ABSTRACT

As bound stellar systems orbit within a galaxy, stars may be tidally stripped to form streams of stars that nearly follow the orbit of their progenitor system. Stellar streams provide one of the most promising avenues for constraining the global mass distribution of the Milky Way and the nature of dark matter (DM). The stream stars' kinematic "track" enables inferring large-scale properties of the DM distribution, while density variations and anomalies provide information about local DM clumps (e.g., from DM subhalos). Using precise astrometric data from the *Gaia* Mission, which enables clean selections of Milky Way stream stars, we now know of a few streams with perturbations and density anomalies. A full accounting of the density tracks and substructures within all > 100 Milky Way stellar streams will therefore enable powerful new constraints on DM. However, methods for discovering and characterizing membership of streams are heterogeneous and often highly customized to individual streams. Here we present a new, flexible framework for modeling stellar stream density and membership. Our framework allows us to include off-track or non-Gaussian components to the stream density, meaning we can capture anomalous features (such as the GD-1 steam's spur). We test our model on GD-1, where we characterize previously-known features and provide the largest catalog of probable member stars to date (1689 stars). Our framework (built on JAX and numpyro) provides a path toward uniform analysis of all Milky Way streams, enabling tight constraints on the Galactic mass distribution and its dark matter.

1. INTRODUCTION

In the Λ-Cold Dark Matter (ΛCDM) cosmological paradigm, galaxies form through hierarchical structure formation. Small matter overdensities in the early universe combine to form dark matter halos, which subsequently merge to create larger structures capable of hosting galaxies (e.g., Peebles 1965; Press & Schechter 1974; White & Rees 1978; Blumenthal et al. 1984; Davis et al. 1985). There is strong evidence supporting this theory across a range of mass and length scales in the universe, from large-scale structure (e.g., White & Frenk 1991; Springel et al. 2005; Eisenstein et al. 2005; Klypin et al. 2011) to the nearby universe (e.g., Bullock et al. 2000; Drlica-Wagner et al. 2015). For example, in our galaxy, observations indicate that over its history, the Milky Way has accreted dozens of dwarf galaxies and

Corresponding author: Kiyan Tavangar k.tavangar@columbia.edu potentially hundreds of smaller objects such as globular clusters (GCs) (Searle & Zinn 1978; Vasiliev 2019).

As these objects fall into the Milky Way, the Galaxy's gravitational force acts on their constituent stars, sometimes unbinding them from their progenitors (Toomre & Toomre 1972). This process, known as tidal stripping, forms structures known as stellar streams and shells (see Bonaca & Price-Whelan 2025 for a recent overview of streams in the Milky Way). Observations of these shells and streams in the Galaxy over the past half-century constitute some of the strongest evidence for the hierarchical build-up of stellar halos and of Λ CDM (e.g., Odenkirchen et al. 2001; Newberg et al. 2002; Belokurov et al. 2006; Shipp et al. 2018; Malhan et al. 2018; Ibata et al. 2024).

In the Milky Way alone, we now count nearly 150 stellar streams (Mateu 2023), with an explosion of stream discoveries over the past decade from surveys such as *Gaia* (Gaia Collaboration et al. 2016), the Sloan Digital Sky Survey (Kollmeier et al. 2017), and the Dark Energy Survey (The Dark Energy Survey Collaboration 2005). In the next decade, we expect telescopes such as the Vera

Rubin Observatory and the Nancy Grace Roman Space Telescope to discover dozens more streams both in the Milky Way and external galaxies (Pearson et al. 2022a; Bonaca & Price-Whelan 2025). Streams are useful objects for tackling two major research questions: understanding the nature of dark matter (Johnston et al. 2002; Ibata et al. 2002; Siegal-Gaskins & Valluri 2008; Carlberg 2009; Yoon et al. 2011; Bonaca et al. 2019; Drlica-Wagner et al. 2019; Foote et al. 2024; Hilmi et al. 2024) and constraining the shape of galaxy potentials (e.g., Springel & White 1999; Dubinski et al. 1999; Johnston et al. 1999, 2005; Binney 2008; Koposov et al. 2010; Law & Majewski 2010; Amorisco et al. 2015; Price-Whelan et al. 2014; Sanders 2014; Erkal et al. 2016; Bovy et al. 2016; Shipp et al. 2021a; Pearson et al. 2022b; Koposov et al. 2023; Ibata et al. 2024).

For the former, streams allow us to constrain dark matter halos on smaller scales than most other objects in the Universe (i.e. dark matter subhalos with masses $M \gtrsim 10^6 \, \mathrm{M_{\odot}}$). A stream formed in a perfectly smooth potential will have a nearly homogeneous density distribution along its length and follow a smooth track in all astrometric coordinates, with density variations caused only by orbital pileups known as "epicyclic overdensities" (e.g., Küpper et al. 2012). However, if a stream interacts with lumps in the potential (e.g., small dark matter subhalos), these perturbations can create density gaps, small-scale fluctuations in the astrometric stream tracks, or stream stars moving off the main track, all of which exist in observed streams. Consequently, streams can be used to study dark matter subhalos below the threshold for galaxy formation $\lesssim 10^8 M_{\odot}$ (Yoon et al. 2011; Bonaca et al. 2014; Benitez-Llambay & Frenk 2020). Identifying subhalos in this mass range would provide key observations of structure in a regime where ACDM differs from competing theories of dark matter, such as fuzzy DM (Hui et al. 2017), warm dark matter (WDM; Bond & Szalay 1983; Bode et al. 2001), and self-interacting DM (SIDM; Spergel & Steinhardt 2000; Elbert et al. 2015). Streams therefore offer a straightforward conceptual path towards an improved understanding of dark matter.

Streams are also powerful tools with which to infer the global mass distribution of the Milky Way because they approximately trace orbits (Bonaca & Hogg 2018). Due to the increased precision from ensemble averaging stream star orbits, even a single well-measured stream can constrain the shape of its host galaxy's potential (Law & Majewski 2010; Ibata et al. 2013; Vera-Ciro & Helmi 2013; Gibbons et al. 2014; Dierickx & Loeb 2017; Newberg et al. 2010; Price-Whelan et al. 2014; Bowden et al. 2015; Küpper et al. 2015; Bovy et al. 2016; Pearson et al. 2022b) and those constraints only tighten when using multiple streams to derive potential parameters (e.g., Erkal et al. 2019; Shipp et al. 2021b; Koposov et al. 2023). Recently, Ibata et al. (2024) leveraged the combined power of 29 stellar streams to present a global mass model of the Milky Way and infer its shape.

Constraining the large-scale and small-scale properties of dark matter around the Milky Way requires excellent empirical models of observed streams. This is a difficult problem because most streams have been orbiting their host potentials for billions of years, and they can differ from idealized simulations in a multitude of ways. A number of streams around the Milky Way, for example, display complex morphological features: ATLAS-Aliqa Uma has a discontinuity in its track (Li et al. 2021); Jhelum appears to be non-Gaussian in its matter distribution across the stream, with both a broad and narrow component (Shipp et al. 2018; Bonaca et al. 2019); and GD-1 contains a "spur", a stream feature lying off its main track (Price-Whelan & Bonaca 2018). Empirical models of stream density and membership must be capable of and effective at capturing these anomalies since they are features of great interest for constraints on dark matter and host potentials.

Over the past decades, many methods have been developed to study the density structure of observed streams (e.g., Odenkirchen et al. 2001; Erkal et al. 2017; Koposov et al. 2019; Li et al. 2021; Ferguson et al. 2022; Tavangar et al. 2022; Patrick et al. 2022; Starkman et al. 2023). These models have generally been effective at recovering gaps and under-densities, but "off-track," non-Gaussian, or discontinuous features of streams have been more difficult to incorporate (for simplicity, future references to "off-track" features refer to all three of these types of features, unless otherwise noted). In particular, off-track features are usually modeled by assuming their existence (e.g., Starkman et al. 2023). Such a model relies on prior knowledge of an off-track feature, most likely based on visual inspection of stream members. Therefore, it is incapable of detecting previously undiscovered or faint off-track structures. In this paper, we present an empirical model of stream density that does accommodate and can recover new off-track components. With the model, we can generate stream tracks in kinematic coordinates (3D positions and velocities) and density as well as calculate membership probabilities for stars in the region.

Along with a description of our model framework and an associated Python package for constructing generic stream models, we present an application to the GD-1 stream, discovered by Grillmair & Dionatos (2006). GD-1 is one of the most promising streams for obtaining

constraints on the Milky Way potential and especially the nature of dark matter (Lux et al. 2013; Bonaca & Hogg 2018; Lu et al. 2025). It is a dynamically cold, thin, and metal-poor globular cluster stream spanning approximately 100° across the sky (de Boer et al. 2018; Price-Whelan & Bonaca 2018). GD-1's proximity (≈ 8 kpc) and high surface brightness mean it is a prime candidate for detailed observations of any inhomogeneities. Indeed, GD-1 contains a few prominent such features: many gaps along the stream along with an off-track "spur" and an off-track "blob" (Price-Whelan & Bonaca 2018). These latter two features are particularly exciting because their observable properties (e.g., angle away from the stream, length, and proper motion) allow an excellent opportunity to constrain the perturbation that caused them. A better constraint on this perturbation in GD-1 (and specifically an improved estimate of the mass of the perturber) could lead to a better understanding of dark matter (Bonaca et al. 2019).

We intend our method to be used in examinations of known streams. While the model could in theory discover new streams, it is designed to function as a characterization tool for known streams, where we already have an idea of stream properties. The paper is organized as follows. In Section 2, we detail the model. In Section 3, we apply the model to GD-1 and show that we recover the best sample of stream stars to date. We discuss the results in Section 5 and finally conclude in Section 6.

2. METHODS: A FLEXIBLE DENSITY MODEL FOR STELLAR STREAMS

The goal of our modeling framework is to infer the intrinsic number density distribution or probability distribution function (PDF) of stars in a stellar stream given noisy observations of its kinematic properties. Here, we focus on the kinematics of stars, but note below that this will be extended to also model the stellar population (or color-magnitude) structure of a stream. We consider observable kinematic coordinates like sky position (ϕ_1, ϕ_2) (longitude and latitude in a spherical coordinate system rotated with respect to standard equatorial coordinates in the International Celestial Reference System), distance d or distance modulus DM, proper motion components¹ $(\mu_{\phi_1}, \mu_{\phi_2})$, and radial (line-of-sight) velocity v_r . For most streams, the rotated coordinate system we work in — (ϕ_1, ϕ_2) — is chosen such that ϕ_1 increases monotonically along the extent of the stream. For brevity, we define $\mu_1 = \mu_{\phi_1}$ and $\mu_2 = \mu_{\phi_2}$. In our notation below, we also define these (or potentially a specified subset of these coordinates) as the data vector $\boldsymbol{y} = (\phi_1, \phi_2, d, \mu_1, \mu_2, v_r)$. Given noisy observations of these phase-space coordinates \boldsymbol{y} for some sample of stars, we then want to infer the parameters $\boldsymbol{\theta}$ of a model for the probability density over the *true* phase-space coordinates $\tilde{\boldsymbol{y}} = (\tilde{\phi}_1, \tilde{\phi}_2, \tilde{d}, \tilde{\mu}_1, \tilde{\mu}_2, \tilde{v}_r)$.

Of course, no practical data set will contain a pure sample of stars in a stellar stream. We must therefore account for non-member "background" stars in our modeling setup. We handle this by constructing a *mixture model* for the probability density of observed phasespace coordinates.

Our flexible stream density model framework is publicly available as the Python package stream-membership on Github.² This package is built using jax (Bradbury et al. 2018) and numpyro (Bingham et al. 2019; Phan et al. 2019); jax enables automatic differentiation, just-in-time (JIT) compilation, and automatic vectorization of the model implementation, and numpyro provides a probabilistic model-building framework for implementing probability density models. These libraries make our model fitting process efficient, user-friendly, and extensible, which we elaborate on in Section 5.1.

