_{\pi,s}, \\ \llbracket \exists x \phi \rrbracket_{\pi,s} &= \sum_{a \in A} \llbracket \phi \rrbracket_{\pi,s(a/x)}, \\ \llbracket \phi \circ \psi \rrbracket_{\pi,s} &= \begin{cases} 1 & \text{if } \llbracket \phi \rrbracket_{\pi,s} \circ \llbracket \psi \rrbracket_{\pi,s}, \\ 0 & \text{otherwise,} \end{cases} & \text{where } \circ \in \{=, \neq, \leq, \not\leq\}. \end{split}$$

If ϕ is a sentence, we write $\llbracket \phi \rrbracket_{\pi}$ for $\llbracket \phi \rrbracket_{\pi,\emptyset}$.

We say that a K-interpretation π is model-defining [21], if for all $R(\bar{a})$, we have $\pi(R(\bar{a})) = 0$ iff $\pi(\neg R(\bar{a})) \neq 0$.

▶ **Example 19.** Suppose A consists of the airport codes HEL, NRT, LAX, MEL, and τ of one edge relation E. Consider the tropical semiring $\mathbb{T} = (\mathbb{R} \cup \{\infty\}, \min, +, \infty, 0)$. An example \mathbb{T} -interpretation $\pi: Lit_{A,\tau} \to \mathbb{T}$ is obtained by assigning E(x, y), for each pair of airports x and y, a number representing the duration of a direct flight between them, as in Figure 1;

if no direct flight exists between two airports x and y, E(x, y) is assigned ∞ . Furthermore each negated fact $\neg E(x, y)$ can be assigned a number so that π is model-defining. Then, we can express in FO[<] that the duration of a direct flight between any two airports x and y is shorter than the sum of durations for flights from x to z and z to y, for any airport z:

$$\phi \coloneqq \forall xyz (R(x,z) \land R(z,y) < R(x,y)).$$

Clearly, $\llbracket \phi \rrbracket_{\pi} = 0$, that is, ϕ evaluates to the identity element of multiplication under π .

Let \mathcal{A} be a structure of vocabulary τ , and let \mathbb{B} be the Boolean semiring. The canonical truth interpretation $\pi_{\mathcal{A}}$, is the \mathbb{B} -interpretation $\pi \colon Lit_{A,\tau} \to \mathbb{B}$ defined for each $R(\bar{a})$ and $\neg R(\bar{a})$ as follows

$$\pi(R(\bar{a})) = \begin{cases} 1 & \text{if } \bar{a} \in R^{\mathcal{A}} \\ 0 & \text{if } \bar{a} \notin R^{\mathcal{A}} \end{cases}$$

and $\pi(\neg R(\bar{a})) = 1 - \pi(R(\bar{a})).$

The following proposition shows that for FO-formulas, the canonical truth interpretation $\pi_{\mathcal{A}}$ under an assignment s corresponds to the usual first-order formula evaluation under s in the structure \mathcal{A} . It can be proven by induction on α .

▶ Proposition 20 ([21]). Let α be an FO-formula, and \mathcal{A} a structure. Then $\llbracket \alpha \rrbracket_{\pi_{\mathcal{A}},s} = 1$ if and only if $\mathcal{A} \models_s \alpha$.

Let $\xi_K \colon K \to \mathbb{B}$ be the characteristic mapping such that $\xi_K(a) = 0$ if a is the zero element of K and $\xi_K(a) = 1$ otherwise.

▶ Proposition 21 ([3]). Let K be a positive semiring, and π : Lit_{A, τ} → K an interpretation. Then for all $\alpha \in \text{FO}$, $[\![\alpha]\!]_{\pi} = 0$ if and only if $[\![\alpha]\!]_{\xi_K \circ \pi} = 0$.

Sentences ϕ and ψ of FO(O) are K-equivalent, written as $\phi \equiv_K \psi$, if $\llbracket \phi \rrbracket_{\pi} = \llbracket \psi \rrbracket_{\pi}$ for all K-interpretations. For logics \mathcal{L} and \mathcal{L}' , we write $\mathcal{L} \leq_K \mathcal{L}'$ if for each sentence ϕ from \mathcal{L} there is a sentence ψ from \mathcal{L}' such that $\phi \equiv_K \psi$. If $\mathcal{L} \leq_K \mathcal{L}'$ and $\mathcal{L}' \leq_K \mathcal{L}$, we write $\mathcal{L} \equiv_K \mathcal{L}'$, and say that \mathcal{L} and \mathcal{L}' are equally expressive under K.

In case of the Boolean semiring \mathbb{B} (with 0 < 1), having access to formula (in)equality does not increase expressivity in the sense of the following proposition.

▶ Proposition 22 ([3]). FO $\equiv_{\mathbb{B}}$ FO(=, \neq , \leq , \leq)

Proof. Follows by simple induction from the fact that we have the following B-equivalences $\phi \leq \psi \equiv_{\mathbb{B}} \operatorname{nnf}(\neg \phi) \lor \psi, \phi \not\leq \psi \equiv_{\mathbb{B}} \phi \land \operatorname{nnf}(\neg \psi), \phi = \psi \equiv_{\mathbb{B}} (\phi \land \psi) \lor (\operatorname{nnf}(\neg \phi) \land \operatorname{nnf}(\neg \psi)), \text{ and } \phi \neq \psi \equiv_{\mathbb{B}} (\operatorname{nnf}(\neg \phi) \land \psi) \lor (\phi \land \operatorname{nnf}(\neg \psi)), \text{ where we use the notation nnf}(\neg \alpha), \alpha \in FO$ for the formula obtained from $\neg \alpha$ by pushing the negation in front of the atomic formulas.

