In the minimal gauged B–L extension of the Standard Model, we demonstrate that PeV-scale dark matter (DM) and the baryon asymmetry of the Universe (BAU) can be simultaneously explained through the three right-handed neutrinos (RHNs) present in the theory. The DM candidate undergoes decay into light neutrinos, providing an explanation for the observed IceCube events, while the other two RHNs generate the BAU via leptogenesis. The breaking of gauge symmetry gives rise to detectable gravitational waves (GWs) from decaying cosmic strings (CS), making this framework testable at several future GW detectors—despite being beyond the reach of conventional collider experiments due to the extremely weak coupling. The symmetry-breaking scale establishes a connection between particle masses, couplings, and the GW spectrum, offering a unified and predictive scenario.

Introduction.– Tiny neutrino masses and flavor mixing [1] have been observed from the neutrino oscillation experiments over a period of time. Another significant finding from the PLANCK observation [2] estimates that the baryon asymmetry of the universe (BAU), characterized by the ratio of difference in baryon-antibaryon number density  $(n_B - n_{\bar{B}})$  to the entropy density (s), as  $Y_B^o \simeq 8.75 \times 10^{-11}$ . Additionally, strong evidence for dark matter (DM) comes from astrophysical and cosmological observations, which indicate a relic abundance of  $\Omega h^2 \simeq 0.12$  [2–4]. The fundamental origin of these phenomena remains unexplained within the Standard Model (SM), compelling us to explore beyond the SM (BSM) frameworks.

In the recent past, the IceCube neutrino observatory reported the detection of three PeV neutrinos, roughly  $3\sigma$  excess above the expected background rates [5–9]. These highest-energy events correspond to deposited energies of 1.04 PeV, 1.14 PeV and 2.0 PeV, respectively. Although the origin of these very high energy events is still unclear, it has been shown that such events could be originated from decays of superheavy DM [10–15]. The neutrino energy spectrum presents a high-energy cut-off at half of the DM mass [11, 12] if two body decays including one neutrino are present. Moreover, the IceCube spectrum sets a lower bound on the DM lifetime  $\tau_{\rm DM} \simeq \mathcal{O}(10^{28})$  s [12, 16], which is largely model-independent and significantly exceeds the age of the Universe.

On the other hand, current observations of Gravitational Waves (GWs) [17–23], have opened a complementary avenue to test BSM physics. For example, if symmetries are broken spontaneously at very high temperature then topological defects, such as cosmic strings and domain walls, may appear in the early stages of the universe [24, 25] and the system of these defects can be considered as a prominent source of a GW background, while the scale of symmetry breaking can be associated with the scale of new physics.

To explore these aspects within a simple yet elegant framework, we consider an extension of the SM featuring an anomaly-free  $U(1)_{B-L}$  gauge group [26, 27], incorporating three generations of SM-singlet right-handed neutrinos (RHNs) and an SM-singlet scalar which acquires a non-zero vacuum expectation value (VEV) resulting in the breaking of the  $U(1)_{B-L}$  symmetry. As a result, the Majorana masses for the RHNs are generated, which in turn induce tiny masses and flavor mixing for the observed left-handed neutrinos via the seesaw mechanism [28–32]. This setup naturally explains the BAU via vanilla leptogenesis if at least two RHN generations contribute to the asymmetry generation, while the third, lightest RHN can serve as a PeV-scale decaying DM candidate, addressing IceCube high-energy neutrino events through the freeze-in mechanism. Additionally, the  $U(1)_{\rm B-L}$  breaking gives rise to one-dimensional topological defects—cosmic strings (CS)—characterized by a string tension  $G\mu \sim BGv_{\Phi}^2$ , where  $v_{\Phi}$  is the VEV of the  $U(1)_{B-L}$  symmetry breaking singlet scalar and  $B \sim 0.1$  [33, 34]. This minimal scenario, therefore, offers a unified explanation for (i) PeV-scale decaying DM linked to IceCube events. (ii) barvogenesis via leptogenesis and (iii) GW from CS which could be tested at future GW detectors. We thus constrain heavy neutral gauge boson mass beyond 1 TeV, with tiny gauge coupling ( $\lesssim \mathcal{O}(10^{-5})$ ), which lies beyond the reach of high energy collider experiments, that typically provide constraints on gauge couplings around  $\mathcal{O}(10^{-2})$  for the B-L scenario at the LHC [35].