In the subsections below, we describe how we represent and parameterize the stream and background components of our density mixture model for our default stream model implementation. However, we note that many of these details are customizable using any standard functionality from jax and numpyro.

2.1. The Stream Model Component

Many stellar streams around the Milky Way appear as over-densities of stars with spatial and velocity trends that vary smoothly along their length. For our default stream density model, we therefore choose to factorize the joint PDF over all phase-space coordinates into a term that specifies the linear density in stream longitude ϕ_1 , with all other phase-space coordinate distributions conditional on longitude ϕ_1 . In detail, we factorize the joint PDF for the stream component, $p_s(\tilde{y} | \boldsymbol{\theta}_s)$, as:

$$p_{s}(\tilde{\boldsymbol{y}} \mid \boldsymbol{\theta}_{s}) = p_{s}(\phi_{1} \mid \boldsymbol{\theta}_{s}) p_{s}(\phi_{2} \mid \phi_{1}, \boldsymbol{\theta}_{s}) p_{s}(d \mid \phi_{1}, \boldsymbol{\theta}_{s})$$
$$\times p_{s}(\tilde{\mu}_{1} \mid \phi_{1}, \boldsymbol{\theta}_{s}) p_{s}(\tilde{\mu}_{2} \mid \phi_{1}, \boldsymbol{\theta}_{s}) p_{s}(\tilde{v}_{r} \mid \phi_{1}, \boldsymbol{\theta}_{s})$$
(1)

where $\boldsymbol{\theta}_s$ are the parameters that specify the stream density model. We have not yet specified the functional form of the coordinate distributions (e.g., $p_s(\tilde{\phi}_2 | \phi_1, \boldsymbol{\theta}_s))$

¹ In notation, we assume that the proper motion value in the longitude μ_{ϕ_1} implicitly contains a multiplicative $\cos \phi_2$ factor.

² https://github.com/stellarstreams/stream-membership

or the parameters of the stream model component: We define these later when specifying our application to the GD-1 stream.

2.2. Background Model Component

To properly characterize the density of structures in the Milky Way halo, it is vital to characterize the density of background (or foreground) stars. When modeling stellar membership of compact structures like globular clusters and dwarf galaxies, one can often assume a constant or linearly varying background density of stars because these structures cover a small area on the sky. However, stellar streams are extended objects that can span tens or hundreds of degrees, meaning the background stellar density can vary substantially along a stream. Our framework is flexible enough to allow for a variety of background models, from simple constant or linearly varying densities to more complex models that vary in multiple dimensions. We represent the background component of our mixture model with the PDF $p_b(\tilde{\boldsymbol{y}} | \boldsymbol{\theta}_b)$, which has its own parameters $\boldsymbol{\theta}_b$.

2.3. Off-track Model Component

Many observed streams are now known to have complex morphological features such as gaps, spurs, blobs, breaks, and multi-component densities (see, e.g., Bonaca & Price-Whelan 2025) that represent populations of stars that are co-moving with a stream but may not be well-represented by a single conditional density model as defined above. We therefore generally add an additional component to our overall mixture model to represent these "off-track" stars. We represent this mixture component with the PDF $p_o(\tilde{\boldsymbol{y}} | \boldsymbol{\theta}_o)$, which has its own parameters $\boldsymbol{\theta}_o$. This component may have more complex joint dependencies, so we do not generically factorize to be fully conditional on ϕ_1 as we did for the stream component. However, we will often either explicitly tie some parameters of this component to the parameters of the stream component, or we will place strong priors on the parameters of this component to ensure that it does not interfere with the main stream component in regions where a 1D stream is well-defined.

2.4. The Full Density Model

In our default stream density model, we represent the full stellar density distribution as a mixture of the stream, background, and off-track components so that the full PDF for a star's true phase-space coordinates \tilde{y} is

$$p(\tilde{\boldsymbol{y}} \mid \boldsymbol{\theta}) = \alpha_s \, p_s(\tilde{\boldsymbol{y}} \mid \boldsymbol{\theta}_s) + \alpha_b \, p_b(\tilde{\boldsymbol{y}} \mid \boldsymbol{\theta}_b) + \alpha_o \, p_o(\tilde{\boldsymbol{y}} \mid \boldsymbol{\theta}_o) \quad (2)$$

where $\boldsymbol{\theta} = (\boldsymbol{\theta}_s, \boldsymbol{\theta}_b, \boldsymbol{\theta}_o)$ and $\boldsymbol{\alpha} = (\alpha_s, \alpha_b, \alpha_o)$ are the mixing coefficients that specify the relative contributions of the stream, background, and off-track components to the overall density distribution (and $\alpha_s + \alpha_b + \alpha_o = 1$). The likelihood of the observed data \boldsymbol{y} given the density model parameters $\boldsymbol{\theta}$ is then

$$p(\boldsymbol{y}, \tilde{\boldsymbol{y}} | \boldsymbol{\theta}) = p(\boldsymbol{y} | \tilde{\boldsymbol{y}}) p(\tilde{\boldsymbol{y}} | \boldsymbol{\theta})$$
(3)

where in most cases we assume (as is standard) that the observational noise is Gaussian with a covariance matrix specified by the survey catalogs we use below (e.g., for Gaia; Hogg 2018). With this assumption,

$$p(\boldsymbol{y}|\tilde{\boldsymbol{y}}) = \mathcal{N}(\boldsymbol{y}|\tilde{\boldsymbol{y}}, \Sigma_{\boldsymbol{y}})$$
(4)

where $\mathcal{N}(\boldsymbol{y}|\tilde{\boldsymbol{y}}, \Sigma_y)$ represents the normal distribution with mean $\tilde{\boldsymbol{y}}$ and the covariance matrix Σ_y is specified by the observational uncertainties in the data. In practice, we have data and true phase-space coordinates for a sample of N stars (indexed by n) so that the total likelihood \mathcal{L} is

$$\mathcal{L}(\{\tilde{\boldsymbol{y}}\}_N, \boldsymbol{\theta}; \{\boldsymbol{y}\}_N) = \prod_n^N p(\boldsymbol{y}_n | \tilde{\boldsymbol{y}}_n) p(\tilde{\boldsymbol{y}}_n | \boldsymbol{\theta}) \quad .$$
 (5)

We are interested in inferring the parameters $\boldsymbol{\theta}$ of the density model and not the true, per-star phase-space coordinates $\tilde{\boldsymbol{y}}_n$. That is, we are most interested in the marginal posterior PDF $p(\boldsymbol{\theta} | \{\boldsymbol{y}\}_N)$. In the next section, we describe how we perform this inference using variational inference.

2.5. Inference

With the model scaffolding in place (details about our choices for parameterizing this model for GD-1 are shown in Section 3), our next goal is to infer the parameters $\boldsymbol{\theta}$ of the density model. As we are interested in the stream density distribution and uncertainties in the parameters, we opt to simultaneously infer and marginalize over the true phase-space coordinates $\tilde{\boldsymbol{y}}$, the background density component parameters $\boldsymbol{\theta}_b$, and the mixture weight coefficients $\boldsymbol{\alpha}$. That is, we are interested in the marginal posterior PDF

$$p(\boldsymbol{\theta}_{s},\boldsymbol{\theta}_{o} | \{\boldsymbol{y}\}_{N}) = \int \mathrm{d}\boldsymbol{\theta}_{b} \,\mathrm{d}\boldsymbol{\alpha} \,\mathrm{d}^{N} \tilde{\boldsymbol{y}} \\ \times p(\boldsymbol{\theta}_{s},\boldsymbol{\theta}_{b},\boldsymbol{\theta}_{o},\boldsymbol{\alpha},\{\tilde{\boldsymbol{y}}\}_{N} | \{\boldsymbol{y}\}_{N})$$
(6)

where the full posterior PDF is specified by multiplying our likelihood (Equation 5) by prior PDFs over all model parameters,

$$p(\boldsymbol{\theta}_{s},\boldsymbol{\theta}_{b},\boldsymbol{\theta}_{o},\boldsymbol{\alpha},\{\tilde{\boldsymbol{y}}\}_{N} \mid \{\boldsymbol{y}\}_{N}) \propto \left[\prod_{n}^{N} p(\boldsymbol{y}_{n} | \tilde{\boldsymbol{y}}_{n}) p(\tilde{\boldsymbol{y}}_{n} \mid \boldsymbol{\theta})\right] p(\boldsymbol{\theta}_{s},\boldsymbol{\theta}_{b},\boldsymbol{\theta}_{o},\boldsymbol{\alpha}) \quad .$$
⁽⁷⁾

A standard approach to this inference problem is to use a Markov Chain Monte Carlo (MCMC) method to sample the full posterior PDF, and consider only values for the parameters of interest. Here, however, our parameter space is high-dimensional (it scales with the number of stars we use in our inference) and MCMC would therefore be computationally prohibitive. In special cases — i.e. when the forms of the component distributions $p_s(\cdot), p_b(\cdot), p_o(\cdot)$ are Gaussian for all coordinates — we can analytically marginalize over the true phase-space coordinates \tilde{y} , greatly reducing the number of parameters we need to infer. In general cases, this marginalization must be done numerically. We therefore use variational inference to approximate the full posterior PDF and enable this high-dimensional marginalization.

Variational inference (VI; Jordan et al. 1999; Wainwright & Jordan 2008; Blei et al. 2017) is a method for approximating the posterior PDF by optimizing a simpler "guide" distribution that is easier to sample from. VI works by maximizing the evidence lower bound (ELBO) of the guide distribution. We use numpyro to perform the VI optimization and typically use a composition of independent normal distributions for each parameter as the guide distribution. This choice is approximate in that it assumes that the posterior PDF is Gaussian and cannot capture covariances between parameters in the posterior PDF, but it is computationally efficient and often provides a conservative approximation to the true posterior PDF.

3. APPLICATION TO THE GD-1 STREAM: MODEL SETUP AND INFERENCE

Having defined the general framework for our model, we now turn to a specific application to the GD-1 stellar stream. GD-1 is a natural choice for this demonstration because of its length ($\approx 100^{\circ}$), relative proximity (distance $d \approx 8 \,\mathrm{kpc}$), high surface brightness, and known density variations (e.g., Ibata et al. 2024). It also contains off-track features (a spur and a blob; Price-Whelan & Bonaca 2018) that provide an excellent test for the major innovation of our method: modeling co-moving, off-track density components of streams.

We choose to model the stream in sky positions, proper motions, and radial velocity (i.e., $\boldsymbol{y} = (\phi_1, \phi_2, \mu_1, \mu_2, v_r)$), but do not model the distance (or parallax) distribution along the stream. For the model to function, every star must have measurements (including uncertainties) for each coordinate. Every star has sky positions and proper motions but only a small fraction have radial velocities. For the stars with no v_r measurement, we assign $v_r = 0 \,\mathrm{km \, s^{-1}}$ with a velocity uncertainty set to a very large number $\sigma_{v_r} = 10^4 \,\mathrm{km \, s^{-1}}$, which effectively treats these as missing measurements. Additionally, the *Gaia* errors on sky position are negligible, so we arbitrarily set those at 10^{-4} deg.

We do not model the stellar population (colormagnitude) of the stream in our probabilistic model. We instead perform selections in color and magnitude to select metal-poor and distant stars. This means we also do not model the stream's distance track: the stellar parallaxes are very low signal-to-noise and thus most distance information would come from modeling the colormagnitude distribution of the stream.

We release the code for this application to GD-1 in a separate repository³ from the more general stream-membership code.

