# Solving the Encoding Bottleneck: Of the HHL Algorithm, By the HHL Algorithm

Guang Ping He\*

School of Physics, Sun Yat-sen University, Guangzhou 510275, China

The Harrow-Hassidim-Lloyd (HHL) algorithm offers exponential speedup for solving the quantum linear-system problem. But some caveats for the speedup could be hard to met. One of the difficulties is the encoding bottleneck, i.e., the efficient preparation of the initial quantum state. To prepare an arbitrary N-dimensional state exactly, existing state-preparation approaches generally require a runtime of O(N), which will ruin the speedup of the HHL algorithm. Here we show that the states can be prepared approximately with a runtime of  $O(poly(\log N))$  by employing a slightly modified version of the HHL algorithm itself. Thus, applying this approach to prepare the initial state of the original HHL algorithm can preserve the exponential speedup advantage. It can also serve as a standalone solution for other applications demanding rapid state preparation.

## I. INTRODUCTION

The success of Shor's factoring algorithm [1] and Grover's search algorithm [2] stimulated the rapid development of quantum computation technology that lasts to this day. But as we entered the 21th century, new quantum algorithms with comparable impacts are rare to find. The Harrow-Hassidim-Lloyd (HHL) algorithm [3] is one of the few remarkable examples. It provides a brilliant solution to the quantum version of the linearsystem problem (LSP), defined as [4]:

**QLSP:** Given a Hermitian  $N \times N$  matrix A and an N-dimensional unit vector  $b = (b_1, ..., b_N)^T$ , find an n-qubit state  $|\tilde{x}\rangle$  such that  $|||x\rangle - |\tilde{x}\rangle|| \leq \epsilon$  and

$$Ax = b, \tag{1}$$

where  $\epsilon$  is the error and  $N = 2^n$ .

The HHL algorithm can solve this problem in  $O(poly(\log(N)))$  runtime, while the best known classical algorithm for the classical LSP takes O(poly(N)) runtime. As LSP is one of the most basic problem in all of science, the HHL algorithm is highly favored in the study of machine learning [5, 6], quantum walk [7], computational fluid dynamics [8], quantum many body problem [9], and electromagnetic scattering cross-sections [10], et al.

However, as pointed out in [11], this exponential speedup requires the following caveats:

(i) The vector b needs to be converted quickly into a quantum computer as the n-qubit quantum state

$$|b\rangle = (b_1, ..., b_N)^T = \sum_{j=0}^{2^n - 1} b_j |j\rangle.$$
 (2)

(ii) The quantum computer needs to be able to apply unitary transformations of the form  $e^{-iAt}$  for various values of t.

(iii) The matrix A needs to be "well-conditioned", i.e., the condition number  $\kappa$  (defined as the ratio in magnitude between the largest and smallest eigenvalues of A) should not grows like  $N^c$ .

(iv) The quantum computer user can use the resultant quantum state  $|x\rangle$  directly, without needing to learn the value of any specific entry of x.

Here we focus on the caveat (i). To initialize the quantum computer to the state  $|b\rangle$  corresponding to an arbitrary known vector b exactly, existing state-preparation approaches generally require O(N) runtime, except for some special states [12–15]. Without a better solution, the exponential speedup of the HHL algorithm will be ruined. This is called "the encoding bottleneck".

In this research, we will show that the state  $|b\rangle$  can be prepared approximately to any desired nonzero error, with the runtime speeded up to  $O(poly(\log(N)))$ . The approach is to apply the HHL algorithm itself to prepare the initial state, with two minor modifications only.

Moreover, the application of our approach is not limited to preparing the initial state of the HHL algorithm. Any other task in need of the preparation of quantum states can be benefited, e.g., when training quantum machine learning models [16–22] using the amplitude encoding method [23, 24] for classical input data.

### II. MAIN IDEA

Eq. (1) means that the HHL algorithm is capable of finding an approximation of the quantum state  $|x\rangle$  where x satisfies

$$x = A^{-1}b, (3)$$

given that A and b are known. Our goal is to find an algorithm to prepare the state  $|b\rangle$  efficiently.

While preparing  $|b\rangle$  for arbitrary values of b is hard in general, some special states does not have to take O(poly(N)) runtime to prepare. Therefore, we can start from such a state, then find an effective method to turn it into any arbitrary  $|b\rangle$ . Interestingly, with some minor twists, the HHL algorithm itself provides such a solution, as elaborated below.