The following example shows that the above proposition does not hold for all K.

Example 23. Let $\mathbb{N} = (\mathbb{N}, +, \cdot, 0, 1)$ be the semiring of natural numbers. Then

 $FO \not\equiv_{\mathbb{N}} FO(=, \neq, \leq, \not\leq).$

Define $\phi = \forall x P(x) = \forall x Q(x)$. We show that ϕ cannot be translated to FO. Suppose for a contradiction that $\alpha_{\phi} \in \text{FO}$ is such that $\alpha_{\phi} \equiv_{\mathbb{N}} \phi$. Let $A = \{1, \ldots, n\}, \tau = \{P, Q\},$ $\operatorname{ar}(P) = \operatorname{ar}(Q) = 1$, and the interpretations $\pi \colon Lit_{A,\tau} \to \mathbb{N}$ and $\pi' \colon Lit_{A,\tau} \to \mathbb{N}$ be such that, for all $i \in A$,

 $\pi(P(i)) = 1, \ \pi(\neg P(i)) = 0, \ \pi(Q(i)) = 1, \ \pi(\neg Q(i)) = 0; \ \text{and}$ $\pi'(P(i)) = 1, \ \pi'(\neg P(i)) = 0, \ \pi'(Q(i)) = 2, \ \pi'(\neg Q(i)) = 0.$ Then $\llbracket \phi \rrbracket_{-} = 1$ because $\llbracket \forall x P(x) \rrbracket_{-} = 1$ and $\llbracket \forall x Q(x) \rrbracket_{-} = 1$. On the other

Then $\llbracket \phi \rrbracket_{\pi} = 1$, because $\llbracket \forall x P(x) \rrbracket_{\pi} = 1$ and $\llbracket \forall x Q(x) \rrbracket_{\pi} = 1$. On the other hand, $\llbracket \phi \rrbracket_{\pi'} = 0$, because $\llbracket \forall x P(x) \rrbracket_{\pi'} = 1$ and $\llbracket \forall x Q(x) \rrbracket_{\pi'} = 2^n$.

Now $[\![\alpha_{\phi}]\!]_{\pi} = [\![\phi]\!]_{\pi} = 1$ and $[\![\alpha_{\phi}]\!]_{\pi'} = [\![\phi]\!]_{\pi'} = 0$, so by Proposition 21, $[\![\alpha_{\phi}]\!]_{\xi_{\mathbb{N}}\circ\pi} \neq 0$ and $[\![\alpha_{\phi}]\!]_{\xi_{\mathbb{N}}\circ\pi'} = 0$. But since $\xi_{\mathbb{N}} \circ \pi = \xi_{\mathbb{N}} \circ \pi'$, this is impossible.

Note that similar arguments show that the sentences $\forall x P(x) \neq \forall x Q(x), \forall x Q(x) \leq \forall x P(x)$, and $\forall x Q(x) \leq \forall x P(x)$ cannot be translated to FO either.

In order to compare this logic to the machine models we introduced, we need to identify it with a fitting set of functions. For any $O \subseteq \{=, \neq, \leq, \not\leq\}$, any FO(O) sentence can essentially be seen as a function from the set of K-interpretations to K. To make this fit in with our machine models, we define an encoding for K-interpretations, so that the function defined by an FO(O) sentence can be seen as function from K^* to K.

▶ **Definition 24.** Let A be a strictly ordered set, let τ be a relational signature, let $Lit_{A,\tau} = \{\ell_1, \ldots, \ell_n\}$, let K be a positive semiring and let π : $Lit_{A,\tau} \to K$ be a K-interpretation. Then we define $enc(\pi)$ to be the concatenation of the values assigned to each literal by π , i.e.,

$$enc(\pi) \coloneqq (\pi(\ell_1), \dots, \pi(\ell_n)) \in K^n$$

For technical reasons, we encode literals of relation symbols R of arity 0 as if they had arity 1, i.e, as |A| copies of $\pi(R())$.

Of particular interest is that we can determine |A| from $|enc(\pi)|$. With this minor technical change at hand, we can now compute |A| from $|enc(\pi)|$ and τ .

▶ Lemma 25. Let A be a strictly ordered set, let τ be a relational vocabulary, let K be a semiring and π : Lit_{A, τ} → K be a K-interpretation. We can compute |A| when given $|enc(\pi)|$ in logarithmic time on a BSS_K machine.

Proof. We can use, e.g., binary search to find the solution for |A| in

$$|enc(\pi)| = \sum_{R \in \tau} |A|^{\max(\operatorname{ar}(R),1)} \cdot 2$$

in logarithmic time.

To characterize circuit classes logically later on, we need to extend this logic by additional "built-int" K-relations that are not part of the K-interpretation. To that end we will slightly extend the syntax of FO(O) to FO(O, F) for particular function families F. We essentially want to allow additional K-relations that may depend on the size of A, but not on A itself. We therefore treat ordered sets of the same cardinality as isomorphic to the first |A| natural numbers and thus define the aforementioned function families accordingly. The set Arb_K is the set of all function families of the aforementioned kind.

<

▶ Definition 26. Let K be a semiring. Then

$$\operatorname{Arb}_{K} \coloneqq \bigcup_{k \in \mathbb{N}} \{ (f_{n})_{n \in \mathbb{N}} \mid f_{n} \colon \{1, \dots, n\}^{k} \to K \text{ for all } n \in \mathbb{N} \}.$$

We also need to extend the notion of a signature to allow to differentiate between built-in K-relations and those given by the input K-interpretation.