3.1. Data pre-selection

For this analysis we use data from *Gaia*'s third data release (DR3; Gaia Collaboration et al. 2016, 2023) and PanSTARRS1's second data release (PS1 DR2; Chambers et al. 2016). Gaia is an all-sky stellar survey that provides positions and velocities for almost two billion stars in the Milky Way, allowing us to constrain their precise orbits. PS1 is a photometric survey of the northern sky ($\delta > -30^{\circ}$), which has a deeper magnitude limit than Gaia and therefore has higher photometric precision. We cross-match the *Gaia* and PS1 datasets and henceforth use *Gaia* astrometry and PS1 photometry unless otherwise noted. We reduce the computational burden by filtering out stars that are highly unlikely to be part of the GD-1 stream with pre-selections on proper motions and the color-magnitude distribution of stars in this cross-matched dataset. We generally use the galstreams track of GD-1 (Mateu 2023) to help define these selections.

We consider the following two factors when forming the dataset on which the model is run. First, a higher purity sample is helpful because it reduces the number of stars and allows easier separation of stream and background stars. These improve the computational efficiency and model performance, respectively. Second, a high completeness sample is necessary. In particular, we cannot have cuts in any modeled coordinate \boldsymbol{y} that excludes stream stars with specific properties $\hat{\boldsymbol{y}}$ because the stream component of our model will then be biased against including the area around $\hat{\boldsymbol{y}}$. Given this, we make as many cuts to the input dataset as possible without a significant effect on stream completeness in the modeled coordinates.

³ https://github.com/ktavangar/gd1-dr3

Figure 1. The distribution of all stars in our *Gaia*-PS1 cross-matched sample in the sky region near GD-1 (grayscale) and a visualization of our initial selections (blue and red polygons). The color scale of the grayscale images is logarithmic. Left: The distribution of proper motions in stream-aligned coordinates (ϕ_1, ϕ_2) . The blue rectangle shows the initial selection we make in this space to create the input data for our model. Right: The distribution of stars in PS1 g - r color and absolute g-band magnitude M_g , using a previously inferred distance track (Valluri et al. 2024). The red polygons show the selections we make to create the input data for our model.

We first select a spatial region around GD-1. Previous works have identified GD-1 members in the $-90^{\circ} <$ $\phi_1 < 10^\circ$ (e.g., Price-Whelan & Bonaca 2018). To make sure we do not omit any stream members outside this ϕ_1 range, we include an additional 10° on either side in our data selection. We then choose $-7.97^{\circ} < \phi_2 < 3.35^{\circ}$, which includes the entirety of the known stream and a few degrees above and below it, which are crucial for creating a background model. We then make two initial cuts: a parallax cut of $\varpi < 1$ arcsecond to eliminate nearby stars and a magnitude cut of Gaia G < 20.5. The latter ensures that our density model does not depend on Gaia's selection function since for G < 20.5 in this sky region, Gaia is $\approx 100\%$ complete with no spatial variation in the selection function (Cantat-Gaudin et al. 2023).

We then make a generous proper motion cut to remove disk and general halo stars that are very unlikely to be part of GD-1. We use results from Price-Whelan & Bonaca (2018) (henceforth PWB18), which published GD-1 tracks for μ_1 and μ_2 as a function of ϕ_1 in the range $-90^{\circ} < \phi_1 < 10^{\circ}$.⁴ Specifically, we extend the tracks to cover our full ϕ_1 range by extrapolating from an interpolated spline of the PWB18 results. We then take the minimum and maximum values of the extended μ_1 and μ_2 tracks and create a buffer of 2 mas/yr around those values. This creates a rectangular selection in proper motion space shown in the left panel of Figure 1. We summarize our data cuts so far with:

- $-100^{\circ} < \phi_1 < 20^{\circ}$
- $-7.97^{\circ} < \phi_2 < 3.35^{\circ}$
- $\varpi < 1$ arcsecond
- G < 20.5 mag
- $-15.10 \,\mathrm{mas} \,\mathrm{yr}^{-1} < \mu_1 < -4.64 \,\mathrm{mas} \,\mathrm{yr}^{-1}$
- $-5.42 \,\mathrm{mas} \,\mathrm{yr}^{-1} < \mu_2 < 1.93 \,\mathrm{mas} \,\mathrm{yr}^{-1}$

We now turn to our stellar population (colormagnitude) cut. Since we do not model this space, we cannot bias the model by being incomplete in this space. Therefore, we can make more stringent cuts and safely increase the purity to aid the stream and background separation as well as the computational efficiency, as mentioned above. We assume GD-1's stars come from a single stellar population, which allows us to use a single isochrone as long as we account for the distance gradient along the stream. To do so, we use the distance modulus track from Valluri et al. (2024):

$$DM = 0.0002440 \phi_1^2 + 0.02441 \phi_1 + 14.98$$
(8)

This allows us to create a color-absolute magnitude diagram $(M_g \text{ vs. } g - r)$, as shown in the right panel of Figure 1. We assume the stream lies along a Dotter isochrone (Dotter 2016) with [Fe/H] = -2.5 dex and age = 12 Gyr (Valluri et al. 2024). This theoretical isochrone may not perfectly match the stream's photometric distribution, so we allow it to shift in both M_q and q - r (with its shape fixed) until it is the best fit to the stream's main sequence. We then draw a polygon around the isochrone's main sequence $(M_q > 3.2)$ to create our selection box. The width of our selection region depends on the M_q uncertainty as well as the intrinsic dispersion of stream stars around the isochrone track. For the former, we follow Shipp et al. (2018) and fit the median M_g error as a function of M_g in PS1 to obtain the following function for observational uncertainties:

$$M_{g,\text{err}} = 0.004 + \exp\left(\frac{M_g - 8.41}{1.10}\right)$$
 (9)

For the latter, we choose an intrinsic width of 0.075 dex in g - r based on visual inspection of the result. This makes the total width w_{g-r} of the selection region in g - r:

$$w_{g-r}(M_g) = 0.075 + 2M_{g,\text{err}}$$
 (10)

where we multiply $M_{g,\text{err}}$ by 2 to ensure we get all stars within 2σ of the theoretical isochrone. This is wide enough for us to be confident that we are almost complete for GD-1's main sequence stars, which we re-assess

⁴ These proper motion tracks, along with those for the other astrometric coordinates (ϕ_2, d, v_r) , are publicly available and easily accessible through the galstreams python package (Mateu 2023).

Figure 2. Three different projections of the sample of stars used as input to the density model, all as a function of stream longitude ϕ_1 . These stars pass the proper motion and CMD selections described in Section 3.1 (and shown in Figure 1). The grayscale images show the number of stars in each bin, and the red shaded regions show the mean track and dispersion of the stream from galstreams (Mateu 2023) that are used for initialization of the density model (described in Appendix C). Top: Sky positions of stars in stream longitude ϕ_1 and latitude ϕ_2 (Koposov et al. 2010). Middle: Proper motion in ϕ_1 for stars in the above sky region. The extent of the y-axis in this panel shows the selection in μ_1 used to create the model input dataset. Bottom: Proper motion in ϕ_2 for stars in the above sky region. The extent of the y-axis in this panel shows the selection in μ_2 used to create the model input dataset.

later. Finally, we also select the horizontal branch region of the CMD space. The specific cut we make is shown in the right panel of Figure 1, along with the main sequence isochrone selection. We do not include the red giant branch of the isochrone because the signal-to-noise (in number of GD-1 stars vs. number of background stars) in this region is low and it would decrease the purity of the sample significantly without much benefit.

We collect radial velocity measurements from several public spectroscopic surveys and data sets: *Gaia* DR3 (Gaia Collaboration et al. 2023), APOGEE DR17 (Majewski et al. 2017; Abdurro'uf et al. 2022), SEGUE (Yanny et al. 2009), DESI (Cooper et al. 2023; DESI Collaboration et al. 2024), and MMT/Hectochelle observations of stars targeted to be associated with GD-1 (Bonaca et al. 2020a). We cross-match these datasets to our *Gaia*–PS1 sample in the GD-1 sky footprint and use the radial velocities from these surveys as our v_r measurements. Out of our full *Gaia*–PS1 sample, 16,610 stars have *Gaia* RVs, 1,339 APOGEE, 16,175 SEGUE, 7,808 DESI, and 1,160 MMT/Hectochelle (with many overlapping between surveys). When multiple measurements are available for a star, we use the inverse-variance weighted average of the measurements using their reported radial velocity uncertainties. For stars with no radial velocity measurement, we assign $v_r = 0 \,\mathrm{km}\,\mathrm{s}^{-1}$ and $\sigma_{v_r} = 10^4 \,\mathrm{km}\,\mathrm{s}^{-1}$ (an arbitrarily large value meant to null out the contribution of stars with missing RVs to the likelihood).

3.2. Model choices for GD-1

We summarize our model choices for the GD-1 background, stream, and off-track components in Table 1 and below. These choices aim to balance model flexibility with computational efficiency and interpretability. The model is designed to be easily adaptable to other streams while capturing the key physical features we expect to see in GD-1 based on previous studies.

Our modeling framework uses cubic splines as a function of ϕ_1 to represent smooth variations in the model parameters. Cubic splines are piecewise functions that connect third-degree polynomial segments at specified points called "knots" to create a twice continuously differentiable curve. In our implementation, the knot locations (in ϕ_1) are fixed hyperparameters that determine the physical scales over which the model can detect structure: small separations between knots enable the model to capture small-scale features, while large separations smooth out the functional dependencies of parameters in the model. We discuss our specific choices for knot placements for each parameter below. For all components, we model the sky positions (ϕ_1, ϕ_2), proper motions (μ_1, μ_2), and radial velocity v_r .

3.2.1. Stream Model Choices

Our stream model represents the distribution of stream stars along the main track of GD-1 in density, position, and velocities. We use a mixture of normals with fixed means separated by 5° to model the density in stream longitude ϕ_1 , motivated by previous results (e.g., Price-Whelan & Bonaca 2018) that show density fluctuations on $\sim 10^{\circ}$ scales. We use truncated normal distributions to model the stream latitude, proper motion, and radial velocity distributions. To control the parameters of these truncated normals, we use cubic splines with knots placed every 10° in ϕ_1 . For the stream latitude and proper motion coordinates, these knots encompass the entire range of $-100^{\circ} < \phi_1 < 20^{\circ}$, but for the radial velocities, we reduce this range to the ϕ_1 range with radial velocity measurements of probable stream member stars $(-82.29^{\circ} < \phi_1 < 2.60^{\circ})$. We make these knot separation choices based on previous studies of GD-1 that show relatively smooth astrometric tracks.

Coordinate	Probability Distribution Parameters				
Background					
ϕ_1	Gaussian mixture model (GMM)	$\{\alpha_k\}_{K_{\phi_1}}, \{\sigma_k\}_{K_{\phi_1}}$			
ϕ_2	uniform	_			
μ_1	mixture of two truncated normals	$oldsymbol{lpha},m_1(\phi_1),m_2(\phi_1),\sigma_1(\phi_1),\sigma_2(\phi_1)$			
μ_2	mixture of two truncated normals	$oldsymbol{lpha},m_1(\phi_1),m_2(\phi_1),\sigma_1(\phi_1),\sigma_2(\phi_1)$			
v_r	mixture of two truncated normals	$oldsymbol{lpha},m_1(\phi_1),m_2(\phi_1),\sigma_1(\phi_1),\sigma_2(\phi_1)$			
Stream					
ϕ_1	GMM	$\{\alpha_k\}_{K_{\phi_1}}, \{\sigma_k\}_{K_{\phi_1}}$			
ϕ_2	truncated normal	$m(\phi_1),\sigma(\phi_1)$			
μ_1	truncated normal	$m(\phi_1),\sigma(\phi_1)$			
μ_2	truncated normal	$m(\phi_1),\sigma(\phi_1)$			
v_r	truncated normal	$m(\phi_1),\sigma(\phi_1)$			
Off-track					
ϕ_2,ϕ_1	GMM	$\{\alpha_k\}_{K_{\phi_1}}, \{\sigma_k\}_{K_{\phi_1}}$			
μ_1	truncated normal	$m(\phi_1),\sigma(\phi_1)$			
μ_2	truncated normal	$m(\phi_1),\sigma(\phi_1)$			
v_r	truncated normal	$m(\phi_1),\sigma(\phi_1)$			

Table 1. Overview of our model choices for GD-1 background, stream, and off-track components. For each of the Gaussian mixture model (GMM) components, we fix the means of the component distributions, but other parameters are allowed to vary (standard deviation σ and mixture weights α). See Section 3.2 for further explanation.

