February 20, 2025

#### Abstract

Existing approaches to asset-pricing under model-uncertainty adapt classical utilitymaximisation frameworks and seek theoretical comprehensiveness. We move toward practice by considering binary model-uncertainties and by switching attention from 'preference' to 'constraints'. Economic asset-pricing in this setting is found to decompose naturally into the viable pricing of model-risk and of non-model risk *separately* such that the former has a unique and intuitive risk-neutral equivalent formulation with convenient properties. Its parameter, a dynamically conserved constant of model-risk inference, allows an integrated representation of *ex-ante* risk-pricing and bias, such that their *ex-post* price-effects can be disentangled, through well-known price anomalies.

# Introduction

### **Motivation and Results**

We study the pricing of model-risks that may be subject to uncertainty in the sense of Knight (1921) and Bewley (2002), where 'uncertainty' refers to randomness governed by probability laws whose parameters are *unknown*. The aim is to move closer to practice and to examine relevant issues missed by existing literature. For our purpose, 'risk' shall refer to randomness generally, with laws known or unknown, and 'model', some chosen probability law.

Our approach exploits potential risk and data hierarchies, exposes model-risk as a dominant source of value gained/lost in the market, and furnishes ways to disentangle risk-pricing from bias, through price-anomalies such as Momentum (Jegadeesh and Titman (1993)) and Low-Risk (Ang et al. (2006)), without ad hoc criteria for what part of an observed drift is 'by design' and what, 'by mistake'. The bias identified this way happens to be Status Quo Bias, a well-known behavioural trait (Samuelson and Zeckhauser (1988), Kahneman et al. (1991)), with a prominent role in Knightian Decision Theory (Bewley (2002)), making our framework a tool for the exploration of these concepts in practical and concrete terms.

Existing works adapting classical theories to incorporate model-risk come under *ambiguity-aversion* or *robust-control*, where agents perform recursive optimisation, against goals such as *maxmin* utility, optimal *smooth-ambiguity* or *variational* preference, over the set of model choices (e.g. Ju and Miao (2012) or Machina and Siniscalchi (2014)). Related is *parameter learning* (e.g. Guidolin and Timmermann (2007), Collin-Dufresne et al. (2016)), carried out usually under a definitive model-risk law, without uncertainty.

Existing focus is the nature of preference/utility under model-risk and model-risk discount in a general equilibrium. Our focus is how model-risk pricing may be achieved or characterised 'minimally', with fewest assumptions and parameters. A natural start is thus the Risk-Neutral Equivalent (RNE) formulation, given the First Theorem of Asset Pricing (FTAP)<sup>1</sup>.

<sup>&</sup>lt;sup>1</sup>Early maxmin utility struggled with FTAP-compliance (e.g. Epstein and Wang (1995)). Its modern form (e.g. Chen and Epstein (2002)) and other approaches have no such issues (e.g. Ju and Miao (2012)), especially when reformulated under the banner of smooth-ambiguity (Proposition 3.6 of Burzoni et al. (2021)).

However, *viability*, No Arbitrage in the FTAP sense, is too weak for most pricing tasks: there are far more *viable processes* than *economically meaningful ones*. Moreover, learning about model-risk makes RNE probabilities path-dependent, and so intractable, even in simple cases (proved formally here, but already observed in Guidolin and Timmermann (2007)).

One way to address such obstacles is to add incremental conditions to the FTAP baseline till RNE formulations that do provide economic asset-pricing can be characterised. It is an inversion of the routine of 'theory making followed by viability checking', and a switch of perspective from 'agent preference' to 'structural constraints'. It culminates in the decomposition of viable economic asset-pricing into *separately viable* components and the identification of a unique and intuitive RNE model-risk pricing formula, whose sole parameter, a constant of motion in the model-risk inference dynamic, allows an integrated treatment of *ex-ante* risk-premia and bias such that their price effects can be made distinct *ex-post*.