<sup>\*</sup>Electronic address: hegp@mail.sysu.edu.cn

Since the classical entries  $b_1, ..., b_N$  of the vector b is known, let us define a matrix

$$B = \begin{bmatrix} b_1 & 0 & \cdots & 0 & 0 \\ 0 & b_2 & \cdots & 0 & 0 \\ \vdots & \vdots & \ddots & \vdots & \vdots \\ 0 & 0 & \cdots & b_{N-1} & 0 \\ 0 & 0 & \cdots & 0 & b_N \end{bmatrix}$$
(4)

and an N-dimensional vector

$$h = (1, 1, ..., 1, 1)^T.$$
(5)

Then we have

$$b = Bh. (6)$$

Thus, the quantum state-preparation problem can be phrased in a way very similar to the QLSP, i.e.:

**QSPP**: Given a matrix *B* and a vector *h*, find an approximation of the quantum state  $|b\rangle$  corresponding to the vector *b*.

Comparing Eq. (6) with Eq. (3), we can see that with the mapping

$$\begin{array}{l}
b \longleftrightarrow x, \\
B \longleftrightarrow A^{-1}, \\
h \longleftrightarrow b,
\end{array}$$
(7)

the original HHL algorithm can be applied here to obtain the approximation of  $|b\rangle$  from known B and h in  $O(poly(\log(N)))$  runtime, except that the matrix B does not need to be inverted during the process. Also, preparing the quantum state  $|h\rangle$  corresponding to h requires  $n = \log(N)$  single-qubit quantum gates only (to be shown below). Thus, the total runtime of preparing  $|b\rangle$  remains at  $O(poly(\log(N)))$ , so that it will preserve the exponential speedup for further using the HHL algorithm to obtain  $|x\rangle$ .

Note that like the matrix A in the original HHL algorithm, the matrix B is not unitary either. Therefore, it cannot be applied directly on the quantum state  $|h\rangle$  to obtain  $|b\rangle$ . Instead, the same treatment on A in [3] is needed. That is, B can be transformed into  $e^{iBt}$  which is unitary so that it becomes physically implementable. Also, when any of  $b_1, \ldots, b_N$  is a complex number, B is not a Hermitian matrix. Then we need to apply the trick in Eq. (1) of [3] to expand it as

$$\tilde{B} = \begin{bmatrix} 0 & B^{\dagger} \\ B & 0 \end{bmatrix}$$
(8)

which is Hermitian. Solving

$$\tilde{b} = \tilde{B} \begin{bmatrix} h\\0 \end{bmatrix} \tag{9}$$

will obtain

$$\tilde{b} = \begin{bmatrix} 0\\b \end{bmatrix}.$$
 (10)

For simplicity, in the following we take B as Hermitian to illustrate our algorithm. In real applications where B is not Hermitian, then apply the above reduction and the desired  $|b\rangle$  can still be obtained.

### **III. OUR STATE-PREPARATION ALGORITHM**

With the above idea in mind, our algorithm for statepreparation can be constructed following the HHL algorithm, with two modifications only. Ref. [25] offered a very clear and concise step-by-step walkthrough of the HHL algorithm. Here we use the same notation and work flow as these in section II of [25], so that it is easy to compare our algorithm with the original HHL algorithm and see the difference.

The algorithm takes  $n_b$  target qubits where the final target state  $|b\rangle$  of the preparation will be stored,  $n_c$  clock qubits (as called in [25]), and another ancilla qubit. At the beginning, all these  $n_b + n_c + 1$  qubits are initialized as

$$|\Psi_0\rangle = |0...0\rangle_h |0...0\rangle_c |0\rangle_a. \tag{11}$$

Then the state-preparation algorithm goes as follows.

(1) Unlike the original HHL algorithm, our first modification is to apply a Hadamard gate H on each of the target qubits to transform them into the quantum state  $|h\rangle$  corresponding to h up to a normalization factor, i.e.,

$$|h\rangle = \frac{1}{\sqrt{2^{n_b}}} \sum_{j=0}^{2^{n_b}-1} |j\rangle = \frac{1}{\sqrt{2^{n_b}}} (1, 1, ..., 1, 1)^T.$$
(12)