**The framework**– Under the SM  $\otimes U(1)_{B-L}$  gauge symmetry, the SM quark fields transform as  $q_L^i = \{3, 2, \frac{1}{6}, \frac{1}{3}\},\$ 

 $u_R^i = \{3, 1, \frac{2}{3}, \frac{1}{3}\}, d_R^i = \{3, 1, -\frac{1}{3}, \frac{1}{3}\}$ , respectively. The SM lepton fields transform as  $\ell_L^i = \{1, 2, -\frac{1}{2}, -1\}$ ,  $e_R^i = \{1, 1, -1, -1\}$ , respectively, while the SM Higgs field  $H = \{1, 2, \frac{1}{2}, 0\}$ . We introduce three SM-singlet RHNs to cancel gauge and mixed gauge-gravity anomalies which transform as  $N_R^i = \{1, 1, 0, -1\}$  with i = 1, 2, 3 and one SM-singlet  $U(1)_{\rm B-L}$  scalar which transforms as  $\Phi = \{1, 1, 0, 2\}$ . The relevant Yukawa interactions read,

$$\mathcal{L} \supset -Y_{\nu_{\alpha\beta}} \overline{\ell_L^{\alpha}} \tilde{H} N_R^{\beta} - \frac{1}{2} Y_{N_{\alpha}} \Phi \overline{(N_R^{\alpha})^c} N_R^{\alpha} + \text{H.c.}, \quad (1)$$

where we start-off in a basis where the  $Y_{N_{\alpha}}$  matrix is diagonal, and  $\tilde{H} = i\tau^2 H^*$  with  $\tau^2$  being the second Pauli matrix. The scalar potential involving two scalar fields is given by

$$V = \sum_{\mathcal{I}=H,\Phi} \left[ m_{\mathcal{I}}^2 (\mathcal{I}^{\dagger} \mathcal{I}) + \lambda_{\mathcal{I}} (\mathcal{I}^{\dagger} \mathcal{I})^2 \right] + \lambda_{\min} (H^{\dagger} H) (\Phi^{\dagger} \Phi) . (2)$$

After the breaking of B–L and electroweak gauge symmetries, the scalar fields H and  $\Phi$  develop their VEVs as

$$\langle H \rangle = \frac{1}{\sqrt{2}} \begin{pmatrix} v+h\\0 \end{pmatrix}$$
, and  $\langle \Phi \rangle = \frac{v_{\Phi}+\phi}{\sqrt{2}}$ , (3)

where electroweak scale is v = 246 GeV at the potential minimum. For  $v_{\Phi} \gg v$ , the mass of the B–L gauge boson can be written as  $M_{Z'} = 2g_X v_{\Phi}$ . The breaking of B–L symmetry induces the Majorana mass term for the RHNs while the electroweak symmetry breaking generates the Dirac mass term for the light left-handed neutrinos from Eq. (1) as

$$M_{\alpha} = \frac{Y_{N_{\alpha}}}{\sqrt{2}} v_{\Phi}, \quad m_{D_{\alpha\beta}} = \frac{Y_{\nu_{\alpha\beta}}}{\sqrt{2}} v.$$
 (4)

From the mass matrices above, the light active neutrino masses can be derived using the standard see-saw formula  $-m_D M_{\alpha}^{-1} m_D^T$  [30, 36, 37]. This mechanism successfully explains the tiny neutrino masses and their flavor mixing.

Out of three generations of RHNs, we identify  $N_1$ as a long-lived decaying DM. Its only decay channel,  $N_1 \rightarrow \ell H$ , produces boosted high-energy neutrinos. The DM lifetime, as required by the IceCube observations, in terms of its mass and Yukawa coupling reads [11, 12, 16, 38]

$$\tau \simeq 10^{28} \text{ s} \left(\frac{(Y_{\nu})_{11}}{2 \times 10^{-29}}\right)^2 \left(\frac{M_1}{4 \,\text{PeV}}\right).$$
 (5)

Due to extremely small Yukawa coupling strength, it is not possible to address right DM abundance via the inverse decay channel  $\ell H \rightarrow N_1$ . Thus, we consider its production via freeze-in [39, 40] from the thermal bath. Consequently, production and decay of  $N_1$  is disentangled, and hence right DM abundance can be satisfied even with a DM decay lifetime of  $\tau_{N_1} \sim 10^{28}$  sec, complying with the IceCube data. Here onward we will consider the following set of parameters as independent in our analysis:  $\{g_X, M_{Z'}, Y_{N_{\alpha}}\}$ , while the DM mass  $(M_1 = Y_{N_1} v_{\Phi} / \sqrt{2})$ is always fixed at 4 PeV.