### **Scope and Premise**

We take the existence of *representative agent/belief* for granted; see Barbosa (2018) and Hands (2017) for recent reviews. The language of rational, Bayesian, inference, is used, to indicate adherence to the laws of probabilities; likewise, 'rational' and 'expectation' signify the same, without implying 'objective correctness', unlike in classical Rational Expectation (RE) frameworks. We work with three types of probabilities: 1) objective ones governing payoffs and data; 2) subjective ones representing inferential beliefs about the objective laws; 3) RNE ones for pricing decisions.

Many real-world pricing tasks concern how something new impacts what is otherwise wellunderstood. It is often how model-risks emerge in practice. As such, let our model-risk B, of micro or macro origin, be *binary*, with outcome b or  $\overline{b} \neq b$ ; the non-binary is outlined at the end. Let our *B*-sure models be uncertainty-free; these represent the known and familiar, which by classical RE principles should have been well-modelled already. That is, only change (e.g. new CEO, R&D results, or regulatory/governmental/geopolitical events) creates model-risk. Our theme is one of 'routines vs breaks'. **Remark 1.** Some such risks may be hedged or diversified away. Our results apply only to any economically priced risk: one deemed worthy of being assigned at each moment a risk-premium through some recursive optimisation scheme taking said risk as an input.

We restrict to *economically consistent* model-risks, under which one alternative is always almost surely more valued than the other. *Only* these can be given viable and consistently signed risk-premia, as it turns out. Existing theories, being universal, are indifferent to such features, although all worked examples in the literature do have this consistency.

In another twist, our model-risk is 'one-off'. How it 'flares up' and the pricing of 'flare-risk' shall remain implicit; that is, we study episodic 'model crises', one at a time. This contrasts with the workhorse Markov regime-switching setting of the literature, where the pricing of the entire process is treated. Further, despite possible uncertainty and indefinite priors, our model-risk may be *resolvable* via regular inference, albeit not before any finite horizon; this is also the case in Hansen-Sargent's robust-control setting (Hansen et al. (2006)). Correspondingly, let horizons be sufficiently long, for model-risk inference and pricing to develop meaningfully, and asset-pricing, *time-homogeneous* ('identical risk-levels identically priced regardless'), at least while the given model-risk is active and relevant.

The law of our model-risk, the unconditional distribution of *B*-outcomes, may be unknown. If the true unconditional probability, denoted  $\mathbf{p}_0^B$  throughout, is known, model-detection (learning) and asset-pricing remain classical, with familiar conclusions. If unknown, the same may involve non-classical cognitive and economic elements. Nevertheless, asset-pricing may be formulated in terms of classical inference, with non-classical aspects reflected through preference and discount mechanisms; this is the usual and our strategy.

Lastly, in theory and practice, data on model-risk (e.g. 'expansion or recession?'), compared to data on non-model risk (e.g. declared payout), tend to be more frequent and impactful. Such data structures, absent in existing studies, are treated explicitly here.

The setup as outlined makes model-risk a prominent feature of asset-pricing, a major source of excess value, and so a likely focus of market effort and activities.

#### **Existing Theories in Our Context**

Most model-risk pricing schemes, ambiguity-aversion, robust-control and some parameterlearning, achieve model-risk discounts by in effect pessimistically distorting a *reference belief* (about model-risk), known as 'reference measure', 'second-order prior', or 'benchmark'.

The set of models for the state space S whose model is sought may be written as  $\mathcal{I}_1(S)$ . It is often identified with the space or a subspace of probability measures on S. We see it simply as an index set, labelling model candidates. Potential laws governing the model-risk may be likewise understood and collected into some set  $\mathcal{I}_2(\mathcal{I}_1(S))$ . In our case:  $\mathcal{I}_1(S) \cong \{Q_b, Q_{\overline{b}}\}$ , one *B*-value for one model, some probability law  $Q_B$  of state space S, and  $\mathcal{I}_2(\mathcal{I}_1(S)) \cong (0, 1)$ .