▶ Definition 27. Let $O \subseteq \{=, \neq, \leq, \not\leq\}$, let τ and σ be relational vocabularies and let K be a positive semiring. Then for any set of function families $F \subseteq \operatorname{Arb}_K$ we define the syntax of $\operatorname{FO}(O, F)$ formulae over a signature (τ, σ) by extending the Backus-Naur-form for $\operatorname{FO}(O)$ formulae by the rule

$$\alpha ::= P(\overline{x}) \mid \neg P(\overline{x}),$$

where $P \in \sigma$ and \overline{x} is a tuple of variables such that $|\overline{x}| = \operatorname{ar}(P)$.

Defining the semantics of FO(O, F) requires a bit of care. We give each function family in F a *fixed* symbol, such that each symbol P in σ is interpreted as its predefined counterpart in F. Note also that, unlike in the classical setting, negative occurrences of each $P \in \sigma$ need a separate interpretation in F.

▶ **Definition 28.** Let $O \subseteq \{=, \neq, \leq, \neq\}$, let K be a positive semiring, let $F \subseteq \operatorname{Arb}_K$ be a family of functions, let τ and σ be finite, relational vocabularies, such that $|F| \ge 2 \cdot |\sigma|$ and let $(\rho_n)_{n \in \mathbb{N}}$ be a family of K-interpretations such that for each $P \in \sigma$ there exist families $(f_n)_{n \in \mathbb{N}}$ and $(f'_n)_{n \in \mathbb{N}}$ in F, such that $\rho_n(P(\overline{a})) = f_n(\overline{a})$ and $\rho_n(\neg P(\overline{a})) = f'_n(\overline{a})$ for all $\overline{a} \in \{1, \ldots, n\}^{\operatorname{ar}(P)}$.

Let furthermore A be a strictly ordered set, let $\pi: Lit_{A,\tau} \to K$ be a K-interpretation and s be an assignment. Then the semantics of $FO(O, F, \rho)$ extend the semantics for FO(O) by

 $[\![P(\overline{x})]\!]_{\pi,\rho,s} = \rho_{|A|}(P(r(s(\overline{x})))), \qquad [\![\neg P(\overline{x})]\!]_{\pi,\rho,s} = \rho_{|A|}(\neg P(r(s(\overline{x})))),$

where $P \in \sigma$, \overline{x} is a tuple of variables such that $|\overline{x}| = \operatorname{ar}(P)$ and $r: A \to \{1, \ldots, |A|\}$ is the ranking function on A, which maps each element of A to its position in the ordering on A.

In the cases where ρ is not relevant for the semantics, it is omitted, to stay consistent with the notation in Definition 18.

With this definition at hand, we can finally define the set of functions definable by FO(O, F) sentences. Note that we omit O (resp. F), if it is empty.

▶ Definition 29. Let $O \subseteq \{=, \neq, \leq, \not\leq\}$ and let $F \subseteq \operatorname{Arb}_K$. For a semiring K and an $\operatorname{FO}(O, F)$ sentence φ , we define the function problem $\operatorname{FO}_K(O, F)$ -EVAL $_{\varphi}$: $K^* \to K$ as follows:

Problem:	$\mathrm{FO}_K(O, F, \rho)$ -EVAL $_{\varphi}$
Input:	an encoded K-interpretation $enc(\pi)$
Output:	$\llbracket \varphi \rrbracket_{\pi,\rho}$

To denote the set of all these function problems, we introduce the following notation.

▶ Definition 30. Let $O \subseteq \{=, \neq, \leq, \not\leq\}$, let K be a positive semiring, and $F \subseteq \operatorname{Arb}_K$. Then

 $FO_{K} \coloneqq \{ FO_{K} \text{-EVAL}_{\varphi} \mid \varphi \in FO \}$ $FO_{K}(O) \coloneqq \{ FO_{K}(O) \text{-EVAL}_{\varphi} \mid \varphi \in FO(O) \}$ $FO_{K}(O, F) \coloneqq \{ FO_{K}(O, F) \text{-EVAL}_{\varphi} \mid \exists \rho : \varphi \in FO(O, F, \rho) \}$

In the upcoming sections, we establish several connections between the previously introduced models of computation and logic. It is noteworthy that our results generalize beyond model-defining K-interpretations, as defined on page 8.

Data: set A, K-interpretation π 1 **Procedure** Eval(formula φ , assignment s) switch φ do // time complexity $\mathbf{2}$ // $\mathcal{O}(n)$ case x = y do return 1 iff s(x) = s(y)3 case $x \neq y$ do return 1 iff $s(x) \neq s(y)$ // $\mathcal{O}(n)$ $\mathbf{4}$ case $R(\bar{x})$ do return $\pi(R(s(\bar{x})))$ // $\mathcal{O}(n^2)$ $\mathbf{5}$ case $\neg R(\bar{x})$ do return $\pi(\neg R(s(\bar{x})))$ // $\mathcal{O}(n^2)$ 6 case $\psi \wedge \theta$ do return $\text{Eval}(\psi, s) \cdot \text{Eval}(\theta, s)$ // $\mathcal{O}(n) + t(\psi) + t(\theta)$ 7 case $\psi \lor \theta$ do return $\text{Eval}(\psi, s) + \text{Eval}(\theta, s)$ // $\mathcal{O}(n) + t(\psi) + t(\theta)$ 8 case $\psi \star \theta$ do return 1 iff $\text{Eval}(\psi, s) \star \text{Eval}(\theta, s)$ // $\mathcal{O}(n) + t(\psi) + t(\theta)$ 9 case $\exists x \psi$ do return $\sum_{a \in A} \texttt{Eval}(\psi, s[a/x])$ $// |A| \cdot \mathcal{O}(n) \cdot t(\psi)$ 10 $// |A| \cdot \mathcal{O}(n) \cdot t(\psi)$ 11 case $\forall x \psi$ do return $\prod_{a \in A} \text{Eval}(\psi, s[a/x])$

Algorithm 1 Evaluation of $\llbracket \varphi \rrbracket_{\pi,s}$, where $\star \in O \subseteq \{=, \neq, \leq, \not\leq\}$

3 The Complexity of Model Checking for FO_K

We assume basic familiarity with computational complexity theory [29]. In the following, we define the model checking problem.