**DM production via freeze-in**– The PeV scale  $N_1$  DM can be produced via (i) on-shell decay of Z', provided  $M_{Z'} > 2 M_1$ , (ii) on-shell decay of  $\phi$ , if  $m_{\phi} > 2 M_1$ and (iii) 2-to-2 scattering off of the bath particles, mediated by Z'. The universal interaction strength  $g_X$ must be feeble to ensure non-thermal DM production via freeze-in (see Sec. II of the supplemental material). As a result, the Z' cannot reach thermal equilibrium, and its comoving number density must be determined by solving a set of coupled Boltzmann equations (BEQs), see Sec. IV of the supplemental material. We consider the mixing between  $\phi$  and the SM Higgs to be negligibly small such that its decay into SM particles are extremely suppressed. Consequently  $\phi$  being a part of the bath and having thermal distribution, it decays dominantly into RHNs and Z' pairs. To fit the observed DM relic density, it is required that  $Y_0 M_1 = \Omega h^2 \frac{1}{s_0} \frac{\rho_c}{h^2} \simeq$  $4.3 \times 10^{-10}$  GeV, where  $Y_0 \equiv y_{N_1}(z \rightarrow \infty)$  is the present DM yield. We use the critical energy density  $\rho_c \simeq 1.05 \times 10^{-5} h^2 \text{ GeV/cm}^3$ , present entropy density  $s_0 \simeq 2.69 \times 10^3 \text{ cm}^{-3}$  [41] and DM relic abundance  $\Omega h^2 \simeq 0.12$ , with  $h \simeq H_0/100 \ (\text{km/s/Mpc})$  being the reduced Hubble rate, where  $H_0 \simeq 67.4 \pm 0.5 \text{ km/s/Mpc}$ is the current Hubble rate [2].

The evolution of DM and Z' yields  $(y_{Z'})$  are shown in the left panel of Fig. 1, as a function of  $z = M_1/T$ , with  $M_1 = 4$  PeV. For the red curves, we fixed  $M_{Z'} > 2 M_{N_1}$ , such that the DM can be produced from the on-shell decay of Z', as well as via Z' mediated scattering. Now, in presence of both channels, DM production via decay dominates since the production rate is proportional to  $g_X^2$ , compared to scattering, which is proportional to  $g_X^4$ . The DM yield  $y_{N_1}$  gradually grows with time, finally reaching the observed abundance in the asymptotic limit. In the first plateau region of the red solid curve, DM is dominantly produced from  $\phi$ -decay. Due to large decay width,  $\phi$  decay is completed earlier and the DM (as well as Z') production from  $\phi$ -decay stops. However, Z' decay still goes on. Thus, the final DM abundance is set by  $Z' \to N_1 N_1$  channel. On the other hand, the blue solid curve represents a scenario where the DM production is instead controlled by Z' mediated scattering, as the decay is kinematically forbidden  $(M_{Z'} < M_1)$ . For  $M_{Z'} = 10^8 (10^5)$  GeV and for DM mass of 4 PeV, the freeze-in occurs at the temperature  $T \sim M_{Z'}(M_1)$ . This is the typical IR feature [40], where the DM yield saturates when  $T = \max[M_{Z'}, M_1]$ .

**Baryon asymmetry from**  $N_2$  **leptogenesis**– The observed BAU is generated via vanilla leptogenesis from the CP-violating, out of equilibrium decays of  $N_2$ . Due to very long lifetime, the lepton asymmetry generated through  $N_1$  decay does not contribute to the genera-

Figure 1. Left: Evolution of DM yield (solid curves) with  $M_1/T$ . The red and blue curves correspond to  $M_{Z'} = \{10^8, 10^5\}$ GeV with corresponding  $g_X = \{2 \times 10^{-12}, 1.2 \times 10^{-6}\}$ , respectively to produce the right DM abundance (shown via gray thick straight line). In all cases DM mass if fixed to 4 PeV. The equilibrium Z' yield  $y_{Z'}^{eq}$  are shown via the dashed curves. *Right:* Evolution of B-L yield (solid curves) with  $M_2/T$ , for  $N_2$  leptogenesis. The red curve produces the observed baryon asymmetry (shown via green thick straight line). The black solid curve shows equilibrium  $N_2$  yield  $y_{N_2}^{eq}$ .

tion of the BAU as its decay takes place far below the sphaleron equilibration temperature. The CP asymmetry from  $N_2$ -decay can be expressed as (see Sec. III of the supplemental material) [42, 43]

$$\epsilon_{\Delta L} \simeq \frac{3\delta_{\rm eff}}{16\,\pi} \, \frac{M_2 \, m_{\nu\,,\rm max}}{v^2} \,, \tag{6}$$

where  $\delta_{\text{eff}}$  is the effective CP violating phase in the neutrino mass matrix with  $0 \leq \delta_{\text{eff}} \leq 1$ , and, we take  $m_{\nu,\text{max}} = 0.05$  eV as the heaviest light neutrino mass following the normal hierarchy. The final B–L asymmetry is obtained by solving a set of coupled BEQs (see Sec. IV of the supplemental material). The sphaleron interactions [42] are in equilibrium within the temperature range 100 GeV to  $10^{12}$  GeV, and they convert a fraction of a non-zero B–L asymmetry into a baryon asymmetry via