A reference model-risk belief thus may be identified with a member of  $\mathcal{I}_2(\mathcal{I}_1(S))$ , generating learning about model-risk given the models in  $\mathcal{I}_1(S)$ . It is in our case some  $\pi_0^B \in (0,1)$ , leading to a model-risk inference process  $\{\pi_n^B\}$  based on competing models  $\{Q_b, Q_{\overline{b}}\}$ .

**Remark 2.** Call the set  $\mathcal{L}_{S} := \{\pi_{0}^{I}Q_{I} | \pi_{0}^{I} \in \mathcal{I}_{2}(\mathcal{I}_{1}(S)), Q_{I} \in \mathcal{I}_{1}(S)\}$  of reference beliefs about the law governing total state space  $\mathcal{I}_{1}(S) \times S$  the set of model-uncertainty, for later reference.

Maxmin utility has the simplest solution: choose at any moment the model with the worst outlook among those deemed possible; in our setting it means using the pessimistic alternative till model-uncertainty resolves. It is a limit of the graded optimisation procedure of the other theories, where pessimism is tempered by reference beliefs (e.g. Hansen and Sargent (2011) penalises distorted beliefs by their *relative entropy* to the reference belief<sup>2</sup>).

Key to all is then the reference belief, by which model-risk pricing is defined and computed. In RE and some parameter-learning settings reference beliefs are known to be true, leading to classical risk-discounts. With model-uncertainty, even if reference beliefs happen to be true, *perceived* uncertainty still triggers extra discounts. All worked examples in the uncertainty literature presume the reference beliefs used by their agents to be true; this in our context is unjustified. At the other extreme, some parameter-learning stances see realised parameter-value as deterministic, meaning  $\mathbf{p}_0^B \equiv 1$  or 0 if adopted here; this would exclude many types of model-risks of practical interest. In our setting then, the norm is  $\pi_0^B \neq \mathbf{p}_0^B \in (0, 1)$ .

<sup>&</sup>lt;sup>2</sup>Our *B*-sure models  $\{Q_b, Q_{\overline{b}}\}$  being uncertainty-free, only the second of their cost parameters is relevant.

Any assertion of equality would mask a basic issue facing all attempts to free classical RE frameworks from any built-in coincidence of beliefs and true laws: pricing theory outputs are *ex-ante* but what can be observed is *ex-post*, so tests and calibrations are impossible without additional theories of *bias*. Manifestations of this difficulty include 'observational equivalence' ('is the large *ex-post* risk-premium due to bias after all?'; see e.g. Cecchetti et al. (2000)) and 'joint-hypothesis' ('is an anomaly a sign of bias in the market or in one's pricing theory?'; see e.g. Fama (2014)). We will illustrate how this issue resolves itself in our approach.

Finally, existing theories require as inputs 'total risk', model and non-model risk together, aggregated across all the assets involved. This makes them unwieldy for tackling bottom-up or cross-sectional questions, especially when the model-risk(s) can be micro, macro or of a variety of causes. Our method, with its isolation of model-risk pricing and RNE formulation, may prove more flexible and convenient in this context.

### **Content and Organisation**

Section 1 defines the objects and structures required; Section 2 derives the RNE formulation of asset-pricing under model-risk; Section 3 demonstrates a potential implication; conclusions and discussions follow at the end. Our approach rests on a property of inferential hypothesis testing: tests that are informationally redundant to each other must be essentially identical (stated and proved as Lemma 1 in Appendix B). This implies that under model-risk the RNE formulations of total-risk pricing are in general path-dependent with respect to *all* reference model-risk beliefs, and so, in effect, unidentifiable (formalised as Proposition 1).

However, in the usual setting of complete markets in continuous or discrete time where Ito-Taylor expansion applies, the above also means that any viable economic pricing must contain a *canonical* model-risk pricing form that has a unique and intuitive RNE formulation (Definition 2 and Proposition 2). This leads to familiar risk-pricing properties (Corollary 1) and price dynamics (Section 2.4.2). One potential implication is that Status Quo Bias may be linked to well-known market-anomalies, whose characteristics reveal the *ex-ante* risk-pricing and bias of market pricing under model-uncertainty (Section 3.5.1&3.5.2).