A more detailed mathematical formulation of this model component is presented in Appendix B.1.

To increase the speed of convergence when optimizing the full density model, it is important to initialize each component with reasonable starting parameter values. We therefore first run a VI optimization of the stream component individually by fitting the model to a dataset only consisting of stars consistent with GD-1's sky position and proper motion tracks. This selection is based on the PWB18 GD-1 tracks, and we show the selected regions in each space with red bands in Figure 2. We detail the initialization of this stream VI run in Appendix C and show the results in Figure 11. We note that this initialization is not perfect (clear from the $\phi_2 - \phi_1$ residual in the bottom panel of Figure 11), but it does provide a reasonable starting point for optimizing the full model.

3.2.2. Background Model Choices

Our background model represents the smooth distribution of non-stream stars in the sky region around GD-1. As with the stream model, we use a mixture of normals to model the density in stream longitude ϕ_1 . Contrary to the stream model, however, we then assume a uniform distribution in stream latitude ϕ_2 , and use mixtures of truncated normal distributions to model the proper motion and radial velocity distribu-

tions. We again use cubic splines to control the parameters of these truncated normal distributions, this time with knots placed every 40° in ϕ_1 . This separation ensures that our background model cannot capture smallscale variations that might be associated with stream features. The detailed mathematical formulation of this model component is presented in Appendix B.2.

As with the stream component, we run a VI optimization of the background component individually to improve the initialization of the full model. We fit the background to the complement of the "stream-only" dataset we use to optimize the stream component (see Section 3.2.1). We detail the initialization of this background VI run in Appendix C and show the results in Figure 10. As with the stream model, this initialization is not perfect, but it provides a reasonable starting point for optimizing the full model.

3.2.3. Off-track Model Choices

Our off-track model represents the distribution of GD-1 stars that do not lie along the main stream track. In other words, these are features in sky positions, (ϕ_1, ϕ_2) , that deviate from the main stream track but have other kinematic observables suggesting a likely association with GD-1. The key assumption for modeling this component is that the proper motions and radial

velocities (referred to collectively in this subsection as "kinematics") of stream stars that migrate off the main stream track have kinematics similar to that of the main stream. This assumption is supported by observed offtrack structures (e.g., GD-1's spur), the precision of our kinematic measurements, and the fact that strong interactions capable of significantly altering proper motions tend to scatter stars over a large area, rather than creating localized positional overdensities away from the main track. Therefore, we adopt the same distributions to model the off-track kinematics as we do for the stream kinematics (i.e., spline models controlling the parameters of truncated normal distributions along the stream). However, while the stream distributions have relatively wide priors (see Appendix B.1), we define narrow priors for our off-track component to keep the kinematics similar to the main stream. To achieve this, we first run a VI optimization of our model without the off-track component. This "background + stream" model provides a (cubic spline) representation of the main stream's kinematic tracks, from which we define priors for the offtrack component kinematics.

The primary element of the off-track component, however, is the density distribution in sky positions (ϕ_1, ϕ_2) . We adopt a similar distribution as for the background and stream density models, but applied in the two dimensional (joint $p(\phi_1, \phi_2)$) space rather than as a conditional (i.e., $p(\phi_2 \mid \phi_1)$). We use a 2D mixture of normals to model the off-track density on the sky, but with means fixed to regularly-spaced grid points in ϕ_1, ϕ_2 . This resulting grid of 2D normals allows us to recover localized overdensities associated with the stream anywhere in our data without assuming such overdensities exist. We choose the separation of "knots" in this 2D space to be 3° in ϕ_1 and 1° in ϕ_2 . We show the resulting grid in the top panel of Figure 4, where the blue points are located at the centers of each 2D normal. As with the other two components, we relegate the detailed mathematical formulation of this component to Appendix B.3.

3.3. VI choices

We use the AutoNormal guide in numpyro to run VI on our model. The AutoNormal guide approximates the posterior distribution by assuming each parameter is both independent and well-represented by a normal distribution. This is not a correct assumption (e.g., spline knot values should be correlated) but it should not bias our results significantly as it is a conservative approximation to the posterior PDF. We then optimize using the Adaptive Moment Estimation (Adam) optimizer with an adaptive learning rate and a maximum gradient for each step of 10. The learning rate is made up of four segments of 2500 steps each. All four segments consist of a learning rate that follows a cosine decay, starting at 0.1, 0.01, 0.001, and 0.0001 respectively, and each decreasing by one order of magnitude over the 2500 steps. This ensures we search a large area of the parameter space at first, and then thoroughly explore the region near the best solution. We initialize this VI run with a reasonably good guess for the stream and background and refer the reader back to Sections 3.2.1, 3.2.2, and 3.2.3 as well as Appendix C for details. After the first VI run, we use the results to initialize a new run and repeat this process a few times until the ELBO stabilizes, signaling model convergence.

4. APPLICATION TO THE GD-1 STREAM: RESULTS

The result of our full model is shown in Figure 3. In the following sections we make use of two different types of results from VI. First, since our VI run generates a posterior distribution for each parameter, we generate samples from these distributions to describe the uncertainty in each parameter's estimate. While these distributions are important, we also want to be able to show the best-fitting parameters found by our model. We do this by taking the mean value outputted for each parameter. For simplicity, we henceforth refer to this parameter set as the best-fitting parameters. In the subsections below, we detail inferred properties of the density model for GD-1 (e.g., off-track features) and derived quantities (e.g., total stellar mass).

4.1. Inferred Properties

4.1.1. Off-Track and Non-Gaussian Features

Our main result is the recovery of off-track and non-Gaussian features that appear associated with the stream. The most significant such feature is the "spur", first identified by PWB18. The spur appears prominently in both panels of Figure 4 at $\phi_2 > 0^\circ$ and $-40^\circ < \phi_1 < -25^\circ$. The model was not told that this feature existed and was not predisposed to find it in any way. The fact that it is able to do so demonstrates its success in the major innovation our model contains over previous versions.

The other previously discovered overdensity (the "blob"; $\phi_1 \approx -16$, $\phi_2 < 0$) is not as prominent in our results, although it is the off-track region with the highest density other than the spur. Interestingly, the slight overdensity we do recover in this region is at both positive and negative ϕ_2 values, in contrast to the blob in PWB18, which is exclusively below the stream. This may be a reason for the relative faintness of this feature and we address this point further in Section 4.2.1.

Figure 3. The complete model for GD-1. The left column shows the data, while the right column shows the model. The bottom panel shows the residual between the data and the model in position space. Each row displays a different space in which the model is created $(\phi_2 - \phi_1, \mu_1 - \phi_1, \mu_2 - \phi_1, \text{ and } v_r - \phi_1 \text{ from the first to the fourth row})$.

We then check whether our model identifies any additional off-track features. We specifically seek overdensities with small-to-medium spatial scales that suggest a complicated origin. In the top panel of Figure 5, we show the linear density of the off-track component in the red shaded region. This shows a low level of structure in the off-track component over the entire stream region. Comparing this to the top panel of Figure 4 suggests that all of this structure is extremely low surface brightness and not at all localized, although the off-track density becomes even less dense further away from the stream (also see Figure 6). The most likely explanation for the general trend of higher off-track density at higher ϕ_2 is that the background is not perfectly uniform in stream latitude, as we assumed. A different, more intriguing explanation is that these stars constitute a "cocoon" around GD-1 (Malhan et al. 2019; Valluri et al. 2024). By examining the high-probability off-track members, rather than surface density maps (see Section 4.1.2 and Figure 6) we do find most of these to lie within a couple degrees of the stream track for the region $-60 < \phi_1 < 0$, similar to the cocoon claimed in Malhan et al. (2019). We do not find evidence that such a cocoon extends the entire length of the stream.

4.1.2. Membership

We calculate the probability that each star in the GD-1 region belongs to either the stream or off-track components of the model (vs. the background component).

Figure 4. Top: The off-track model for GD-1 on a logarithmic color scale, as described in Section 3.2.3. The blue points represent the centers of our 2D normals used to create the off-track density. We call special attention to the fact that we recover both the "spur" and the "blob" first seen in Bonaca et al. (2019). Bottom: The combined stream and off-track model in $\phi_1-\phi_2$ space with a logarithmic color scale so that the off-track components are visible.

We refer to this as the membership probability of the star, which we compute using the posterior predictive distribution of the model tracks. In Figure 6, we show those stars with membership probabilities above 50%. In the right panel, we show the color-magnitude diagram of all stars with membership probability > 0.5. The red shaded region shows an example selection polygon around the best fit isochrone (same isochrone as used to make the original CMD selection in Section 3.1, but including the red giant branch, and the blue straggler population). For most studies the best balance between purity and completeness will likely come from a combination of this CMD cut with the membership probabilities. We show such a cut in the middle left panel. To complement this paper, we provide a catalog of stars in our original footprint with their Gaia and PS1 astrometric and photometric properties as well as columns to help create pure or complete samples (membership probability and CMD mask). We show three columns of this catalog for ten sample stars in Table 2 and provide the rest of the rest of the catalog with this paper.

4.1.3. GD-1 Linear Density

As in previous studies, GD-1 appears to extend from $\phi_1 \sim -90$ to $\phi_1 \sim 10$. Outside of this region, the main stream track density approaches 0. In between, we recover density fluctuations along the stream, including

Gaia source ID	$memb_prob$	pass_CMD_cut
582446459246191232	0.9584	True
582459584666428032	0.9371	True
582461371372666752	0.8824	False
576748068435698048	2.254e-93	True
576748244530543488	1.155e-70	False
576750301818727936	1.040e-05	False
576760064280542592	5.345e-63	False
576760300502579328	4.498e-60	True
576760334862325504	6.697 e-07	False
576760437941539712	1.607e-17	False

Table 2. 10 abridged sample rows from our membership probability table. For readability, the membership probabilities (second column) are truncated to four significant figures. As an example, the first three are stars with high membership probabilities and the others have low membership probabilities. The full table has many additional columns, with all relevant *Gaia* astrometric and PS1 photometric data.

four prominent gaps and four peaks. The gaps occur at $\phi_1 \approx -40, -20, -5, 5^{\circ}$ while the density peaks lie at $\phi_1 \approx -50, -33, -15, 0, 10$ (seen best in the top panel of Figure 5). Fitting a power spectrum to the density profile, we recover the typical scale of density fluctuations to be 2.35 kpc. This is within 2σ of the 2.64 ± 0.18 kpc fluctuation scale reported in Ibata et al. (2020), which

Figure 5. Properties of the GD-1 stream as a function of ϕ_1 . Top panel: Linear density of GD-1. The blue shaded region represents the linear density on the main stream track and the red shaded region shows the linear density of the off-track components. The black line traces the combined linear density from both components. The green dashed lines show the locations of the density peaks expected from the best-fit epicycles (2.35 kpc apart). We indicate the knot separations for our stream and off-track ϕ_1 Gaussian mixture model in the upper right corner of the panel. Second panel: Mean ϕ_2 track (traced by the black line) and 1σ width (shown as the blue shaded region) of our GD-1 model's stream component. We indicate the knot separations for our stream and off-track velocity splines (μ_1, μ_2 , and v_r) in the upper right corner of the panel. Third panel: Mean μ_1 track (traced by the black line) and 1σ width (shown as the blue shaded region) of our GD-1 model's stream component. The red shaded region shows the 1σ width of the off-track μ_1 track. Fourth panel: Same as the third panel but for μ_2 . Fifth panel: Same as the third panel but for v_r . Bottom row: The width of the main stream track (also represented by the red shaded region in the second panel). The solid curve traces the width of the main stream track when including the off-track component and the dashed line shows the width when only using background and stream components. This shows the importance of using an off-track component to characterize GD-1 properly. In the third and fourth panel, we show the median proper motion errors of high probability GD-1 members (≈ 0.35 mas yr⁻¹)

Figure 6. High probability members of GD-1. Left: Each panel shows an example cut one might make to select GD-1 members. The top panel shows all stars with a membership probability > 0.5. The middle panel shows all stars with membership probability > 0.5 that also pass a CMD cut (shown with the red shaded region on the right). The bottom panel shows all non-main sequence stars with membership probability > 0.5 that also pass a CMD cut (shown with the red shaded region on the right). The bottom panel shows all non-main sequence stars with membership probability > 0.5 that also pass a CMD cut, colored based on their location on the CMD diagram. Right: Distance-corrected color-magnitude diagram of stars with GD-1 membership probability > 0.5. The color-scale shows the membership probability. The red shaded region represents the best-fit isochrone and horizontal branch of GD-1 based on a combination of prior studies and a fit to the CMD data (see Section 3.1 for details). We also label with rectangles or polygons the approximate locations of blue horizontal branch (BHB) stars, red horizontal branch (RHB) and RR Lyrae (RRL) stars, blue stragglers (BS), and the red giant branch (RGB) in purple, green, orange, and red boxes, respectively.

they attribute to epicyclic motion.⁵ This theory is compelling given how evenly spaced many of the density peaks appear to be (green dashed vertical lines in the top panel of Figure 5. The amplitude of these fluctuations in the central stream region $(-60^{\circ} < \phi_1 < 0^{\circ})$ is significant, with density peaks having $\approx 2-8$ times the linear density as the gaps.