Problem:	$FO_K(O)$ -MC, $O \subseteq \{=, \neq, \leq, \not\leq\}$, semiring K
Input:	an $FO_K(O)$ formula φ , a K interpretation π , an assignment s, a set A
Question:	$\llbracket \varphi \rrbracket_{\pi,s} \neq 0?$

For instance, if we are interested in the data complexity of the problem, then we write, e.g., $FO_K(O)$ -MC $_{\varphi}$ to emphasise on the fact that φ is fixed.

Regarding input values, we assume for φ , s, and A standard polynomial-time computable encodings, e.g., binary encoding. For π , we use $enc(\pi)$ specified in Def. 24.

▶ **Theorem 31.** Fix a positive commutative semiring K. Given an FO_K formula φ , a K interpretation π , an assignment s, and a set A. The value $\llbracket \varphi \rrbracket_{\pi,s}$ can be computed in time $\mathcal{O}(n^2 \cdot |\varphi| \cdot |A|^{|\varphi|})$ and space in $\mathcal{O}(\text{poly}(n))$, with $n = |\varphi| + |\pi| + |s| + |A|$ the sum of the encoding lengths.

Proof. The procedure Eval in Algorithm 1 is a recursive algorithm that runs on a K-TM to solve the model checking problem. Set A and π are used as "global variables" as they are never modified in the recursive steps. They are accessible by every recursive algorithmic call. The correctness follows inductively by semantics (Def. 18).

Now let *n* be the input length, i.e., $n = |\varphi| + |\pi| + |s| + |A|$. To measure the space used by the machine, we need to prove an upper bound on the recursion depth and the space used in a recursive step. For every conjunction and disjunction there are two recursive steps. For every quantifier there are |A|-many recursive steps. So altogether, we can bound the number of recursive steps as follows for a given formula φ :

 $(2 \cdot (\#_{\wedge}(\varphi) + \#_{\vee}(\varphi)) + 1) \cdot |A|^{(\#_{\exists}(\varphi) + \#_{\forall}(\varphi))} \in \mathcal{O}(|\varphi| \cdot |A|^{|\varphi|}),$

where $\#_O(\varphi)$, for $O \in \{\land, \lor, \exists, \forall\}$, is the number of occurrences of O in φ . Now, we turn towards the space and time bound of a single recursive step. We do a case distinction according to the **switch**-expression in the algorithm.

- $x = y / x \neq y$: Use separate registers in R to copy and check if such an expression is true. This needs constant space and linear time in n.
- $R(\bar{x}) / \neg R(\bar{x})$: Copy the values of $s(\bar{x})$ to the end of the tape and return the specified value according to π . For that purpose, we need additional markings to "remember" which positions have been compared. Altogether this can be done in quadratic time in n and linear space in n.
- \wedge / \vee : Here, we need to copy the respective parts from the input yielding $\mathcal{O}(n)$ time and space.
- \star : Analogously as for the previous case.
- \exists / \forall : Again, we essentially need to copy parts from the input and patch the assignment. Regarding the *A*-values we need to iterate through this part of the input yielding $\mathcal{O}(n)$ time and space.

We see that the space of each step is bounded by $\mathcal{O}(n)$. Regarding time complexity, the time needed at each step is in $\mathcal{O}(n^2)$ and the number of recursive steps was bounded by $\mathcal{O}(|\varphi| \cdot |A|^{\varphi})$ yielding a time bound of $\mathcal{O}(n^2 \cdot |\varphi| \cdot |A|^{|\varphi|})$.

▶ Corollary 32. Let $O \subseteq \{=, \neq, \leq, \not\leq\}$ and $F \subseteq \operatorname{Arb}_K$. Every $f \in \operatorname{FO}_K(O, F)$ can be computed in polynomial space.

The following two corollaries are obtained via utilisation of Algorithm 1 and merely checking whether the computed value of $[\![\varphi]\!]_{\pi,s}$ is not 0.

▶ Corollary 33. $FO_K(O)$ -MC_{\varphi} $\in P_K$ for every $O \subseteq \{=, \neq, \leq, \not\leq\}$.

▶ Corollary 34. $FO_K(O)$ -MC \in PSPACE_K for every $O \subseteq \{=, \neq, \leq, \not\leq\}$.

4 A Circuit Characterisation of FO_K

The following is an adaptation of a result in the Boolean setting, first established by Immerman [23]. It made rigorous intuition that first-order logic and constant-depth circuits more or less do the same thing. More recently, this result has been generalized to metafinite logics over the reals [4] and more general integral domains [2]. We establish a similar result, moving from integral domains to positive, commutative semirings and replacing logics over metafinite structures with a logic that is evaluated directly in the semiring.

▶ **Theorem 35.** Let $O \subseteq \{=, \neq, \leq, \not\leq\}$ and let K be a positive, commutative semiring. Then for K-interpretations $\pi: Lit_{\tau,A} \to K$, where A is strictly ordered: $FO_K(O, Arb_K) = FAC_K^0[O]$.