# 1 Setup

### 1.1 Regular Hypothesis Testing

Consider a *cumulative* data process  $\{D^n\}$ , whose state space  $S^{\mathbb{N}} \ni \omega$  (e.g.  $(\mathbb{R}^d)^{\mathbb{N}}$ ,  $d \in \mathbb{N}$  fixed) may be identified with that of its sample-paths  $\{D^n\}(\omega)$ , with  $D^n(\omega) \in S^n$  being a sample-path of data up to  $n \in \mathbb{N}$ , generating a natural filtration  $\{F_n\}$  satisfying usual conditions. Further:

- 1. Let the two *B*-labelled alternative hypotheses be represented as probability measures  $Q_b(\cdot)$  and  $Q_{\overline{b}}(\cdot)$  on the filtered space  $(S^{\mathbb{N}}, F_{\infty}; \{F_n\})$  of total data;
- 2. Let equivalence  $Q_b|_n \sim Q_{\overline{b}}|_n$  hold on any partial-data subspace  $(S^n, F_n)$ ,  $\forall n \in \mathbb{N}$ ;
- 3. If mutual singularity  $Q_b \perp Q_{\overline{b}}$  holds for total data on  $(\mathcal{S}^{\mathbb{N}}, F_{\infty})$ , call the test regular;
- 4. If equivalence  $Q_b \sim Q_{\overline{b}}$  holds for total data on  $(\mathcal{S}^{\mathbb{N}}, F_{\infty})$ , call the test *non-resolving*.

**Remark 3.** A widely applicable class of regular tests has each data-point  $n \in \mathbb{N}$  independently sampled from some distribution  $\mu_b^{(n)} \sim \mu_{\overline{b}}^{(n)}$ ,  $\mu_b^{(n)} \neq \mu_{\overline{b}}^{(n)}$ , on  $\mathbb{R}^d$ ; the product measures  $\bigotimes_{n=1}^{\mathbb{N}} \mu_b^{(n)}$  and  $\bigotimes_{n=1}^{\mathbb{N}} \mu_{\overline{b}}^{(n)}$  are well-defined on  $(\mathbb{R}^d)^{\mathbb{N}}$  and mutually singular (Kakutani's Theorem).

This setup allows a well-behaved *B*-detection process on  $S_{\mathcal{B}}^{\mathbb{N}} := \mathcal{B} \times S^{\mathbb{N}}$ ,  $\mathcal{B} := \{b, \overline{b}\}$ , under product measure  $\pi_0^B Q_B(\cdot)$ : at any  $n \in \mathbb{N}$ , for any  $\omega_B \in S_{\mathcal{B}}^{\mathbb{N}}$ , given the *B*-labelled models  $Q_B$  and *a priori* (i.e. unconditional) belief  $\pi_0^{B(\omega_B)}$  in outcome  $B(\omega_B) \in \mathcal{B}$ ,

$$\pi_0^B Q_B|_n \big(\omega_B \in \cdot\big) := \pi_0^{B(\omega_B)} \times Q_{B(\omega_B)}|_n \big(D^n(\omega_B) \in \cdot\big).$$
(1)

### **1.2 The Underlying Inference Process**

Tests using likelihood ratios is optimal in the general sense of Neyman-Pearson Lemma. Test dynamic is best seen through the *log-likelihood-ratio process* (log-LRP)  $\{l_n^{b\overline{b}}\}$ :  $\forall n \in \mathbb{N}$ , given dataflow to date  $D^n$ , denoting the *n*th data-point by  $D^n(n)$  and setting  $l_0^{b\overline{b}}(D^0) \equiv 0$ ,

$$l_{n}^{b\overline{b}}(D^{n}) := \log \frac{Q_{b}|_{n}(D^{n})}{Q_{\overline{b}}|_{n}(D^{n})} = l_{n-1}^{b\overline{b}}(D^{n-1}) + \Delta l_{n}^{b\overline{b}}(D^{n}(n)),$$
(2)

$$\Delta l_n^{b\overline{b}}(D^n(n)) := \log \frac{Q_b|_n (D^n(n)|F_{n-1})}{Q_{\overline{b}}|_n (D^n(n)|F_{n-1})}.$$
(3)

The log-LRPs of dataflow with *independent and small increments* (Appendix A) are randomwalks and become Wiener processes in the continuous limit.