It takes  $n_b$  single-qubit gates in total, and the state of the whole system becomes

$$\begin{split} |\Psi_{1}\rangle &= \left(H^{\otimes n_{b}} \otimes I^{\otimes n_{c}} \otimes I\right) |\Psi_{0}\rangle \\ &= \frac{1}{\sqrt{2^{n_{b}}}} (|0\rangle + |1\rangle)^{\otimes n_{b}} |0...0\rangle_{c} |0\rangle_{a} \\ &= \left(\frac{1}{\sqrt{2^{n_{b}}}} \sum_{j=0}^{2^{n_{b}}-1} |j\rangle\right) |0...0\rangle_{c} |0\rangle_{a} \\ &= |h\rangle |0...0\rangle_{c} |0\rangle_{a} \,. \end{split}$$
(13)

(2) From now on, we follow the HHL algorithm except where noted. That is, we launch the quantum phase estimation (QPE) process, which starts from applying a Hadamard gate H on each of the clock qubits, turning the state into

$$\begin{aligned} |\Psi_2\rangle &= (I^{\otimes n_b} \otimes H^{\otimes n_c} \otimes I) |\Psi_1\rangle \\ &= |h\rangle \left(\frac{1}{\sqrt{2^{n_c}}} \sum_{k=0}^{2^{n_c}-1} |k\rangle\right) |0\rangle_a \,. \end{aligned} \tag{14}$$

(3) The controlled rotation part of the QPE: apply  $n_c$  controlled gates on  $|h\rangle$ , as shown in Fig. 2 of [25]. That is, the *r*th controlled gate  $(r = n_c - 1, n_c - 2, ..., 0)$  performs

the transformation  $U^{2^r}$  on  $|h\rangle$ , with the *r*th clock qubit as the control qubit. Here the unitary transformation Uis defined as

$$U = e^{iBt}.$$
 (15)

The state becomes

$$\begin{aligned} |\Psi_{3}\rangle &= \left(QPE \otimes I\right) |\Psi_{2}\rangle \\ &= \sum_{j=0}^{2^{n_{b}}-1} \frac{1}{\sqrt{2^{n_{b}}}} |j\rangle \\ &\otimes \left(\frac{1}{\sqrt{2^{n_{c}}}} \sum_{k=0}^{2^{n_{c}}-1} e^{2\pi i \phi_{j} k} |k\rangle\right) |0\rangle_{a}, \quad (16) \end{aligned}$$

where

$$\phi_j = \frac{b_j t}{2\pi} \tag{17}$$

with t being the parameter in the HHL algorithm. According to [3], the operator  $e^{iBt}$  can be simulated using the approach in [26] in time  $\tilde{O}[\log(N)s^2t]$  (where the  $\tilde{O}$ suppresses more slowly growing terms) when the matrix B is s sparse. In our case, from Eq. (4) we know that s = 1. (To understand how Eq. (16) is obtained, it is highly recommended to read the derivation of Eqs. (14) and (20) of [25], and note the fact that  $b_j$  (j = 1, ..., N)are exactly the eigenvalues of our matrix B in the computational basis, and  $|h\rangle$  is a uniform superposition of the eigenvectors.)

(4) Perform the inverse quantum Fourier transform (IQFT) on the clock qubits. This ends the QPE and the resultant state (as analog to Eq. (21) of [25]) is

$$\Psi_{4} \rangle = (I^{\otimes n_{b}} \otimes IQFT \otimes I) |\Psi_{3}\rangle$$
$$= \sum_{j=0}^{2^{n_{b}}-1} \frac{1}{\sqrt{2^{n_{b}}}} |j\rangle \left|\tilde{\lambda}_{j}\right\rangle |0\rangle_{a}$$
(18)

with

$$\tilde{\lambda}_j = N\phi_j = N\frac{b_j t}{2\pi}.$$
(19)

(5) Rotate the ancilla qubit using the clock qubits as control qubits. In the original HHL algorithm, this rotation transforms  $|\Psi_4\rangle$  into

$$|\Psi_5'\rangle = \sum_{j=0}^{2^{n_b}-1} \frac{1}{\sqrt{2^{n_b}}} |j\rangle \left|\tilde{\lambda}_j\right\rangle \left(\sqrt{1 - \frac{C^2}{\tilde{\lambda}_j^2}} |0\rangle_a + \frac{C}{\tilde{\lambda}_j} |1\rangle_a\right).$$
(20)