Proof. This proof follows the same general pattern as a similar result about circuits over the reals and first-order logic over metafinite \mathbb{R} -structures [4, Theorem 30].

The basic idea is for the direction $FO_K(O, \operatorname{Arb}_K) \subseteq FAC_K^0[O]$ to mimic the behaviour of quantifiers and logical connectives by means of the arithmetic gate types. E.g., existential quantification can be simulated by an unbounded addition and a disjunction can be modeled by a multiplication gate.

For the converse direction, we define a sentence that essentially describes the way a circuit is evaluated, using the additional built-in relations to describe the structure of the circuit.

The full proof can be found in Appendix C.

5 Conclusion

In this paper, we introduced several models of computation to analyze the complexity of problems with respect to semirings. In particular, we adapted BSS-machines and arithmetic circuits for semirings to generalize previously established models for computation with fields or rings. We then characterized the complexity of the model checking and evaluation problem of first-order logic with semiring semantics using these models.

The work in establishing a complexity theory started here gives rise to an abundance of further research directions.

Continuing from the model checking question, other possible connections between semiring logics and sequential computation merit investigation. In particular, the well-known theorem by Fagin, establishing a connection between second-order logic and NP [12], which has been adapted to BSS machines and logics over the real numbers by Grädel and Meer [17], warrants analysis with respect to semirings.

Furthermore, there is much work to be done with regard to arithmetic circuits over semirings. The result shown in this paper only pertains to so-called *non-uniform* circuit families, meaning circuit families, where there is no restriction on how computationally difficult it is to obtain any individual circuit. In general, this can lead to problems solvable by such circuit families, that are not computable with regard to BSS machines. In order to view a circuit family as an algorithm, a restriction on how hard it is to obtain any given circuit is required. Given the constructive nature of our proof, there is no doubt that it can be made uniform. The exact nature of that uniformity still needs to be examined, however. Additionally, larger circuit classes than FAC_K^0 could be characterized, following, e.g., the characterization to the entire AC and NC hierarchies over the reals [2].

Appendix

Figure 2 Init subroutine. Converts an input of a BSS_K machine into gap normal form. The elements on the right of the dot are always x_1, x_2, \ldots during the computation. And σ_l (resp. σ_r) shift the **state space** to the left (right) with respect to the dot. The intuition of the algorithm is to iteratively pair each x value with a 1. Also the shift and compare nodes are placed in such a way that no comparison with the input is made. This avoids problems when the input has 0 or 1 values.

Figure 3 Reverse Init subroutine, i.e., $Init^{-1}$. Converts the gap normal form into the input/output form of a BBS_K machine. The elements on the right of the dot are always x_1, x_2, \ldots during the computation. And σ_l (resp. σ_r) shift the **state space** to the left (right) with respect to the dot. The intuition of the algorithm is to iteratively decouple $(x_i, 1)$ pairs. Also the shift and compare nodes are placed in such a way that no comparison with the x_i values is made. This avoids problems when they contain 0 or 1 values.

B Proof of Lemma 11

Proof. Let $M = (Q, q_0, R, O, P, \Gamma, b, K, \delta)$. We give an informal description of the simulation of the Turing machine M using a BSS_K machine. The simulation proceeds through three consecutive phases.

- 1. The input $x \in K^*$ of M is first converted to the gap normal form using Proposition 8, thus allowing Remark 9 to be applied. This intermediate string is then converted to a further normal form that allows the machine M' to simulate the use of the tape alphabet Γ along with the K-valued registers of M. To this end, the state space is conceptually divided into blocks of a fixed number (2k) of consecutive cells, in effect, allowing the state space to be used in the form $(K^{2k})_*$, corresponding to length 2k shift operations for the underlying BSS_K machine. In total, the required conversions incur a quadratic overhead in time and a linear overhead in space, based on the length of the input x.
- 2. The computation of the machine M is simulated step by step according to the transition function δ , using the conceptual state space $(K^{2k})_*$. Based on the fixed length 2k of the extended blocks, each simulated computation step of M incurs a constant overhead in time for the underlying BSS_K machine, thus yielding a total running time linear in t(|x|)and space usage linear in s(|x|).
- 3. Once the simulation phase is completed, the encoded output string corresponding to f(x) in the state space $(K^{2k})_*$ is first converted to the gap normal form, and then to the output format of a BSS_K machine by evoking Proposition 8. These conversions can be achieved in quadratic time and linear space based on the length of the output f(x).

All in all, the use of time and space satisfy the condition stated in the claim of Lemma 11.

Once the input is converted to the gap normal form in Phase 1, the machine can be thought of as if it were using an alphabet of the form $\{\hat{a} \mid a \in K\} \cup \{\varepsilon\}$, where for each element $a \in K$, the symbol \hat{a} encodes the semiring value a in a block of two consecutive cells of the state space in the form a1, and furthermore, ε carries the meaning of the blank symbol of the alphabet and is encoded with two consecutive 0 elements, i.e., the string 00. As in Remark 9, the underlying BSS_K machine can simulate an extended BSS_K machine using the alphabet $\{\hat{a} \mid a \in K\} \cup \{\varepsilon\}$ and a conceptual state space $(K^2)_*$ in such a manner that the simulated machine is capable of computing the arithmetic operations of the semiring, comparing elements of the state space with constant values of the semiring, as well as comparing non-consecutive elements at fixed coordinates of the state space with each other. Each of these operations can be defined using a constant number of computation steps on the underlying BSS_K machine.