4.1.4. GD-1 Track and Width

Apart from the linear density, our model also infers ϕ_2 and proper motion tracks along the stream (middle three panels), together with the widths of those tracks (bottom panel). GD-1's track in ϕ_2 , as shown in the second panel of Figure 5, does not have any major features of interest; it is smooth and contains no small scale variations. The uniformity of the stream track is naively expected from simple models of stellar streams. However, some streams, such as ATLAS-Aliqa Uma and Phoenix, have ϕ_2 -track discontinuities or small scale wiggles (Li et al. 2021; Tavangar et al. 2022), most likely caused by a past interaction or some complicated history. Since

the spur in GD-1 indicates it may have had a significant interaction within the last Gyr, it is notable that the cause of that feature did not also impact the stream track on small scales. We note, however, that the lack of sharp kinks or small scale wiggles does not necessarily imply that the spur-causing interaction had no effect on the track. It is plausible that such an interaction could uniformly shift large segments of the stream off its original orbital path. This could happen if the perturber impacting the stream is on a close-to-parallel orbit with the stream stars, such that it affects an extended region of the stream.

The width of GD-1 is shown in the bottom panel of Figure 5. Similarly to the track, we see no small scale changes in the width. However, the width track still contains two interesting features: the gradual increase in stream width at $\phi_1 \leq -30$ and its oscillation in this region. One advantage of having an off-track model is that we can test whether these features are real or caused by an extra component such as the spur. To do this, we compare the width of our full GD-1 model with the stream width in a model with no off-track component. The two are nearly identical except in the outskirts and in the spur region $(-40 \leq \phi_1 \leq -20)$, where the stream+background model is slightly wider in an attempt to fit the spur without an off-track component. This mischaracterization of the spur region reinforces

⁵ In Figure 22 of Ibata et al. (2024), the authors show the epicyclic separation derived in Ibata et al. (2020). Although they have improved data in the more recent paper, they do not re-perform this analysis and a visual inspection suggests that their initial result may have been a slight overestimate, and an updated result would be more in line with our epicyclic separation of 2.35 kpc.

Figure 7. High probability (membership probability > 0.5 and passing the CMD cut) members of GD-1 with radial velocity measurements, converted to the Galactic Standard of Rest frame (GSR). We show the radial velocity track from our model (including its width) in red and the best-fit radial velocity track from Valluri et al. (2024) in blue.

the need for an off-track component to ensure unbiased studies of stream properties. The identical result at lower ϕ_1 also confirms that the gradual width increase and oscillation for $\phi_1 \leq -30$ is real. Since the stream is more distant in this region (lower ϕ_1), this increase in angular width also corresponds to an increase in physical (i.e., kpc) width.

4.1.5. GD-1 Velocity Tracks

The kinematic tracks and widths (shown in the third, fourth, and fifth panels of Figure 5) are relatively simple, in the sense that these properties vary smoothly along the stream with no small angular scale features. They also have good agreement with the previous literature as documented in galstreams (Ibata et al. 2021; Price-Whelan & Bonaca 2018).

One of the main results of this work is an up-to-date catalog of radial velocities for GD-1 members. We find 353 high probability members (membership probability > 0.5 and passing the CMD cut) with radial velocity measurements in our sample, which we show in Figure 7. Our radial velocity track, including its width, is over-plotted in the red shaded region. For comparison, Valluri et al. (2024) find 331 GD-1 stars with radial velocities by making rough position, proper motion, and color-magnitude cuts and selecting all stars with radial velocity measurements within 30 km s⁻¹ of their best fit curve (shown in blue in Figure 7).

4.1.6. Velocity Dispersion

Absent of any external heating, velocity dispersion along a stream is expected to (locally) decrease as the stream spreads out spatially (Helmi & White 1999). However, in the presence of massive perturbers (e.g., dark matter subhalos, dwarf galaxies, etc.), the velocity dispersion of a stellar stream is indicative of its past heating from external structures within the halo. This is because we can predict the intrinsic velocity dispersion, which depends on the progenitor and orbital properties. A more massive progenitor will have a higher intrinsic velocity dispersion, as will a stream closer to apocenter. The actual stream velocity dispersion then also depends on heating the stream experiences from encounters with external objects. Each encounter will increase the velocity dispersion. By comparing the expected intrinsic velocity dispersion with the observed one, we can estimate the population of subhalos in the Milky Way halo.

We show the velocity dispersion derived from our model in Figure 8, where each black line represents one sample from the posterior distribution and the red line is the result from our best-fit model. The proper motion dispersions (converted into velocity using the adopted distance track from Valluri et al. 2024) are relatively constant at $\approx 3-5 \,\mathrm{km \, s^{-1}}$ for the central region of the stream $(-65^{\circ} < \phi_1 < 5^{\circ})$. It is surprising that, given the average proper motion uncertainty for GD-1 stars $(\approx 0.35 \,\mathrm{mas} \,\mathrm{yr}^{-1} \,\mathrm{or} \approx 12.5 \,\mathrm{km \, s}^{-1}$ in each dimension), the model converges to a finite value less than this uncertainty, rather than be consistent with zero. This is tentatively exciting but it is also possible that mistakes in calibration or error estimates created this effect (any systematic uncertainties will be interpreted as intrinsic velocity dispersion). We neglect the uncertainty on the distance track, which will impact the uncertainties on these velocity dispersion profiles, but this should only add an additional $\sim 10\%$ uncertainty to the inferred dispersions.

The radial velocity dispersion is more varied, with $\sigma_{v_r} \lesssim 5 \,\mathrm{km \, s^{-1}}$ for $-40 \lesssim \phi_1 \lesssim -10$ but higher dispersions elsewhere. The minimum occurs at two locations: $\phi_1 \approx -15^\circ, -32^\circ$. Under CDM, it is reasonable to expect the radial velocity dispersion to be smallest at the progenitor location and larger at the stream edges, so this result could give another clue towards the progenitor location. However, we caution that because we combined multiple surveys to create our radial velocity dataset: offsets between these surveys or inaccurately reported uncertainties could bias our inferred v_r dispersion profile. If instead of the model results we use the 353 high-probability (> 50%) members with radial velocity measurements and fit a 3rd degree polynomial to them as a function of ϕ_1 , we recover a velocity dispersion

Figure 8. The black lines show 1000 samples of the total velocity dispersion of GD-1 as well as the velocity dispersion in each coordinate, as a function of ϕ_1 . The red line shows our best-fit model results.

of 2.35, slightly lower than Valluri et al. (2024) but in good agreement with Gialluca et al. (2021) and Nibauer et al. (2024). This value is consistent with expectations from CDM and a dark matter model with more compact subhalos $(0.5 \times r_s^{\text{CDM}}(M))$ but disfavors lower numbers of subhalos like one would expect in WDM or FDM (Nibauer et al. 2024).

4.2. Derived GD-1 Properties 4.2.1. Off-track Velocity Offset

In theory, in order for a star to drift away from the main stream track, it must have a different velocity from the main stream. If it does not, it has no way of distancing itself from other stream stars. Therefore, we check the velocity difference between the spur and the main stream track at the equivalent ϕ_1 . We do so by evaluating the stream and off-track μ_1 , μ_2 , and v_r cubic splines at the ϕ_1 location of the spur ($\phi_1 = -33^\circ$). We find the mean proper motions of the spur to be entirely consistent with the main stream's velocity. However, the spur does appear to have a slightly lower radial velocity than its main track counterpart. We show these off-track and main stream velocity distributions in the top row of Fig-

ure 9, where we plot histograms of the inferred velocities at the spur location from our posterior samples.

We then check the other previously discovered offtrack feature (the blob). and show the distributions of velocities in the blob region in the bottom row of Figure 9. In contrast to the spur, the main difference for the blob is in μ_1 , where the off-track component has a higher μ_1 than the main stream. This difference could explain why we recover a less robust blob than PWB18. By itself, a velocity difference should have no effect on the model's ability to recover this overdensity, since we allow off-track proper motions to differ slightly from the main stream. However, our current model still recovers off-track proper motions as a function of ϕ_1 only, meaning the proper motion distributions are assumed to be independent of ϕ_2 . Therefore, if the off-track features above and below the main stream in the blob region have separate proper motion distributions (e.g., there is a μ_1 gradient along ϕ_2 at $\phi_1 \approx -16$) the model will have difficulty recovering the off-track μ_1 distribution accurately. This gradient theory is supported by the fact that if we run a version of our model with no proper motion errors (i.e., no deconvolution and therefore broader proper motion distributions) we obtain a prominent blob for $\phi_2 < 0$ very similar to PWB18. In future work, we will address this limitation.

4.2.2. Stellar Mass

From our list of probable members, we can estimate both the initial and current stellar mass of GD-1. We assume a Kroupa (Kroupa 2001, 2002) initial mass function (IMF) for the GD-1 progenitor and leverage the fact that we are complete for Gaia G < 20.5. Specifically, the Kroupa IMF allows us to calculate that 6.1%of the initial mass currently remains on part of the observable and complete part of the main sequence (3.2 mag $\lesssim M_g \lesssim$ 5.9 mag). We detect 1278 stars with high membership probability on this part of the main sequence, and the sum of their masses, assuming a Kroupa IMF is $\approx 941 \,\mathrm{M}_{\odot}$. This means that, under these assumptions, the initial mass of the GD-1 progenitor was $1.53 \times 10^4 \,\mathrm{M_{\odot}}$. This is a factor of ≈ 3 lower than the 5×10^4 value often assumed when creating dynamical models of GD-1 (e.g., Ibata et al. 2024).

For the current mass, we can use a similar idea. By the same logic as above, $\approx 36\%$ of the initial mass of GD-1 remains undetected. Combining this with the observed main sequence, we deduce that the total current main sequence mass of GD-1 is $\approx 6484 \,\mathrm{M_{\odot}}$. To account for the mass of the stars brighter than the main sequence, we rely on the stellar masses from the best Dotter (Dotter 2016) isochrone fit to the GD-1 data

Figure 9. Histogram of the mean proper motion and radial velocities for the stream and off-track components from our model posterior near the spur (top row) and the blob (bottom row). We obtain this by creating a proper motion and radial velocity spline from each posterior sample and evaluating μ_1 and μ_2 at $\phi_1 \approx -33$ (spur) and $\phi_1 \approx -16$ (blob). The off-track distributions are consistent with the main tracks' except for the radial velocity of the spur and the μ_1 of the blob.