**Remark 4.** For example, an i.i.d coin-toss test of heads-probability  $\alpha_B \in \{\alpha_b, \alpha_{\overline{b}}\}$  by heads-count  $h_n := \sum_{i=1}^n \mathbf{1}_{\{D^n(i)=heads\}}$  has  $log-LRP\{l_n^{b\overline{b}}\} = \{h_nA - (n-h_n)C\}$ ,  $A := log[\alpha_b/\alpha_{\overline{b}}] \approx C := log[\underline{\alpha}_{\overline{b}}/\underline{\alpha}_b]$  under small increments, where the convention  $(\cdot) := 1 - (\cdot)$  for binary likelihoods is used.

Any likelihood-ratio  $L_n^{b\overline{b}} := \exp[l_n^{b\overline{b}}]$  of the data up to n can be  $C^{\infty}$ -mapped to an *a posteriori* belief  $\pi_n^b \in (0,1)$  about  $\{B = b\}$ , and vice versa, by the Bayes' Rule, which, in terms of *odds-in-favour*  $O_f[\pi_n^b] := \pi_n^b/\underline{\pi}_n^b$  of  $\{B = b\}$ , given *a priori* odds  $O_f[\pi_0^b] \in (0,\infty)$ , reads:

$$O_f[\pi_n^b] = O_f[\pi_0^b] \cdot \exp[l_n^{b\overline{b}}] \propto L_n^{b\overline{b}} \in (0,\infty);$$
(4)

so new-odds = old-odds × likelihood-ratio of interim data, making it clear that inferential odds follow *geometric* random-walks (geometric Wiener processes in continuous settings).

### 1.3 Model-Risk Resolution

Regular tests, by construction, finds *B*-values almost surely under either *B*-sure measure at *resolution time*  $T(B) = \infty$ . Such a model-risk, even if uncertain (with indefinite prior), resolves:

$$\lim_{n \to \infty} l_n^{b\overline{b}} \left( D^n(\omega_B) \right) = (-1)^{\mathbf{1}_{\{B=\overline{b}\}}} \cdot \infty.$$
(5)

Non-resolving tests, whose defining measures are equivalent even on total data, must have *convergent* log-LRPs almost surely (Radon-Nikodym Theorem). Such situations are encountered naturally under the RNE approach to asset-pricing.

**Remark 5.** By (5) and (A.4-A.5), a log-LRP is resolving iff. its cumulative variance diverges. This in continuous time simply re-states the Novikov's Condition (Item-4, Appendix A).

#### **1.4** The Asset and Its Information Basis

For clarity, consider assets with no cashflows other than a *bullet-payoff*  $Y(\cdot) \in \mathbb{R}$  at horizon  $1 \ll T \leq \infty$ . Further, let time- and risk-free discount be exogenous and set to nil (in a suitable numéraire), and let payoffs/prices be log-valued and obey the small-increment condition.