$$Y_B \simeq a_{\rm sph} \, y_{B-L} = \frac{8 \, N_F + 4 \, N_H}{22 \, N_F + 13 \, N_H} \, y_{B-L} \,, \qquad (7)$$

where  $N_F(=3)$  and  $N_H(=1)$  are numbers of fermion generations and Higgs doublets,  $a_{\rm sph} \simeq 28/79$  and  $Y_B^o \simeq$  $8.75 \times 10^{-11}$ . We show the evolution of yields for RHN  $(y_{N_2})$  and B–L  $(y_{\rm B-L})$  as a function of  $z = M_2/T$  in the right panel of Fig. 1. The population of  $N_2$  receives contributions from two sources: (i) the thermal bath, through the inverse decay process  $\ell H \to N_2$  and (ii) decay of Z' and  $\phi$ . Notably, the bath contribution is the dominant one, as all other production channels are suppressed due to tiny  $g_X$  to satisfy freeze-in conditions. Following the Davidson-Ibarra (DI) bound [44],  $M_2 \gtrsim 10^9$ GeV is required for a successful thermal leptogenesis. Thus, to produce  $N_2$  from on-shell decay of Z', we need to have  $M_{Z'} > 10^9$  GeV, which requires a super-Planckian  $v_{\Phi}$  for tiny  $g_X$  values. Since the RHN mass depends on

 $v_{\Phi}$  from Eq. (4), in order to satisfy DI bound,  $v_{\Phi} \gtrsim 10^9$ GeV for  $y_{N_2} \sim \mathcal{O}(1)$ , which translates into  $g_X \gtrsim 10^{-6}$ . This bound on  $g_X$  becomes more stringent for  $y_{N_2} \leq 0.1$ . GW Spectrum from cosmic strings-Numerical simulations based on the Nambu-Goto action [45, 46] have found that for gauged symmetry, the dominant channel of energy loss from CS is through GW radiation from oscillating loops. The rate of energy loss or the power of GW emission is given by [47]  $P_{\rm GW} = \frac{G}{5} (\ddot{Q})^2$ , where Q is the quadrupole moment of the oscillating loop, and the triple time derivative  $\ddot{Q} \propto \mu$ . Thus, the rate of energy loss can be written as  $\frac{dE}{dt} = -\Gamma G \mu^2$ , where  $\Gamma \approx 50$  [48]. Due to GW emission, the loop starts to shrink from its initial length  $l_i = \alpha t_i$  at the time of formation  $(t_i)$  as  $l(t) = \alpha t_i - \Gamma G \mu (t - t_i)$ , where  $\alpha$  is the loop size parameter and considered to be  $\alpha \approx 0.1$  from simulation studies [49, 50]. The total energy loss from a loop constitutes a set of normal mode oscillations with frequencies  $f_k = 2k/l(t)$ , where k represents number of modes  $(k = 1, 2, 3...\infty).$ 

The GW density parameter is defined as

$$\Omega_{\rm GW}(t_0, f) = \frac{f}{\rho_c} \frac{d\rho_{\rm GW}(t_0, f)}{df} = \sum_k \Omega_{\rm GW}^{(k)}(t_0, f) \,, \quad (8)$$

where f and  $t_0$  represent the current frequency and the present time, while  $\rho_c = 3M_P^2 H_0^2$  is the critical energy density where  $M_P$  is reduced Planck mass and Hubble parameter. Since the GW energy density redshifts as  $a^{-4}$ , we have [49]

$$\frac{d\rho_{\rm GW}^{(k)}}{df} = \int_{t_F}^{t_0} \left[\frac{a(t_E)}{a(t_0)}\right]^4 P_{\rm GW}(t_E, f_k) \frac{dF}{df} dt_E ,\qquad(9)$$

where  $f_k$  denotes emitted frequency  $(f_E)$  at the time  $t_E$ ,  $t_F$  is the loop formation time,  $\frac{dF}{df} = f\left[\frac{a(t_0)}{a(t_E)}\right]$  accounts

Figure 2. Summary of parameter space: The red thick contour corresponds to right DM abundance for  $M_1 = 4$  PeV. The diagonal contours correspond to different  $v_{\phi}$ 's, some of which fall within the sensitivity of a few GW detectors, as denoted. The shaded regions are disallowed from Davidson-Ibarra (DI) bound ( $M_2 < 10^9$  GeV), BBN bound on Z'-lifetime and by having super-Planckian VEV-values.

for the redshift of the frequency, and

$$P_{\rm GW}(t_E, f_k) = \frac{2 k G \mu^2 \Gamma_k}{f \left[\frac{a(t_0)}{a(t_E)}\right]^2} n \left(t_E, \frac{2k}{f} \left[\frac{a(t_E)}{a(t_0)}\right]\right), \quad (10)$$

is the power emitted by the loops.