(discussed in Section 3.1). Since all these stars have recently evolved off the main sequence, they all have similar masses $M \approx 0.82 \,\mathrm{M}_{\odot}$. Since we recover 191 stars with high membership probability which pass the CMD cut in this region and we know we are complete there, we now have the mass of every part of the current GD-1 stellar population. Summing these masses yields a current GD-1 mass of $\approx 6645 \,\mathrm{M}_{\odot}$, approximately 43% of its initial mass.

4.2.3. GD-1 Progenitor

The GD-1 stream has no known surviving progenitor and is therefore assumed to have been fully disrupted. If it recently disrupted, it may be identifiable as an area of higher density surrounded by equidistant gaps on either side (corresponding to epicyclic over-densities). If it is fully disrupted and this happened long ago, the final location of the progenitor would leave behind an underdensity in the stream. Both of these signatures exist at several locations in GD-1. Based on these features, other studies have suggested final progenitor locations of $\phi_1 \approx -40, -30, -20$ (Carlberg & Grillmair 2013; Webb & Bovy 2019; Ibata et al. 2024). Another possible signature is a sharp "kink" in the stream track on the sky, as seen in Palomar 5 (e.g., Bonaca et al. 2020b), provided that this kink does not occur along the line of sight. We do not find such a feature in our inferred stream model, with the caveat that the large separation of knots in the ϕ_2 stream track would not allow us to recover a localized (degree-scale) change in the track. However, the off-track component would be able to detect such a feature and it does not appear to have done so. The only part of the stream with a gap and an apparent change in the concavity of the stream track is at $\phi_1 \approx -6^\circ$. We therefore do not find any additional kinematic evidence of the final progenitor location.

Another uncertainty with GD-1 is the nature of the progenitor (i.e., whether it was a star cluster or lowmass dwarf galaxy). Based on its stellar mass, low velocity dispersion, low metallicity, and small (unmeasured) spread in iron abundance, it is likely that GD-1 was a star cluster (e.g., Bonaca et al. 2020a). Here, we find a number of horizontal branch (HB) and blue straggler (BS) stars associated with the stream. The ratio of the number of HB stars to BS stars has been shown to correlate with the type of progenitor system (Momany 2015; Deason et al. 2015). For GD-1, we find $N_{\rm BS}/N_{\rm HB} = 32/26 \approx 1.23$ with a total absolute magnitude $M_V \approx -4.7$. This unfortunately places GD-1 in a region consistent with both a globular cluster and low-mass dwarf galaxy progenitor, meaning this test is unable to resolve conclusively the nature of GD-1's progenitor.

5. DISCUSSION

We now place our work in the context of the current state of the field and look ahead to future improvements. We have largely built on previous work that uses cubic spline modeling methods, but add the key addition of an off-track component, giving us the flexibility to characterize known inhomogeneities and discover new ones. This has worked well when applied to GD-1 but we anticipate the possibility to needing to tweak certain aspects of the model when it is applied to other streams which will be more difficult to characterize. Our model currently has a number of limitations that we outline in Section 5.2, the most notable of which is that we currently make a CMD cut as opposed to modeling that space in the same way we do the astrometry. We aim to make this improvement, among others, in future iterations of this model.

5.1. Comparison to Past Density Models

Our modeling framework builds upon past stellar stream density modeling methods. Previous analyses of stream density variations used STAN (Carpenter et al. 2017) for statistical modeling and efficient probabilistic sampling (Erkal et al. 2017; Koposov et al. 2019; Li et al. 2021; Tavangar et al. 2022; Ferguson et al. 2022) or custom statistical modeling methods (e.g., Bonaca et al. 2020b). These past efforts have revealed important stream features, like the track discontinuity in ATLAS-Aliqa Uma (Li et al. 2021), varying density fluctuation scales between streams (Tavangar et al. 2022), and variations in the track and width of individual streams (e.g., Bonaca et al. 2020b; Ferguson et al. 2022). Patrick et al. (2022) then analyzed 13 Milky Way streams to provide a population-level view of stream density structures. Given that we now know of almost 150 streams in the Milky Way (Bonaca & Price-Whelan 2025), it is clear that robust, automated, and efficient stream density modeling methods will be a critical tool for understanding this population.

Our framework builds upon these past methods by providing a more generalizable and accessible tool for stream density modeling. In particular, our implementation is in Python and uses jax (Bradbury et al. 2018) and numpyro (Bingham et al. 2019; Phan et al. 2019) for gradient-based optimization and flexible specification of probabilistic models. We also provide a mechanism for modeling off-track density features in streams, which will be important for understanding the full extent of a stream and a full accounting of its member stars. Our approach maintains computational efficiency while adding critical functionality for modeling complex stream morphology, as demonstrated in our application to GD-1.

5.2. Future Improvements and Extensions

Our model's performance on GD-1 is very promising for its application to other streams. In the near future, this model will fold into ongoing work by the Community Atlas of Tidal Streams (CATS) collaboration. CATS' objective is to build on the galstreams library by creating the tools necessary to perform analyses using multiple streams. This involves developing analysis tools that are transferable from stream to stream, allowing easy comparisons. CATS is also working on making easy-to-use selection boxes in different spaces for various streams, allowing users to make different selections of probable members depending on their use cases. Our analysis will provide an improvement on such binary selections by outputting membership probabilities and a density model.

Despite this model's success, we see multiple areas of future improvement. The most consequential change is to incorporate the CMD as part of the mixture model. We remind the reader that in our work, photometric information is only used to create the dataset that our model uses as input. However, since stream stars should lie along an isochrone, the color-magnitude distribution of stars in this field should be extremely informative for discovering and characterizing streams. An improved model should make use of this additional information and add CMD modeling to the framework we have built here. This will be crucial as we discover new streams in deep photometric surveys such as the Legacy Survey of Space and Time (LSST). These streams will have limited proper motion information, especially below the main sequence turnoff, where we expect to find the majority of its members. Therefore, characterization of those streams will rely heavily on CMD modeling.

CMD modeling is challenging because, in contrast to the astrometric background, the photometric background is too complex to model with simple analytic distributions. This makes it difficult to model the isochrone overdensity lying atop the background. There are a couple ways to tackle this challenge. Patrick et al. (2022) split the CMD into pixels (similar to our off-track cells) and modeled the background CMD as a discrete probability distribution of a star belonging to a certain pixel. They were interested in modeling some streams without deep astrometric data, so it was critical for them to develop a successful CMD modeling method. More recently, Starkman et al. (2023) used normalizing flows to learn the background distribution of the CMD. Normalizing flows provide flexible probability density descriptions by transforming samples from simple distribution (e.g., Gaussian), to a more complex one (Tabak & Vanden-Eijnden 2010; Rippel & Prescott Adams 2013; Jimenez Rezende & Mohamed 2015). They combine this with an astrometric model and demonstrate that their method works well on the GD-1 and Palomar 5 streams. Given the success of both these methods, we plan to allow future versions of our code to allow for easy inclusion of various CMD modeling techniques.

Once we model the color-magnitude distribution along with the kinematics, another important improvement will be to incorporate the survey completeness in our density modeling. In any observational survey, the probability of detecting a star depends on a variety of factors, including its position and magnitude. These selection effects can affect the density of certain types of stars on the sky, creating the illusion of stream features which do not truly exist. Here, we have simply made a Gaia G cut to ensure there is no variation of the selection function with sky position. This limits us because we are not using fainter stars on the main sequence which could help us characterize the stream. This is an active area of research as shown by recent papers modeling the Gaiaselection function (e.g., Cantat-Gaudin et al. 2023).

There are also a couple smaller improvements we would like to implement. For instance, when using a spline model, one must specify the number and placement of knots used to create the model. The spacing should be related to the scale on which one expects to see structure in the object of interest. For streams, this scale can vary by about an order of magnitude ($\approx 1^{\circ}$ -10°) (Tavangar et al. 2022). Often, researchers choose the knot spacing by eye, simply trying to find the middle ground between under- and over-fitting. In our case, as discussed in Section 3.2, we used prior studies of GD-1 (e.g. Bonaca et al. 2019) to approximate a knot spacing and ensured that small differences to this spacing did not significantly alter the model output. Finding that it did not, we chose not to expend the significant computational expense required to create a full optimization algorithm for the knot spacing. However, a more robust version of this model would include such an algorithm. This will be useful for all streams, particularly those for

which we do not yet know the density variation physical scales.

6. SUMMARY AND CONCLUSIONS

We summarize our paper as follows:

- We present a new method for modeling the kinematic density distributions of stellar streams. Our method recovers the astrometric tracks of streams, the density of streams along their length, and the density of any off-track or non-Gaussian features associated with the streams. This framework lays the basis for uniformly inferring robust models of stellar streams to use as inputs to obtain tight constraints on the Galactic mass distribution and the nature of dark matter.
- We apply our model to the GD-1 stream, which we know contains off-track features, to test its functionality. We recover similar results to previous efforts in terms of the astrometric tracks. We also recover previously-identified features (the spur and the blob) but provide more robust membership probabilities for stars associated with these substructures. In addition, the off-track component of our model indicates that there may be other diffuse low surface brightness GD-1 structure particularly in the region $-40^{\circ} < \phi_1 < 0^{\circ}$.
- With our model for GD-1, it is straightforward to calculate membership probabilities for all stars in the region. We present a catalog of 466571 stars, 1689 of which have membership probability > 0.5 and pass our CMD cut.
- Our GD-1 model results suggest an initial stellar mass of $1.53 \times 10^4 \, M_{\odot}$, an average velocity dispersion along the main stream track of $\approx 6-15 \, \rm km \, s^{-1}$.
- We find the spur to have a slightly higher radial velocity than the main stream at the same ϕ_1 while the other two velocity components are statistically consistent. Additionally, the blob is offset from its main stream velocity in μ_1 , while the other two components are statistically consistent.

This contribution joins a number of recent analyses that define new methods for modeling the density of streams. While it is useful to improve the methods we use for stream modeling, major scientific results will only come from a combined analysis of dozens of streams. Therefore, we emphasize that once we have incorporated the improvements mentioned in Section 5.2, a broader application of our modeling framework is critical. These population level analyses will reduce the small number statistics problem we currently have when attempting to constrain dark matter using only one stream at a time.

7. ACKNOWLEDGMENTS

The authors thank Kathryn Johnston, Jake Nibauer, Nathaniel Starkman, and the larger CATS Collaboration for useful discussions.

APPENDIX

A. NOTATION

Here we summarize notation used in equations and probabilistic expressions throughout the article.

Symbol	Domain	Description		
α	[0, 1]	Mixture weight		
m	$[-\infty,\infty]$	Mean (used instead of μ , which here is proper motion)		
σ	$(0,\infty]$	Standard deviation (i.e. square-root of variance)		
<i>y</i>	$[-\infty,\infty]$	A vector of data values		
$\tilde{x}, \tilde{y}, \dots$		Represents the "true" (i.e. independent of noise) value of a variable (e.g., $x, y,$)		
K,M,N,\ldots		Capitalized Roman characters represent integer numbers		
$\{x\}_K, \{y\}_M, \dots$		A collection of values with size specified by the subscript		
${\cal S}^{(K)}(x)$		A cubic spline function with K knots as a function of the coordinate x		
w_k		Spline knot values for the K knots of a spline function		
$\mathcal{U}(x a, b)$		Uniform distribution for x with lower bound a and upper bound b		
$\mathcal{N}(x m,\sigma^2)$		Normal distribution for x with mean m and standard deviation σ		
$\mathcal{N}(x m, \sigma^2)_{[a,b]}$		Truncated normal distribution for x with mean m, standard deviation σ , and bounds $[a, b]$		
Table 3.				