In particular, the gap normal form permits the use of symbols $\hat{0}$ and $\hat{1}$ for binary encoding. We exploit this fact in order to convert the set Γ of tape alphabet symbols into strings of a fixed length l using the alphabet $\{\hat{a} \mid a \in K\} \cup \{\varepsilon\}$. These strings in turn correspond to length 2l strings in the state space of the underlying BSS_K machine. In addition to the symbols of the set Γ , the encoding that is used in Phase 2 allows elements of K to be used as tape symbols, and simulates the use of registers corresponding to the set R. Overall, this results in an encoding using strings of elements of K with a fixed length of 2k, for a fixed k.

Next, we give an exact definition for this encoding. Let, e.g., $l := \lceil \log_2(|\Gamma|) \rceil$, k := l + |R| + 1, and let $e \colon \Gamma \setminus \{b\} \to \{\hat{0}, \hat{1}\}^l$ be an injection. Each element of the set $\Gamma \cup K$ is matched with a (possibly infinite) set of length k strings of the alphabet $A := \{\hat{a} \mid a \in K\} \cup \{\varepsilon\}$ as follows: the blank symbol $b \in \Gamma$ corresponds to each εs with $s \in A^{k-1}$,

■ each symbol $a \in \Gamma \setminus \{b\}$ corresponds to the concatenation $\hat{0}e(a)s$, for every $s \in A^R$,

■ each $a \in K$ corresponds to every $\hat{1}\hat{a}s$, where $s \in A^{k-2}$.

In particular, the three types are distinguished by the first A-element of each sequence.

The last |R| elements of these strings are used to carry the K-values of the registers in such a manner that whenever the extended head of the machine in the conceptual state space $(A^k)_*$ (or, more generally, $((K^2)^k)_*$) is shifted left or right, corresponding to a shift of length 2k for the underlying BSS_K machine, the elements stored in the simulated registers are copied to their respective places in the new position of the simulated head.

Since the length k of the extended cells of the state space $(A^k)_*$ is fixed, each operation type of the transition function δ can be simulated using a fixed number of computation steps of the underlying BSS_K machine. The states in the set Q of the Turing machine M are kept track of using the nodes that labelled by $1, \ldots, N$ in Definition 4.

As the last part of the proof, we explain in short how to implement the remaining conversions in Phases 1 and 3. In order to convert a string that is in the gap normal form to the encoding used in the simulation, we repeatedly apply the procedure of replacing the rightmost $\hat{0}$ or $\hat{1}$ by ε and copying the replaced symbol to be the leftmost element corresponding to the string of the simulation alphabet. During the process, the remaining part of the string of symbols in $\{\hat{a} \mid a \in K\}$ and the converted part are separated using the string ε^k . The conversion back to the gap normal form in Phase 3 can be implemented in a similar manner. Both of these conversions can be accomplished in quadratic time and linear space based on the length of the string to be converted.

C Proof of Theorem 35

Proof. $FO_K(O, Arb_K) \subseteq FAC_K^0[O]$:

Given a FO(O, Arb_K)-sentence φ , the idea is to construct a circuit family that computes the function FO_K(O, Arb_K)-EVAL $_{\varphi}$. This is achieved by structural induction on φ . For any $n \in \mathbb{N}$, we essentially built the *n*th circuit "top-down", i.e., starting at the output gate and continuing towards the input gates. While doing so, we maintain the invariant at each step in the induction, that if the predecessor gates of the one we are currently constructing compute the same function as the subformulae which they will represent, then our circuit as a whole computes f.

Let $\varphi \in \text{FO}(O, \operatorname{Arb}_K)$ over the signature (τ, σ) . For any length n of valid encoded K-interpretations π for (τ, σ) , we are going to define a circuit C_n such that $f_{C_n}(enc(\pi)) = \operatorname{FO}_K(O, \operatorname{Arb}_K)$ -EVAL $_{\varphi}(\pi)$. If φ contains k variables x_1, \ldots, x_k , we will do this by for each subformula ψ of φ and any $(m_1, \ldots, m_k) \in A^k$ creating a circuit $C_n^{\psi(m_1,\ldots,m_k)}$ such that for any K-interpretation π , where $|enc(\pi)| = n$, it holds that $[\![\psi[m_1/x_1,\ldots,m_k/x_k]]\!]_{\pi} = f_{C_n^{\psi(m_1,\ldots,m_k)}(enc(\pi))$, where $\psi[m_1/x_1,\ldots,m_k/x_k]$ is the formula ψ , where each occurrence of x_i is replaced by m_i for all $1 \leq i \leq k$. The m_1,\ldots,m_k are essentially used to keep track of the values "selected" by the quantifiers and we initialize them to be 0.

We proceed by structural induction on φ . W.l.o.g. let φ have exactly k variables.

At the very top is the output gate, so $C_n^{\varphi(0,\ldots,0)}$ consists of the output gate in addition to the circuit as described by the following induction.

For any subformula ψ of φ , we proceed as follows.

- 1. Let $\psi = \exists x_i \xi$. Then $C_n^{\psi(m_1,...,m_k)}$ consists of an addition gate with the predecessors $C_n^{\xi(m_1,...,m_{i-1},a,m_{i+1},...,m_k)}$ for all $a \in A$.
- 2. Let $\psi = \forall x_i \xi$. Then $C_n^{\psi(m_1,...,m_k)}$ is defined as above, except that it has a multiplication gate at the top.
- **3.** Let $\psi = \xi_1 \vee \xi_2$. Then $C_n^{\psi(m_1,...,m_k)}$ consists of a sum gate with the predecessors $C_n^{\xi_1(m_1,...,m_k)}$ and $C_n^{\xi_2(m_1,...,m_k)}$.