The GW spectrum depends on the nature of smallscale structure in the loops which can appear in the form of cusps or kinks [51, 52]. For our study, we consider cusp-like structures to dominate the GW spectra. Here we have  $\Gamma_k = \frac{\Gamma k^{-4/3}}{\sum_{m=1}^{\infty} m^{-4/3}}$ , with  $\sum_k \Gamma_k = \Gamma$  and *n* denotes the number density of loops which, in a cosmological background with scale factor  $a \propto t^{\beta}$ , is found from the Velocity dependent One Scale (VOS) model [53–55] and numerical simulations to be [49]

$$n(t_E, l_k(t_E)) = \frac{A_\beta}{\alpha} \frac{(\alpha + \Gamma G \mu)^{3(1-\beta)}}{[l_k(t_E) + \Gamma G \mu t_E]^{4-3\beta} t_E^{3\beta}}, \quad (11)$$

where  $A_{\beta}$  is a constant depending on the cosmological background.

Using Eqs. (8)-(11), we obtain the current GW energy density for the mode k as

$$\Omega_{\rm GW}^{(k)}(t_0, f) = \frac{2kG\mu^2\Gamma_k}{f\rho_c} \int_{t_{osc}}^{t_0} dt \left[\frac{a(t)}{a(t_0)}\right]^5 n(t, l_k) , \quad (12)$$

where the integration over time is from the moment  $t_{\rm osc}$ when loops start oscillating after damping due to thermal friction [56] and hence producing sub-dominant effect. For the case of loops formed and radiated during radiation domination, the GW spectrum has a typical flat plateau, with the amplitude given by

$$\Omega_{\rm GW}^{(k=1),\rm plateau}(f) = \frac{128\pi G\mu}{9\zeta(4/3)} \frac{A_r}{\epsilon_r} \Omega_r \left[ (1+\epsilon_r)^{3/2} - 1 \right] (13)$$

where  $\epsilon_r = \alpha/\Gamma G\mu$ , and  $A_r = 0.54$  [55] for radiation domination. CMB measurements require  $G\mu \lesssim 10^{-7}$  [57] and hence we have  $\alpha \gg \Gamma G\mu$ . This gives  $\Omega_{\rm GW}^{(k=1)}(f) \propto v_{\Phi}$ , and hence a higher symmetry breaking scale is more likely to be probed by the GW detectors.

The viable parameter space is furnished in Fig. 2, where the thick red contour corresponds to observed DM abundance for  $M_{N_1} = 4$  PeV. The diagonal dashed lines denote different  $v_{\Phi}$  providing the correct value of  $M_{Z'}$ for the corresponding  $g_X$ . A few of such  $v_{\Phi}$ 's are within the reach of proposed GW detectors: Big Bang Observer (BBO) [58, 59], ultimate DECIGO (uDECIGO) [60, 61], LISA [62], the cosmic explorer (CE) [63] and the Einstein Telescope (ET) [64–67]. The gray shaded region in top left corner is disallowed by the DI bound on the RHN mass for  $Y_N \lesssim \sqrt{4\pi}$ . The light gray shaded region in the bottom left corner corresponds to the combination of  $g_X$  and  $M_{Z'}$  that gives rise to  $\tau_{Z'} = 1/\Gamma_{Z'} > 1$ sec, thereby jeopardizing the big bang nucleosynthesis (BBN) predictions. The dark gray shaded region in the bottom right corner demands (super-)Planckian  $v_{\Phi}$ . As the  $Z' \rightarrow N_1 N_1$  decay channel opens up, one needs  $g_X \lesssim 10^{-10}$  to produce the right relic abundance, satisfying the non-thermal condition for freeze-in. As a consequence, the thick red curve takes a sharp bend at

 $M_{Z'}/2 = M_1$ . For  $M_{Z'} < M_1$ , final DM yield approximately reads  $Y(T_{\rm FI}) \sim \sigma(T_{\rm FI}) M_P T_{\rm FI} \sim g_X^4 M_P / M_1$ , where  $\sigma(T_{\rm FI}) \sim g_X^4/T_{\rm FI}^2$ , with freeze-in temperature  $T_{\rm FI} \sim M_1$  as  $M_1 > M_{Z'}$ . Consequently, the DM abundance becomes almost independent of the mediator mass. Along the red contour, away from the shaded regions, it is always possible to produce the right BAU from  $N_2$ -decay. Conclusions- We have proposed a scenario that simultaneously accounts for both DM and the BAU while remaining testable at IceCube as well as at several proposed GW detectors. Notably, our approach is broadly applicable to the general class of  $U(1)_X$  models. A key element of our framework is the symmetry breaking scale, which unifies all BSM masses and couplings, offering a coherent and compact picture, as illustrated in Fig. 2. This provides bounds on extremely small  $g_X$  along with  $M_{Z'} \gtrsim$ 1 TeV, both lying beyond the reach of standard collider experiments. This work underscores the essential role of multi-messenger astronomy in probing feebly coupled new physics.