B. APPLICATION TO THE GD-1 STREAM: MODEL CHOICES AND PRIORS

In this appendix, we describe our choices for the distributions and parameter priors the components of our density model. As described in Section 2.4, the total PDF used in our density model is a three component (background, stream, and off-track) mixture given by

$$p(\tilde{\boldsymbol{y}} \mid \boldsymbol{\theta}) = \alpha_s \, p_s(\tilde{\boldsymbol{y}} \mid \boldsymbol{\theta}_s) + \alpha_b \, p_b(\tilde{\boldsymbol{y}} \mid \boldsymbol{\theta}_b) + \alpha_o \, p_o(\tilde{\boldsymbol{y}} \mid \boldsymbol{\theta}_o) \tag{B1}$$

where $\boldsymbol{\alpha} = (\alpha_s, \alpha_b, \alpha_o)$ are the mixture weights and $p_{\{s,b,o\}}(\tilde{\boldsymbol{y}} | \boldsymbol{\theta}_{\{s,b,o\}})$ are the mixture component distributions. For our application to GD-1, we choose to model all observed phase-space coordinates except distance (parallax), so the true phase-space vector is $\tilde{\boldsymbol{y}} = (\tilde{\phi}_1, \tilde{\phi}_2, \tilde{\mu}_1, \tilde{\mu}_2, \tilde{v}_r)$. For brevity in the equations below, we may drop subscripts from parameters of PDFs where it is clear what phase-space coordinate they correspond to — for example, in the expression $p(\boldsymbol{y} | \boldsymbol{\theta}) = \mathcal{N}(\boldsymbol{y} | \boldsymbol{m}, \sigma^2)$, we should technically make the generic mean and variance parameters (\boldsymbol{m}, σ) have subscripts \boldsymbol{y} to identify them as related to the coordinate \boldsymbol{y} , but we do not do this where it is clear. The density distributions for $\tilde{\phi}_1, \tilde{\phi}_2, \tilde{\mu}_1, \tilde{\mu}_2$, and \tilde{v}_r are truncated to the domains $\tilde{\phi}_1 \in [-100, 20]^\circ, \tilde{\phi}_2 \in [7.97, 3.35]^\circ, \tilde{\mu}_1 \in [-15.10, -4.64] \text{ mas yr}^{-1},$ $\tilde{\mu}_2 \in [-5.42, 1.93] \text{ mas yr}^{-1}$, and $\tilde{v}_r \in [-500, 500] \text{ km s}^{-1}$.

B.1. Stream

As introduced in Section 3.2.1, our stream component density model factorizes into a PDF over stream longitude $\tilde{\phi}_1$ multiplied by the other PDFs, conditioned on stream longitude:

$$p_s(\tilde{\boldsymbol{y}} \mid \boldsymbol{\theta}_s) = p_s(\tilde{\phi}_1 \mid \boldsymbol{\theta}_s) \, p_s(\tilde{\phi}_2 \mid \boldsymbol{\theta}_s) \, p_s(\tilde{\mu}_1 \mid \tilde{\phi}_1, \boldsymbol{\theta}_s) \, p_s(\tilde{\mu}_2 \mid \tilde{\phi}_1, \boldsymbol{\theta}_s) \, p_s(\tilde{v}_r \mid \tilde{\phi}_1, \boldsymbol{\theta}_s) \quad . \tag{B2}$$

We model the ϕ_1 density with a mixture of truncated normals with fixed mean locations (spaced by 5° along ϕ_1 from -100° to 20°),

$$p_s(\tilde{\phi}_1 \mid \boldsymbol{\theta}_s) = \sum_{i}^{25} \alpha_i \,\mathcal{N}(\tilde{\phi}_1 \mid m_i, \sigma_i^2) \tag{B3}$$

where $m_i = (-100, -95, -90, ..., 10, 15, 20)^\circ$ are the fixed means of the normals, σ_i are the scales of the normal components with truncated normal priors $\mathcal{N}(\sigma_i | 2.5^\circ, (2.5^\circ)^2)_{[0.5^\circ, \infty]}$, and α_i are the mixture weights with a uniform Dirichlet prior.

The parameters of the latter four conditional distributions in Equation B2 are controlled by cubic spline functions, and the remaining parameters of the stream model component are the values of these spline functions at (fixed) knot locations. We fix the knot locations for all spline functions of ϕ_1 every 10° from -100° to 20°, inclusive. We summarize these coordinate distributions and parameters in Table 1.

The ϕ_2 , μ_1 , μ_2 , and v_r density distributions are each given by a truncated normal distribution with mean (m) and scale (σ) parameters $(m \text{ and } \sigma, \text{ respectively})$ set by spline functions with fixed knot locations,

$$p_{s}(\tilde{\phi}_{2} | \phi_{1}, \boldsymbol{\theta}_{s}) = \mathcal{N}(\tilde{\phi}_{2} | m(\phi_{1}), \sigma^{2}(\phi_{1}))_{[-7.97^{\circ}, 3.35^{\circ}]}$$

$$p_{s}(\tilde{\mu}_{1} | \phi_{1}, \boldsymbol{\theta}_{s}) = \mathcal{N}(\tilde{\mu}_{1} | m(\phi_{1}), \sigma^{2}(\phi_{1}))_{[-15.10 \text{ mas } \text{yr}^{-1}, -4.64 \text{ mas } \text{yr}^{-1}]}$$

$$p_{s}(\tilde{\mu}_{2} | \phi_{1}, \boldsymbol{\theta}_{s}) = \mathcal{N}(\tilde{\mu}_{2} | m(\phi_{1}), \sigma^{2}(\phi_{1}))_{[-5.42 \text{ mas } \text{yr}^{-1}, 1.93 \text{ mas } \text{yr}^{-1}]}$$

$$p_{s}(\tilde{\nu}_{r} | \phi_{1}, \boldsymbol{\theta}_{s}) = \mathcal{N}(\tilde{\nu}_{r} | m(\phi_{1}), \sigma^{2}(\phi_{1}))_{[-500 \text{ km s}^{-1}, 500 \text{ km s}^{-1}]}$$
(B4)

where the mean (m) and scale (σ) parameters are set by spline functions with fixed knot locations

$$m(\phi_1) = \mathcal{S}^{(K_m)}(\tilde{\phi}_1)$$

$$\sigma(\phi_1) = \mathcal{S}^{(K_\sigma)}(\tilde{\phi}_1)$$
(B5)

The knot values $w_{K_m,m}$ and $w_{K_{\sigma},\sigma}$ are free parameters. Because GD-1 is such a well-studied stream, we have the advantage of being able to establish reasonable priors on the $w_{K_m,m}$ knot values. In detail, we take cubic splines of the PWB proper motion tracks $(\mathcal{S}_{pwb}^{(K_m)}(\tilde{\phi}_1))$ and evaluate them at our knot locations $\phi_{1,K}$. These provide the means of our truncated normal distributions at each knot. The PWB track for radial velocity is less well-measured so we choose a uniform prior instead for those knots. Mathematically, we represent this by saying that the knot values for the mean functions $w_{K_m,m}$ have truncated normal priors

$$\phi_{2}: \mathcal{N}(w_{K_{m},m} | \mathcal{S}_{\text{pwb},\phi_{2}}^{(K_{m})}(\phi_{1,K}), (1^{\circ})^{2})_{[-7.97^{\circ},3.35^{\circ}]} \\
\mu_{1}: \mathcal{N}(w_{K_{m},m} | \mathcal{S}_{\text{pwb},\mu_{1}}^{(K_{m})}(\phi_{1,K}), (2 \max \text{ yr}^{-1})^{2})_{[-15.10 \max \text{ yr}^{-1},-4.64 \max \text{ yr}^{-1}]} \\
\mu_{2}: \mathcal{N}(w_{K_{m},m} | \mathcal{S}_{\text{pwb},\mu_{2}}^{(K_{m})}(\phi_{1,K}), (2 \max \text{ yr}^{-1})^{2})_{[-5.42 \max \text{ yr}^{-1},1.93 \max \text{ yr}^{-1}]} \\
\nu_{r}: \mathcal{U}(w_{K_{m},m} | -500 \text{ km s}^{-1}, 500 \text{ km s}^{-1})$$
(B6)

where we have chosen the scales to be to allow some variation on the literature values but not too much, to aid the optimization process. The knot values for the scale functions $w_{K_{\sigma},\sigma}$ also have truncated normal priors

$$\begin{aligned} \phi_2 : & \mathcal{N}(w_{K_{\sigma},\sigma} \mid 0.5^{\circ}, (0.5^{\circ})^2)_{[0.05^{\circ},\infty]} \\ \mu_1 : & \mathcal{N}(w_{K_{\sigma},\sigma} \mid 0.5 \text{ mas } \text{ yr}^{-1}, (0.5 \text{ mas } \text{ yr}^{-1})^2)_{[2.78 \times 10^{-3} \text{ mas } \text{ yr}^{-1},\infty]} \\ \mu_2 : & \mathcal{N}(w_{K_{\sigma},\sigma} \mid 0.5 \text{ mas } \text{ yr}^{-1}, (0.5 \text{ mas } \text{ yr}^{-1})^2)_{[2.78 \times 10^{-3} \text{ mas } \text{ yr}^{-1},\infty]} \\ v_r : & \mathcal{N}(w_{K_{\sigma},\sigma} \mid 1 \text{ km s}^{-1}, (5 \text{ km s}^{-1})^2)_{[0.1 \text{ km s}^{-1}, 100 \text{ km s}^{-1}]} \end{aligned}$$
(B7)

The 2.78×10^{-3} mas yr⁻¹ number comes from converting 0.1 km s^{-1} to a proper motion at 8 kpc, to avoid proper motion distributions with widths that approach 0. We use $K_m = K_{\sigma} = 13$ knots for the *m* and σ spline functions in proper motions and $K_m = K_{\sigma} = 9$ for the radial velocities. The difference comes from the fact that while all our knots are separated by 10°, the radial velocity data for likely stream members has a smaller ϕ_1 range (-82.29° < ϕ_1 < 2.60°). The stream model component parameter vector $\boldsymbol{\theta}_s$ therefore consists of:

• the scales and mixture weights of the ϕ_1 normal mixture,

• the knot values for spline functions that control the ϕ_2 , μ_1, μ_2 , and v_r means, and scales

In total, the stream model has 146 free parameters.

B.2. Background

As with our stream model, our background component density model – introduced in Section 3.2.2 – factorizes into a PDF over stream longitude $\tilde{\phi}_1$ multiplied by the other PDFs, conditioned on stream longitude:

$$p_b(\tilde{\boldsymbol{y}} \mid \boldsymbol{\theta}_b) = p_b(\tilde{\phi}_1 \mid \boldsymbol{\theta}_b) \, p_b(\tilde{\phi}_2 \mid \boldsymbol{\theta}_b) \, p_b(\tilde{\mu}_1 \mid \tilde{\phi}_1, \boldsymbol{\theta}_b) \, p_b(\tilde{\mu}_2 \mid \tilde{\phi}_1, \boldsymbol{\theta}_b) \, p_b(\tilde{v}_r \mid \tilde{\phi}_1, \boldsymbol{\theta}_b) \quad . \tag{B8}$$

THE GD-1 STREAM IN Gaia DR3

The parameters of the latter three conditional distributions are controlled by cubic spline functions, and most of the parameters of the background model are the values of these spline functions at the (fixed) knot locations. We fix the knot locations for all spline functions of ϕ_1 below at $(-100, -60, -20, 20)^\circ$. We opt not to do a cross-validation of the knot spacing for this application (because of the computational cost), but we do test the background model with alternate knot spacings of 20° and 30°. The former clearly over-fits the data, while the latter gives nearly identical results to the 40° separations. This simple test suggests that the total model should not be very sensitive to the precise knot spacings of the background model. We summarize these coordinate distributions and parameters in Table 1.