But here we introduce our second and last modification to the HHL algorithm. Instead of Eq. (20), we replace the controlled rotation with another one which results in

$$|\Psi_5\rangle = \sum_{j=0}^{2^{n_b}-1} \frac{1}{\sqrt{2^{n_b}}} |j\rangle \left|\tilde{\lambda}_j\right\rangle (\sqrt{1 - C^2 \tilde{\lambda}_j^2} |0\rangle_a + C \tilde{\lambda}_j |1\rangle_a).$$
(21)

Here the real constant C should be chosen to ensure that  $|C\tilde{\lambda}_j|^2 \leq 1$  for all  $j = 0, ..., 2^{n_b} - 1$ . According to Sec. 4.3 of [27], this rotation can be implemented using  $O[(\log \epsilon_1^{-1})^4]$  quantum operations and  $O[(\log \epsilon_1^{-1})^3]$  qubits with error  $\epsilon_0 = \epsilon_1^2$ . In other words, when the desired error is  $\epsilon_0$ , we need  $n_c = O[(\log \epsilon_0^{-1/2})^3]$  clock qubits and  $O[(\log \epsilon_0^{-1/2})^4] = O(n_c^{4/3})$  quantum operations.

(6) Now return to the HHL algorithm to disentangle the target qubits from other qubits. Namely, we first measure the ancilla qubit in the basis  $\{|0\rangle_a, |1\rangle_a\}$ . If the result is  $|0\rangle_a$  then the state-preparation fails and we need to restart the whole process over again. Else if the result is  $|1\rangle_a$  then we continue. The state of the system in this case is

$$\begin{aligned} |\Psi_{6}\rangle &= \frac{1}{\sqrt{\sum_{j=0}^{2^{n_{b}-1}} \left|\frac{C\tilde{\lambda}_{j}}{\sqrt{2^{n_{b}}}}\right|^{2}}} \sum_{j=0}^{2^{n_{b}-1}} \frac{C\tilde{\lambda}_{j}}{\sqrt{2^{n_{b}}}} |j\rangle \left|\tilde{\lambda}_{j}\right\rangle |1\rangle_{a} \\ &= \frac{1}{\sqrt{\sum_{j=0}^{2^{n_{b}-1}} \left|\tilde{\lambda}_{j}\right|^{2}}} \sum_{j=0}^{2^{n_{b}-1}} \tilde{\lambda}_{j} |j\rangle \left|\tilde{\lambda}_{j}\right\rangle |1\rangle_{a} . \end{aligned} (22)$$

(7) Perform the inverse quantum phase estimation (IQPE) process, starting by applying the quantum Fourier transform (QFT) on the clock qubits. The resultant state (as analog to Eq. (24) of [25]) is

$$\begin{aligned} |\Psi_{7}\rangle &= \left(I^{\otimes n_{b}} \otimes QFT \otimes I\right) |\Psi_{6}\rangle \\ &= \frac{1}{\sqrt{\sum_{j=0}^{2^{n_{b}-1}} \left|\tilde{\lambda}_{j}\right|^{2}}} \sum_{j=0}^{2^{n_{b}-1}} \tilde{\lambda}_{j} \left|j\right\rangle QFT \left|\tilde{\lambda}_{j}\right\rangle \left|1\right\rangle_{a} \\ &= \frac{1}{\sqrt{\sum_{j=0}^{2^{n_{b}-1}} \left|\tilde{\lambda}_{j}\right|^{2}}} \sum_{j=0}^{2^{n_{b}-1}} \tilde{\lambda}_{j} \left|j\right\rangle \\ &\otimes \left(\frac{1}{2^{n_{c}/2}} \sum_{y=0}^{2^{n_{c}-1}} e^{2\pi i y \tilde{\lambda}_{j}/N} \left|y\right\rangle\right) |1\rangle_{a}. \end{aligned}$$
(23)

(8) The controlled rotation part of the IQPE: similar to step (3),  $n_c$  controlled gates are applied on the target qubits with the clock qubits as the control qubits. But the unitary transformation U is replaced by  $U^{-1} = e^{-iBt}$ .