# Supplemental Material

### I. RELEVANT DECAY WIDTHS AND CROSS-SECTIONS

The partial decay width of Z' into a pair of single generation SM fermions and DM reads,

$$\Gamma_{Z' \to f_i \bar{f}_i} = N_c \frac{g_X^2 M_{Z'}}{24\pi} \Big[ (Q_L^2 + Q_R^2) \Big], \quad \Gamma_{Z' \to N_1 N_1} = \frac{g_X^2 M_{Z'}}{24\pi} \left( 1 - \frac{4 M_1^2}{M_{Z'}^2} \right)^{\frac{3}{2}}$$
(14)

where  $N_c = 1(3)$  is the color factor for leptons (quarks) and  $Q_{L(R)}$  is the B–L charge for the left(right handed) SM fermions, and we have taken the limit in which  $M_{Z'}$  is much heavier compared to the SM particles.

The dominant decay rates of  $\phi$  are given by,

$$\Gamma_{\phi \to Z'Z'} = \frac{g_X^2}{8\pi r^4} \frac{M_{Z'}^2}{m_{\phi}} \sqrt{1 - 4r^2} \left(12r^4 - 4r^2 + 1\right), \quad \Gamma_{\phi \to N_i N_i} = \frac{g_X^2}{2\pi} \left(\frac{M_i}{M_{Z'}}\right)^2 m_{\phi} \left(1 - \frac{4M_i^2}{m_{\phi}^2}\right)^{3/2} \tag{15}$$

where  $r = M_{Z'}/m_{\phi}$ .

For very heavy Z' and DM, the total annihilation cross-section mediated by Z' reads,

$$\sigma(s)_{\mathrm{SM}\,\mathrm{SM}\to N_1\,N_1} = \frac{170\,g_X^4}{2592\,\pi} \,\frac{s}{\left[(s-M_{Z'}^2)^2 + \Gamma_{Z'}^2\,M_{Z'}^2\right]} \,\left(1 - \frac{4\,M_1^2}{s}\right)^{3/2} \tag{16}$$

where  $\Gamma_{Z'}$  is the total decay width of Z' into all possible final states.

# **II. DARK MATTER PRODUCTION RATE**

Figure 3. Left: DM production rate from Z' decay, as a function of the bath temperature T, for different choices of  $g_X$ . Here we have fixed  $M_{Z'} = 10^7$  GeV. Right: Same as left, but considering DM production from 2-to-2 scattering, mediated by Z', where  $M_{Z'} = 10^5$  GeV. In all cases the DM mass is fixed at 4 PeV.

The DM production rate from Z' decay is given by the production rate densities as

$$\gamma_D = \frac{g_a}{2 \pi^2} m_a^2 \, \Gamma_{Z' \to N_1 \, N_1} \, T \, K_1 \left(\frac{m_a}{T}\right) \,, \tag{17}$$

while production from 2-to-2 scattering off of the bath particles reads

$$\gamma_s = \frac{T}{32\pi^4} g_a g_b \times \int_{\max\left[(m_a + m_b)^2, 4M_1^2\right]}^{\infty} ds \, \frac{\left[\left(s - m_a^2 - m_b^2\right)^2 - 4m_a^2 m_b^2\right]}{\sqrt{s}} \, \sigma\left(s\right)_{a, b \to N_1 \, N_1} \, K_1\left(\frac{\sqrt{s}}{T}\right) \,. \tag{18}$$

Here, the subindices a, b correspond to the SM states,  $g_{a,b}$  are the corresponding degrees of freedom and  $K_i$  denotes the modified Bessel functions of  $i^{\text{th}}$  kind. In order to ensure out of equilibrium DM production, the following condition needs to be satisfied

$$\mathcal{R}_i \equiv \frac{\gamma_i}{n_{\text{eq}}^{N_1} H} < 1\,,\tag{19}$$

where H is the Hubble parameter during radiation domination and  $n_{eq} = (T/(2\pi^2)) m^2 K_2(m/T)$  is the equilibrium number density. Note that, here we use the equilibrium number density for the DM itself in order to obtain the conservative bound on the masses and couplings. In Fig. 3 we show the evolution of DM production rate, as a function of the temperature of the thermal bath. Due to  $g_X^2$  dependence, it is not possible to have  $g_X \gtrsim 10^{-4}$  in order to ensure  $\mathcal{R} < 1$  till  $T \simeq M_{Z'}$  in the case of DM genesis via decay. However, for scattering it is still possible to have  $g_X$  as large as about  $10^{-3}$ , while ensuring  $\mathcal{R} < 1$  because of the  $g_X^4$  dependence of the scattering cross-section. Note that, in this case the DM production starts at  $T \sim M_1$ , as prior to that the thermal bath is not energetic enough to produce such a massive DM.