We model the ϕ_1 density with a mixture of truncated normals with fixed mean locations (spaced by 40° along ϕ_1),

$$p_b(\tilde{\phi}_1 \mid \boldsymbol{\theta}_b) = \sum_i^4 \alpha_i \,\mathcal{N}(\tilde{\phi}_1 \mid m_i, \sigma_i^2) \tag{B9}$$

where $m_i = (-100, -60, -20, 20)^\circ$ are the (fixed) means of the normals, σ_i are the scales of the normal components with truncated normal priors $\mathcal{N}(\sigma_i | 20^\circ, (20^\circ)^2)_{[4^\circ,\infty]}$, and α_i are the mixture weights with a uniform Dirichlet prior.

The ϕ_2 distribution is assumed to be uniform — from visual inspection (top panel of Figure 2), this is a reasonable assumption for the sky region around GD-1. The density is therefore given by

$$p_b(\hat{\phi}_2 \mid \boldsymbol{\theta}_b) = \mathcal{U}(\hat{\phi}_2 \mid -7.97^\circ, 3.35^\circ)$$
(B10)

and has no free parameters.

The μ_1 and μ_2 density distributions are both given by a mixture of two truncated normal distributions,

$$p_{b}(\tilde{\mu}_{1} \mid \phi_{1}, \boldsymbol{\theta}_{b}) = \sum_{i}^{2} \alpha_{\mu_{1},i} \mathcal{N}(\tilde{\mu}_{1} \mid m_{\mu_{1},i}, \sigma_{\mu_{1},i}^{2})_{[-15.10 \text{ mas } \text{yr}^{-1}, -4.64 \text{ mas } \text{yr}^{-1}]}$$

$$p_{b}(\tilde{\mu}_{2} \mid \phi_{1}, \boldsymbol{\theta}_{b}) = \sum_{i}^{2} \alpha_{\mu_{2},i} \mathcal{N}(\tilde{\mu}_{2} \mid m_{\mu_{2},i}, \sigma_{\mu_{2},i}^{2})_{[-5.42 \text{ mas } \text{yr}^{-1}, 1.93 \text{ mas } \text{yr}^{-1}]}$$
(B11)

where the parameters of the mixtures (component means m_i , and component scales σ_i) are controlled by spline functions. We assume the mixture weights α_i are constant along ϕ_1 . For each coordinate μ_1, μ_2 , the parameters are treated as cubic spline functions of $\tilde{\phi}_1$,

$$m_i(\phi_1) = \mathcal{S}^{(K_m)}(\tilde{\phi}_1)$$

$$\sigma_i(\phi_1) = \mathcal{S}^{(K_\sigma)}(\tilde{\phi}_1)$$
(B12)

with fixed knot locations x_k for the K_m knots for the mean functions, and K_σ knots for the scale functions. The values of these 4 spline functions at the knot locations, w_k , are free parameters of the background model. The knot values for the mean functions $w_{K_m,m}$ have a uniform prior $\mathcal{U}(w_{K_m,m}| - 10 \text{ mas yr}^{-1}, 10 \text{ mas yr}^{-1})$ and the knot values for the scales $w_{K_{\sigma},\sigma}$ have a truncated normal prior $\mathcal{N}(w_{K_{\sigma},\sigma}|4 \text{ mas yr}^{-1}, (3 \text{ mas yr}^{-1})^2)_{[2.78\times10^{-3} \text{ mas yr}^{-1},\infty]}$. We use $K_m = K_{\sigma} = 4$ knots for both the μ_1 and μ_2 mean and scale spline functions.

The v_r probability density is analogous to the proper motion ones:

$$p_b(\tilde{v}_r \mid \phi_1, \boldsymbol{\theta}_b) = \sum_{i}^{2} \alpha_{v_r, i} \mathcal{N}(\tilde{v}_r \mid m_{v_r, i}(\phi_1), \sigma^2_{v_r, i}(\phi_1))_{[-500, 500]}$$
(B13)

where

$$m_{v_r,i}(\phi_1) = \mathcal{S}^{(K_m)}(\tilde{\phi}_1)$$

$$\sigma_{v_r,i}(\phi_1) = \mathcal{S}^{(K_\sigma)}(\tilde{\phi}_1)$$
(B14)

with knot values $w_{K_m,m}$ and $w_{K_{\sigma},\sigma}$ as free parameters. The knot values for the mean function $w_{K_m,m}$ have a uniform prior $\mathcal{U}(w_{K_m,m}|-500\,\mathrm{km\,s^{-1}},500\,\mathrm{km\,s^{-1}})$ and the knot values for the scale function $w_{K_{\sigma},\sigma}$ have a truncated normal prior $\mathcal{N}(w_{K_{\sigma},\sigma}|100\,\mathrm{km\,s^{-1}},(100\,\mathrm{km\,s^{-1}})^2)_{[0.1\,\mathrm{km\,s^{-1}},\infty]}$. As with the proper motions, we use $K_m = 4$ and $K_{\sigma} = 4$ knots for the *m* and σ spline functions, respectively.

The background model component parameter vector $\boldsymbol{\theta}_b$ therefore consists of:

- the scales and mixture weights of the ϕ_1 normal mixture,
- the knot values for spline functions that control the μ_1, μ_2 , and v_r means and scales,
- the mixture weights α_i for the μ_1 , μ_2 , and v_r truncated normal mixtures.

In total, the background model has 62 free parameters.

B.3. Off-track

Finally, our off-track component density model – introduced in Section 3.2.3 – factorizes into a PDF over the joint $(\tilde{\phi}_1, \tilde{\phi}_2)$ space, multiplied by the PDFs for the kinematic coordinates, still conditioned on stream longitude ϕ_1 :

$$p_o(\tilde{\boldsymbol{y}} \mid \boldsymbol{\theta}_o) = p_o(\phi_1, \phi_2 \mid \boldsymbol{\theta}_o) \, p_o(\tilde{\mu}_1 \mid \phi_1, \boldsymbol{\theta}_o) \, p_o(\tilde{\mu}_2 \mid \phi_1, \boldsymbol{\theta}_o) \, p_o(\tilde{v}_r \mid \phi_1, \boldsymbol{\theta}_o) \tag{B15}$$

We model the (ϕ_1, ϕ_2) density with a mixture of truncated 2D normal distributions with fixed mean locations placed on a grid separated by 3° in ϕ_1 and 1° in ϕ_2 ,

$$p_{o}(\tilde{\phi}_{1}, \tilde{\phi}_{2} | \boldsymbol{\theta}_{o})) = \sum_{i}^{390} \alpha_{i} \mathcal{N}(\tilde{\phi}_{1}, \tilde{\phi}_{2} | m_{i,1}, m_{i,2}, \sigma_{i,1}^{2}, \sigma_{i,2}^{2})$$
(B16)

where $m_{i,1}$ and $m_{i,2}$ are the (fixed) ϕ_1 and ϕ_2 positions of the means of the normals, respectively, while $\sigma_{i,1}$ and $\sigma_{i,2}$ are the scales of the normal components in ϕ_1 and ϕ_2 , respectively. These scales have truncated normal priors $\mathcal{N}((\sigma_{i,1}, \sigma_{i,2}) | (3^\circ, 1^\circ), (3^\circ, 1^\circ)^2)_{[(0,3^\circ, 0.1^\circ), (\infty, \infty)]}$. Lastly, α_i are the mixture weights with a uniform Dirichlet prior.

The probability density of the proper motions and radial velocities is similar to that of the stream. For the stream, we created priors based on the PWB tracks in the three velocity dimensions. For the off-track component, we create them based on the results of an initial "stream+background" VI run. This ensures that the off-track velocities remain close to those of the stream. Specifically, letting $\mathcal{S}_{\text{stream},\mu_1}^{(K_m)}$, $\mathcal{S}_{\text{stream},\mu_2}^{(K_m)}$, and $\mathcal{S}_{\text{stream},v_r}^{(K_m)}$ denote the splines for the mean stream velocities, the knot values for the mean off-track functions $w_{K_m,m}$ have truncated normal priors

$$\mu_{1}: \mathcal{N}(w_{K_{m},m} \mid \mathcal{S}_{\text{stream},\mu_{1}}^{(K_{m})}(\phi_{1,K}), (0.25 \,\text{mas yr}^{-1})^{2})_{[\mathcal{S}_{\text{stream},\mu_{1}}^{(K_{m})}(\phi_{1,K}) - 1 \,\text{mas yr}^{-1}, \mathcal{S}_{\text{stream},\mu_{1}}^{(K_{m})}(\phi_{1,K}) + 1 \,\text{mas yr}^{-1}]$$

$$\mu_{2}: \mathcal{N}(w_{K_{m},m} \mid \mathcal{S}_{\text{stream},\mu_{2}}^{(K_{m})}(\phi_{1,K}), (0.25 \,\text{mas yr}^{-1})^{2})_{[\mathcal{S}_{\text{stream},\mu_{2}}^{(K_{m})}(\phi_{1,K}) - 1 \,\text{mas yr}^{-1}, \mathcal{S}_{\text{stream},\mu_{2}}^{(K_{m})}(\phi_{1,K}) + 1 \,\text{mas yr}^{-1}]$$

$$v_{r}: \mathcal{N}(w_{K_{m},m} \mid \mathcal{S}_{\text{stream},v_{r}}^{(K_{m})}(\phi_{1,K}), (5 \,\text{km s}^{-1})^{2})_{[\mathcal{S}_{\text{stream},v_{r}}^{(K_{m})}(\phi_{1,K}) - 20 \,\text{km s}^{-1}, \mathcal{S}_{\text{stream},v_{r}}^{(K_{m})}(\phi_{1,K}) + 20 \,\text{km s}^{-1}]$$

$$(B17)$$

The off-track velocity scales are also drawn from truncated normals centered on the stream velocity scales with standard deviation equal to 1/3 the stream velocity scales. We truncate the distributions at $0.00278 \text{ mas yr}^{-1}$ and 0.1 km s^{-1} on the lower end for the proper motions and radial velocities, respectively, and twice the stream velocity scale on the upper end. These are tight priors because we want to ensure that off-track features are capturing local overdensities related to the stream.

The off-track model therefore consists of:

• the scales and mixture weights of the (ϕ_1, ϕ_2) normal mixture,

• the knot values for spline functions that control the μ_1, μ_2 , and v_r means and scales,

In total, the off-track model has 850 free parameters.

(V)

C. BACKGROUND AND STREAM OPTIMIZATION INITIALIZATION

Given the large number of parameters in our GD-1 model, we want to improve computation time by using an initialization that is reasonably close to the true solution. To do so, we run VI optimization on the stream and background components individually (using data subsets described in Section 3.2.2) and use the results to initialize the full model. Here, we provide the initialization choices for these individual runs.

Background: The background density weights are set to be equal at each knot, with the scales set to 40°. The weights of each of the two components in the three velocity dimensions are set to 0.5. We initialize both μ_1 normals with mean 0 mas yr⁻¹ and scale 5 mas yr⁻¹. We initialize both μ_2 normals with mean -3 mas yr^{-1} and scale 3 mas yr⁻¹. We initialize both ν_r normals with mean -100 km s^{-1} and scale 50 km s⁻¹.

Stream: The stream density weights (α in Appendix B.1) are set to be equal at each knot with scales set to 10°. We initialize the ϕ_2 , μ_1 , μ_2 , and v_r normal means at each node based on the tracks in PWB18. The scales are set to 0.5°, 0.35 mas yr⁻¹, 0.35 mas yr⁻¹, and 4 km s⁻¹, respectively, where the proper motion scales are based on the average proper motion uncertainty of GD-1 members.

The results of the individual component runs are shown in Figures 10 and 11.

Figure 10. The same as Figure 3 but for the background model described in Section 3.2.2.

Figure 11. The same as Figure 3 but for the stream model described in Section 3.2.1.