The result is

 $\overline{j=0}$ 

$$\begin{aligned} |\Psi_{8}\rangle &= (IQPE \otimes I) |\Psi_{7}\rangle \\ &= \frac{1}{2^{n_{c}/2} \sqrt{\sum_{j=0}^{2^{n_{b}-1}} \left|\tilde{\lambda}_{j}\right|^{2}}} \sum_{j=0}^{2^{n_{b}-1}} \tilde{\lambda}_{j} |j\rangle \\ &\otimes \left(\sum_{y=0}^{2^{n_{c}-1}} e^{-ib_{j}ty} e^{2\pi i y \tilde{\lambda}_{j}/N} |y\rangle\right) |1\rangle_{a} \qquad (24) \\ &\frac{1}{2^{2^{n_{b}-1}}} \sum_{j=0}^{2^{n_{b}-1}} e^{-ib_{j}(\sum_{j=0}^{2^{n_{c}-1}} |y\rangle) |1\rangle \end{aligned}$$

$$= \frac{1}{2^{n_c/2}} \frac{1}{\sqrt{\sum_{j=0}^{2^{n_b}-1} |b_j|^2}} \sum_{j=0}^{j=0} |b_j| j \rangle \left(\sum_{y=0}^{2^{n_b}-1} |y\rangle\right) |1\rangle_a$$
$$= \sum_{j=0}^{2^{n_b}-1} b_j |j\rangle \left(\frac{1}{2^{n_c/2}} \sum_{y=0}^{2^{n_c}-1} |y\rangle\right) |1\rangle_a. \tag{25}$$

where we made use of  $\tilde{\lambda}_j = N b_j t / 2\pi$  and  $\sum_{j=0}^{2^{n_b}-1} |b_j|^2 =$ 1.

(9) End the IQPE by applying a Hadamard gate Hon each of the clock qubits. This completes the whole preparation process and we eventually yield

$$\begin{aligned} |\Psi_{9}\rangle &= \left(I^{\otimes n_{b}} \otimes H^{\otimes n_{c}} \otimes I\right) |\Psi_{8}\rangle \\ &= \left(\sum_{j=0}^{2^{n_{b}}-1} b_{j} |j\rangle\right) |0...0\rangle_{c} |1\rangle_{a} \\ &= |b\rangle |0...0\rangle_{c} |1\rangle_{a} \,. \end{aligned}$$

$$(26)$$

That is, the target state  $|b\rangle$  of the preparation is successfully stored in the target qubits.

#### IV. ERROR AND RUNTIME

As shown in step (5), when the desired error of the quantum operation for achieving Eq. (21) is  $\epsilon_0$ , it takes  $n_c = O[(\log \epsilon_0^{-1/2})^3]$  clock qubits and  $O[(\log \epsilon_0^{-1/2})^4] = 1$  $O(n_c^{4/3})$  quantum operations. The error of other steps is the same as that of the original HHL algorithm, which was analyzed in [3]. That is, the dominant source of error is phase estimation, which can be done with error  $\epsilon$  in time proportional to

$$ts^2(t/\epsilon)^{o(1)} =: \tilde{O}(ts^2) \tag{27}$$

- [1] P. W. Shor, DIMACS technical report 94-37, June 1994. Algorithms for quantum computation: discrete log and factoring

for a s sparse matrix A.

Therefore, to reach a successful computation, the runtime of the original HHL algorithm is [3]

$$\tilde{O}(\log(N)s^2\kappa^2/\epsilon).$$
(28)

In our case, A is replaced by B and we have s = 1in the above two equations, as can be seen from Eq. (4). Meanwhile, our first modification (step (1)) takes  $n_b$  Hadamard gates. The second modification (step (5)) replaces Eq. (20) with Eq. (21), which takes  $O(n_c^{4})$ quantum operations to implement. Putting these three parts together, the total runtime of our state-preparation algorithm remains at  $O(\log(N))$ , as long as the condition number  $\kappa$  of the matrix B does not grow like  $N^c$  (in the case where  $\kappa$  is large, the treatment in [28] may help). Therefore, for preparing quantum states satisfying this condition, it can offer exponential speedup in comparison with other existing state-preparation methods.

#### DISCUSSION v.

In conclusion, our modified algorithm can prepare a quantum state with a runtime at the same level of the original HHL algorithm. Thus, using it to prepare the initial state will preserve the exponential speedup advantage of the HHL algorithm.

Note that among the four caveats that we mentioned at the beginning of this paper, our approach conquers the first one only. To ensure that the speedup brought by the HHL algorithm will not be ruined, the other three caveats still need to be satisfied. Nevertheless, as our approach solves the encoding bottleneck, it surely extends the potential application scope of the HHL algorithm. Also, in other application scenarios which have intensive needs of preparing initial states, e.g., quantum machine learning, our approach can serve as a standalone solution to speed up the process.