- 4. Let $\psi = \xi_1 \wedge \xi_2$. Then $C_n^{\psi(m_1,\dots,m_k)}$ is defined as above, except that it has a multiplication gate at the top.
- **5.** Let $\psi = \xi_i \circ \xi_j$ for $o \in O$. Then $C_n^{\psi(m_1,...,m_k)}$ is defined as above, except that it has a o gate at the top.
- **6.** Let $\psi = x_i \star x_j$ for $\star \in \{=, \neq\}$ and variables x_i, x_j . Then $C_n^{\psi(m_1, \dots, m_k)}$ consists of a constant 1 gate if $m_i = m_j$ and a constant 0 gate, otherwise.
- 7. Let $\psi = R(\overline{x})$ for $R \in \tau$. Then $C_n^{\psi(m_1,\ldots,m_k)}$ is the input gate representing the literal $R(\overline{x})[m_1/x_1,\ldots,m_k/x_k]$ in $enc(\pi)$.
- 8. Let $\psi = \neg R(\overline{x})$ for $R \in \tau$. Then $C_n^{\psi(m_1,\ldots,m_k)}$ is the input gate representing the literal $\neg R(\overline{x})[m_1/x_1,\ldots,m_k/x_k]$ in $enc(\pi)$.
- **9.** Let $\psi = P(\overline{x})$ for $P \in \sigma$. Then $C_n^{\psi(m_1,\ldots,m_k)}$ is a constant gate that has the value $[\![P(\overline{x})[m_1/x_1,\ldots,m_k/x_k]]\!]_{\pi,\rho}$.
- 10. Let $\psi = \neg P(\overline{x})$ for $P \in \sigma$. Then $C_n^{\psi(m_1,\ldots,m_k)}$ is a constant gate that has the value $[\![\neg P(\overline{x})[m_1/x_1,\ldots,m_k/x_k]]\!]_{\pi,\rho}$.

This construction ensures that the function defined by each subformula of φ is exactly the one of the respective subcircuit and thus the circuit $C_n^{\varphi(0,\ldots,0)}$ computes exactly the function $[\![\varphi]\!]_{\pi,\rho}$. Therefore, for each FO(O, Arb_K)-sentence ϕ , we have that FO_K(O, Arb_K)-EVAL_{ϕ} \in FAC⁰_K(O) and thus FO_K(O, Arb_K) \subseteq FAC⁰_K(O).

$\operatorname{FAC}_{K}^{0}[O] \subseteq \operatorname{FO}_{K}(O, \operatorname{Arb}_{K}):$

Given a $\operatorname{FAC}_{K}^{0}(O)$ family $\mathcal{C} = (C_{n})_{n \in \mathbb{N}}$, the idea is to define a single sentence φ , such that $\llbracket \varphi \rrbracket_{\pi,\rho} = f_{\mathcal{C}}(enc(\pi))$. The sentence φ essentially describes how circuits in the family \mathcal{C} are evaluated. It does this by making use of the Arb_{K} extension to FO. Since we have access to arbitrary functions that may depend on the size of the input K-interpretation, the interpretation of these functions can be chosen according to the number of input gates of the circuit. This way, φ will describe the entire circuit family. We will use these built-in functions to describe the gates of our circuit. In particular, they will give us information about gate types, edges, constant values and indices of input gates.

Let $C_n \in \mathcal{C}$ and let $q \in \mathbb{N}$ such that $\operatorname{size}(C_n) \leq n^q$. As per Lemma 16, we can assume that each gate in C_n has fan-out 1 and that for each gate g, each input-g path has the same length. This essentially gives all of the circuits of \mathcal{C} a layered form, such that one can talk in an unambiguous way about the depth of any individual gate, in the sense that it is the distance to an input gate.

Additionally, the fact that $\operatorname{size}(C_n) \leq n^q$ allows us to encode each gate in C_n as a q long tuple of values in $\{1, \ldots, n\}$. This will enable us to effectively talk about the structure of C_n logically.

The sentence φ will have the signature $(\{R^1\}, \{t^q, c^q, in^{q+1}, e^{2\cdot q}, left^{2\cdot q}\})$. For all $n \in \mathbb{N}$, we define the functions $t_n \colon \{1, \ldots, n\}^q \to \{0, 1\}^4, c_n \colon \{1, \ldots, n\}^q \to K, in_n \colon \{1, \ldots, n\}^{q+1} \to \{0, 1\}, e_n \colon \{1, \ldots, n\}^{2\cdot q} \to \{0, 1\}$ and $left \colon \{1, \ldots, n\}^{2\cdot q} \to \{0, 1\}$, where $t_n(x_1, \ldots, x_q)$ yields the gate type in binary of the gate encoded by (x_1, \ldots, x_q) as per Table 1 on page 7, $c_n(x_1, \ldots, x_q)$ returns the value of the gate encoded by (x_1, \ldots, x_q) if it is a constant gate and 0, if it is not, $in_n(x_1, \ldots, x_q, y)$ yields 1, if the gate encoded by (x_1, \ldots, x_q) is the yth input gate and 0, if it is not and $e_n(x_1, \ldots, x_q, y_1, \ldots, y_q)$ returns 1, if there is an edge from the gate encoded by $(x_1, \ldots, x_q, y_1, \ldots, y_q)$ and 0, if there is not. The additional function left is only needed if $\leq \in O$ or $\langle \in O$, and $left(x_1, \ldots, x_q, y_1, \ldots, y_q)$ returns 1, if the gate encoded by $(x_1, \ldots, x_q, y_1, \ldots, y_q)$ returns 1, if the gate encoded by $(x_1, \ldots, x_q, y_1, \ldots, y_q)$ is the left neighbour of the gate encoded by (y_1, \ldots, y_q) . The K-interpretation ρ will assign the literals over the symbols $\{t, c, in, e, left\}$ to the respective aforementioned function families. It is worth to note that R, as the unary

only relation symbol in τ , yields the individual elements of the input to the circuit. We make use of that fact when we characterize the input gates logically.