- 1. Let there be a cumulative vector asset-data process  $\{\mathbf{D}^n\}$ , of state-space  $S^T$ , as characterised in Section 1.1, with natural filtration  $\{\mathbf{F}_n\}$  satisfying usual conditions, such that the bullet-payoff Y is measurable only to  $\mathbf{F}_T$  and is the only horizon data-point:  $\mathbf{D}^T(T) \equiv Y$ . Adapted to  $\{\mathbf{F}_n\}$  is a price process  $\{S_n\}$ , with  $S_T \equiv Y$  by definition.
- 2. With respect to binary risk *B* of interest, the asset has state-space  $S_B^T$  and law  $\pi_0^B \mathbf{Q}_B^{(T)}$ , as in (1), with '(*T*)' denoting 'restriction to' for  $T < \infty$ , in which case  $\mathbf{Q}_b^{(T)} \sim \mathbf{Q}_{\overline{b}}^{(T)}$ . Write the overall asset-process as  $(Y, \{S_n\}; (S_B^T, \{\mathbf{F}_n\}, \pi_0^B \mathbf{Q}_B^{(T)}))$ . Let law  $\pi_0^B \mathbf{Q}_B^{(T)}$  be such that it allows meaningful inference and is objectively true *up to equivalence*.
- 3. Let *B*-outcomes be such that one is always and almost surely economically better off:  $\forall m < T, \forall n < T, \text{ and } \forall \omega_B \in S_B^T$  almost surely,

$$sign[b\overline{b}] := sign[Y_n^{b-\overline{b}}](\omega_B) := sign[Y_n^b - Y_n^{\overline{b}}](\omega_B) = sign[Y_m^{b-\overline{b}}](\omega_B) \neq 0,$$
(6)

$$Y_n^B := \mathbf{E}_B[Y|\mathbf{F}_n] := \mathbf{E}[Y|B, \mathbf{F}_n],$$
(7)

where  $\mathbf{E}_B[\cdot|\cdot]$  denotes *B*-sure expectations. Call this the *economic consistency* of risk *B*; a simpler definition suffices under continuity:  $sign[Y_t^{b-\overline{b}}] \neq 0$ ,  $\forall t < T$ , almost surely.

4. Let *B*-sure pricing  $S_n^B$ ,  $\forall n < T$ , be known and given, and the  $\{\mathbf{F}_n\}$ -adapted *B*-impact process  $\{S_n^{b-\overline{b}}\} := \{S_n^b - S_n^{\overline{b}}\}$ , economically consistent:  $sign[S_n^{b-\overline{b}}] = sign[b\overline{b}]$ ,  $\forall n < T$ .

**Remark 6.** Consider assets based on the coin-toss of Remark 4. Asset-1:  $Y(B) \sim Bin(T, \alpha_B)$ ; Asset-2:  $Y(B) = h_n + [(Y(B) - h_n) \sim Bin(T - n, \alpha_B)]$  given heads-count  $h_n$ , n < T. Asset-1 realises payoff at T, where it is binary but for a static randomness obscuring B-value; coinflip data inform on its B-risk but not its B-sure risks. Asset-2 realises payoff one unit at a time (still paid only at T); coinflip data inform on its B-risk as well as its B-sure risks.

**Remark 7.** Discrete regular inference resolves B at  $T(B) = \infty$ , ensuring market completeness with respect to B-risk. In continuous time the same is possible for  $T(B) < \infty$  under regular inference (Item-1 to 3, Appendix A).

# 2 Canonical RNE Asset-Pricing under Model-Risk

### 2.1 The FTAP Baseline

Translated to our setting, FTAP states: a given asset-process  $(Y, \{S_n\}; (S_B^T, \{\mathbf{F}_n\}, \pi_0^B \mathbf{Q}_B^{(T)}))$  is viable iff. there is some equivalent measure  $\widehat{\pi_0^B \mathbf{Q}_B^{(T)}} \sim \pi_0^B \mathbf{Q}_B^{(T)}$  on  $S_B^T$ , called the RNE measure, such that  $S_n = \hat{\mathbf{E}}[Y|\mathbf{F}_n]$ ,  $\forall n < T$ , where  $\hat{\mathbf{E}}[\cdot|\cdot]$  denotes expectations under the RNE measure<sup>3</sup>. The RNE expectation may be expressed in two stages:

$$\hat{S}_n^B := \hat{\mathbf{E}}_B[Y|\mathbf{F}_n] := \hat{\mathbf{E}}[Y|B,\mathbf{F}_n], \tag{8}$$