## III. CP-ASYMMETRY FROM N<sub>2</sub> DECAY

Since  $N_1$  is a long-lived DM, the CP asymmetry generated from  $N_2$  decay is given by

$$\epsilon_{\Delta L} \equiv \frac{\Gamma_{N_2 \to \ell_i H} - \Gamma_{N_2 \to \bar{\ell}_i \bar{H}}}{\Gamma_{N_2 \to \ell_i H} + \Gamma_{N_2 \to \bar{\ell}_i \bar{H}}} \simeq \frac{1}{8\pi} \frac{1}{(Y_\nu^\dagger Y_\nu)_{22}} \operatorname{Im} \left(Y_\nu^\dagger Y_\nu\right)_{23}^2 \times \mathcal{F}\left(\frac{M_3^2}{M_2^2}\right),\tag{20}$$

where

$$\mathcal{F}(x) \equiv \sqrt{x} \left[ \frac{1}{1-x} + 1 - (1+x) \log\left(\frac{1+x}{x}\right) \right].$$
(21)

For  $x \gg 1$ ,  $\mathcal{F} \simeq -3/(2\sqrt{x})$ , and Eq. (20) becomes

$$\epsilon_{\Delta L} \simeq -\frac{3}{16\pi} \frac{1}{(Y_{\nu}^{\dagger} Y_{\nu})_{22}} \times \left[ \operatorname{Im} \left( Y_{\nu}^{\dagger} Y_{\nu} \right)_{23}^{2} \right] \frac{M_{2}}{M_{3}}.$$
 (22)

Then

$$\epsilon_{\Delta L} \simeq -\frac{3\,\delta_{\rm eff}}{16\,\pi}\,\frac{|(Y_{\nu})_{23}|^2\,M_2}{M_3}\,,\tag{23}$$

while the effective CP violating phase is given by

$$\delta_{\text{eff}} = \frac{1}{(Y_{\nu})_{23}^2} \frac{\text{Im}(Y_{\nu}^{\dagger} Y_{\nu})_{23}^2}{(Y_{\nu}^{\dagger} Y_{\nu})_{22}}.$$
(24)

To connect with the light neutrino mass, we impose the seesaw relation

$$m_{\nu,3} = \frac{|(Y_{\nu})_{23}|^2 v^2}{M_1}, \qquad (25)$$

which corresponds to the heaviest left-handed neutrino in the normal hierarchy. This leads to

$$\epsilon_{\Delta L} \simeq -\frac{3 \,\delta_{\text{eff}}}{16 \,\pi} \,\frac{M_2 \, m_{\nu,3}}{v^2} \,.$$
 (26)

# IV. BOLTZMANN EQUATIONS

#### For freeze-in

The coupled BEQs for freeze-in production of the DM,  $N_1$ , read

$$\frac{dy_{\phi}}{dz} = -\frac{z}{\mathcal{H}} \langle \Gamma_{\phi} \rangle y_{\text{eq}}^{\phi} + \frac{s}{\mathcal{H}} \frac{1}{z^2} \langle \sigma v \rangle_{\text{SM SM} \to \phi \phi} \left( y_{\text{eq}}^{\phi} \right)^2,$$

$$\frac{dy_{Z'}}{dz} = -\frac{z}{\mathcal{H}} \langle \Gamma_{Z'} \rangle y_{Z'} + \frac{z}{\mathcal{H}} \langle \Gamma_{\phi \to Z'Z'} \rangle \left( y_{\text{eq}}^{\phi} - y_{Z'} \right),$$

$$\frac{dy_{N_1}}{dz} = \frac{z}{\mathcal{H}} \langle \Gamma_{Z' \to N_1 N_1} \rangle y_{Z'} + \frac{z}{\mathcal{H}} \langle \Gamma_{\phi \to N_1 N_1} \rangle y_{\text{eq}}^{\phi} + \frac{s}{\mathcal{H}} \frac{1}{z^2} \langle \sigma v \rangle_{\text{SM SM} \to N_1 N_1} y_{\text{eq}}^2,$$
(27)