With all that at hand, we will now define φ by induction on the layers of the circuit, i.e., we start at depth 0 and move towards the output gate. We will do this by defining φ_d for each $0 \le d \le \text{depth}(C_n)$.

At depth 0, we have only input gates. Therefore $\varphi_0(x_1, \ldots, x_q) \coloneqq \exists y \ in(x_1, \ldots, x_q, y) \times R(y)$.

For $1 \leq d \leq \operatorname{depth}(C_n)$, we define φ_d as follows:

$$\begin{split} \varphi_d(x_1, \dots, x_q) &\coloneqq t(x_1, \dots, x_q) = (0010) \times T_{2,d}(x_1, \dots, x_q) + \\ t(x_1, \dots, x_q) &= (0011) \times T_{3,d}(x_1, \dots, x_q) + \\ t(x_1, \dots, x_q) &= (0100) \times T_{4,d}(x_1, \dots, x_q) + \\ t(x_1, \dots, x_q) &= (0101) \times T_{5,d}(x_1, \dots, x_q) + \\ t(x_1, \dots, x_q) &= (0110) \times T_{6,d}(x_1, \dots, x_q) + \\ t(x_1, \dots, x_q) &= (0111) \times T_{7,d}(x_1, \dots, x_q) + \\ t(x_1, \dots, x_q) &= (1000) \times T_{8,d}(x_1, \dots, x_q) + \\ t(x_1, \dots, x_q) &= (1001) \times T_{9,d}(x_1, \dots, x_q), \end{split}$$

where

$$\begin{split} T_{2,d}(x_1,\ldots,x_q) &= c(x_1,\ldots,x_q) \\ T_{3,d}(x_1,\ldots,x_q) &= \exists y_1,\ldots,y_q \ e(y_1,\ldots,y_q,x_1,\ldots,x_q) \land \varphi_{d-1}(y_1,\ldots,y_q) \\ T_{4,d}(x_1,\ldots,x_q) &= \forall y_1,\ldots,y_q \ e(y_1,\ldots,y_q,x_1,\ldots,x_q) \land \varphi_{d-1}(y_1,\ldots,y_q) \\ T_{5,d}(x_1,\ldots,x_q) &= \exists y_1,\ldots,y_q \ e(y_1,\ldots,y_q,x_1,\ldots,x_q) \land \varphi_{d-1}(y_1,\ldots,y_q) \\ T_{6,d}(x_1,\ldots,x_q) &= \exists y_1,\ldots,y_q, z_1,\ldots,z_q \\ e(y_1,\ldots,y_q,x_1,\ldots,x_q) \land e(z_1,\ldots,z_q,x_1,\ldots,x_q) \land \\ \left(\bigvee_{1\leq i\leq q} y_i \neq z_i\right) \land \varphi_{d-1}(y_1,\ldots,y_q) = \varphi_{d-1}(z_1,\ldots,z_q) \\ T_{7,d}(x_1,\ldots,x_q) &= \exists y_1,\ldots,y_q, z_1,\ldots,z_q \\ e(y_1,\ldots,y_q,x_1,\ldots,x_q) \land e(z_1,\ldots,z_q,x_1,\ldots,x_q) \land \\ \left(\bigvee_{1\leq i\leq q} y_i \neq z_i\right) \land \varphi_{d-1}(y_1,\ldots,y_q) \neq \varphi_{d-1}(z_1,\ldots,z_q) \\ T_{8,d}(x_1,\ldots,x_q) &= \exists y_1,\ldots,y_q, z_1,\ldots,z_q \\ e(y_1,\ldots,y_q,x_1,\ldots,x_q) \land e(z_1,\ldots,z_q,x_1,\ldots,x_q) \land \\ left(y_1,\ldots,y_q,z_1,\ldots,z_q) \land \varphi_{d-1}(y_1,\ldots,y_q) \leq \varphi_{d-1}(z_1,\ldots,z_q) \\ T_{9,d}(x_1,\ldots,x_q) &= \exists y_1,\ldots,y_q,z_1,\ldots,z_q \\ e(y_1,\ldots,y_q,x_1,\ldots,x_q) \land e(z_1,\ldots,z_q,x_1,\ldots,x_q) \land \\ left(y_1,\ldots,y_q,z_1,\ldots,z_q) \land \varphi_{d-1}(y_1,\ldots,y_q) \leq \varphi_{d-1}(z_1,\ldots,z_q) \end{split}$$

Now, it holds for the formula

 $\varphi \coloneqq \exists x_1, \dots, x_q \ t(x_1, \dots, x_q) = (0110) \land \varphi_{\operatorname{depth}(C_n)}(x_1, \dots, x_q)$

T. Barlag et al.

that $\llbracket \varphi \rrbracket_{\pi,\rho} = f_{C_n}(enc(\pi))$. Thus, for each $\operatorname{FAC}^0_K(O)$ -circuit family, there exists a sentence φ such that $\operatorname{FO}_K(O, \operatorname{Arb}_K)$ -EVAL $_{\varphi} = f_{C_n}$. Therefore, $\operatorname{FO}_K(O, \operatorname{Arb}_K) \subseteq \operatorname{FAC}^0_K(O)$ and putting it all together $\operatorname{FO}_K(O, \operatorname{Arb}_K) = \operatorname{FAC}^0_K(O)$.