where  $y_i \equiv n_i/s$  is the yield of a certain species *i*, with

$$y_j^{\text{eq}} = \frac{45}{4\pi^4} \frac{g_j}{g_{\star s}} z^2 K_2[z], \qquad (28)$$

is the equilibrium yield, with  $g_j$  being the degrees of freedom for the corresponding j particle and  $z = M_1/T$  is a dimensionless variable. Here,  $\mathcal{H} = (\pi/3) \sqrt{g_\star/10} (T^2/M_P)$  is the Hubble parameter for a standard radiation dominated (RD) Universe and  $s = (2\pi^2/45) g_{\star s}(T) T^3$  is the entropy density. The number of relativistic degrees of freedom in the bath corresponding to energy density and entropy density are tracked by  $g_\star(T)$  and  $g_{\star s}(T)$ , respectively. At temperatures well above the QCD phase transition we have  $g_\star(T) \simeq g_{\star s}(T) \approx 106$ . The first line of Eq. (27) corresponds to the yield of  $\phi$ , with  $\Gamma_{\phi}$  being its decay rate as reported in Appendix. I, where the thermally averaged decay rate is given by

$$\langle \Gamma_{\phi \to jj} \rangle = \frac{K_1(z)}{K_2(z)} \times \Gamma_{\phi \to jj} , \qquad (29)$$

with  $z = M_1/T$ , and j represents the final state particle. The second line of Eq. (27) takes care of the Z' yield, sourced from the decay of  $\phi$ . Finally, in the third line, we provide the evolution equation for DM yield, sourced from Z'-decay,  $\phi$ -decay and Z'-mediated scattering channels.

#### For baryon asymmetry

To track the evolution of RHN number density and the corresponding B-L asymmetry with time, we solve the following set of BEQs (along with the first one in Eq. (27)),

$$\frac{dy_{Z'}}{dz} = -\frac{z}{\mathcal{H}} \langle \Gamma_{Z'} \rangle y_{Z'} + \frac{z}{\mathcal{H}} \langle \Gamma_{\phi \to Z'Z'} \rangle \left( y_{eq}^{\phi} - y_{Z'} \right) 
\frac{dy_{N_2}}{dz} = \frac{z}{\mathcal{H}} \langle \Gamma_{Z' \to N_2 N_2} \rangle y_{Z'} + \frac{z}{\mathcal{H}} \langle \Gamma_{\Phi \to N_2 N_2} \rangle y_{eq}^{\phi} + \frac{s}{\mathcal{H}} \frac{1}{z^2} \langle \sigma v \rangle_{\mathrm{SM \, SM \to N_2 N_2}} \left( y_{N_2}^{\mathrm{eq}\, 2} - y_{N_2}^2 \right) - \frac{z}{\mathcal{H}} \langle \Gamma_{N_2} \rangle \left( y_{N_2} - y_{N_2}^{\mathrm{eq}} \right) 
\frac{dy_{B-L}}{dz} = \frac{\langle \Gamma_{N_2} \rangle}{\mathcal{H}} z \,\epsilon_{\Delta L} \left( y_{N_2} - y_{N_2}^{\mathrm{eq}} \right) - \frac{\langle \Gamma_{N_2} \rangle}{\mathcal{H}} \frac{z^3}{4} \frac{\widetilde{m}_2}{m_\star} K_1(z) \, y_{B-L}$$
(30)

where  $z = M_2/T$ . Once again, the first line of the set of equations above takes into account the production of Z' from the thermal bath, via the decay of  $\phi$  and the decay of Z' into several final states. The second line corresponds to the evolution of  $N_2$  yield. The produced  $N_2$ 's then undergo CP violating out of equilibrium decay producing a net B–L asymmetry. The evolution of this asymmetry is tracked by the last line of the equation, where we also include the contribution of inverse decays to the washout term. Here,  $\tilde{m}_2 = \left(m_D^{\dagger} m_D\right)_{22}/M_2 \approx m_{\nu,2}^2/M_2$  and and  $m_{\star} \simeq 10^{-3}$ eV is the equilibrium neutrino mass [42]. In our scenario, we find,  $\tilde{m}_2 > m_{\star}$ , as a result we are always in the strong washout regime. Thermally averaged  $N_2$  decay width is given by

$$\langle \Gamma_{N_2} \rangle = \frac{K_1(M_2/T)}{K_2(M_2/T)} \frac{M_2}{4\pi} \frac{m_{\nu,2} M_2}{v^2} \,. \tag{31}$$

In the second line we have utilized the seesaw relations, where, following normal hierarchy,  $m_{\nu,1} \simeq 0$ ,  $m_{\nu,2} \simeq 0.0086$  eV and  $m_{\nu,3} \simeq 0.0506$  eV.