$$S_n = \Sigma_B \hat{\pi}_n^B \hat{S}_n^B := \hat{\pi}_n^b \hat{S}_n^b + \hat{\pi}_n^{\overline{b}} \hat{S}_n^{\overline{b}}, \tag{9}$$

with  $\hat{\mathbf{E}}_{B}[\cdot|\cdot]$ , the *B*-conditional expectations under the RNE measure, and  $\Sigma_{B}(\cdot)(\cdot)$ , the taking of convex combinations, such as that under  $\{\mathbf{F}_{n}\}$ -adapted RNE beliefs  $\{\hat{\pi}_{n}^{B}\}$ , computed under Bayes' Rule (4) given  $\hat{\pi}_{0}^{B}$  and the RNE log-LRP  $\{\hat{l}_{n}^{b\overline{b}}\} := \{\log \frac{\hat{\mathbf{Q}}_{b}^{(T)}|_{n}}{\hat{\mathbf{Q}}_{t}^{(T)}|_{n}}\}$ .

Any pricing viable to a belief in the equivalence class  $[\pi_0^B \mathbf{Q}_B^{(T)}]$  is viable to any other in the class. There are far more viable processes than economically valid ones (e.g. any based on RNE measure of the form  $\tilde{\pi}_0^B \tilde{\mathbf{Q}}^{(T)} \sim \pi_0^B \mathbf{Q}_B^{(T)}$ ,  $T < \infty$ , cannot react to *B*-informative data). Our goal is to characterise RNE measures that do correspond to sensible economic theories.

Consider thus *risk-premium*, the gap between *ex-ante* price and expectation:  $\forall n < T$ ,

$$RP_n := Y_n - S_n := \Sigma_B \pi_n^B Y_n^B - S_n, \tag{10}$$

where  $\{\pi_n^B\}$  is the inference process about model-risk *B* based on law  $\pi_0^B \mathbf{Q}_B^{(T)}$ , the reference belief (of some representative agent). By inserting  $\pm \Sigma_B \hat{\pi}_n^B Y_n^B$ , we have,

$$RP_n = \Sigma_B \hat{\pi}_n^B R \hat{P}_n^B + B_{-} \widehat{RP}_n, \qquad (11)$$

$$\hat{RP}_n^B := Y_n^B - \hat{S}_n^B,\tag{12}$$

$$B_{-}\widehat{RP}_{n} := RP_{n} - \Sigma_{B}\hat{\pi}_{n}^{B}\widehat{RP}_{n}^{B} = (\pi_{n}^{b} - \hat{\pi}_{n}^{b})Y_{n}^{b-\overline{b}},$$
(13)

where  $\Sigma_B \hat{\pi}_n^B \hat{RP}_n^B$  stems from risks within *B*-sure models, and  $B_{-}\widehat{RP}_n$ , from model-risk *B*.

<sup>&</sup>lt;sup>3</sup>The original statement is about  $\{S_n\}$  being a martingale under the RNE measure; we have however  $S_T \equiv Y$ .

The standard deviation of  $B_{-}\widehat{RP}_{n}$  is  $|Y_{n}^{b-\overline{b}}|\sigma_{n}^{\pi}$ ,  $\sigma_{n}^{\pi} := (\pi_{n}^{b}\underline{\pi}_{n}^{b})^{\frac{1}{2}}$ , free from *B*-risk pricing choices. It allows a well-defined RNE price-of-*B*-risk associated with the RNE belief process  $\{\hat{\pi}_{n}^{B}\}$ :

$$k_n^{\hat{\pi}} := \frac{B_{-}\widehat{RP}_n}{|Y_n^{b-\overline{b}}|\sigma_n^{\pi}} \equiv sign[b\overline{b}] \frac{\pi_n^b - \hat{\pi}_n^b}{(\pi_n^b \pi_n^b)^{\frac{1}{2}}}.$$
(14)

### 2.2 The Economic Decomposition of Risk-Pricing under Model-Risk

Regardless of the asset-pricing scheme used, classical or otherwise, the resulting asset-price  $\{S_n\}$ , risk-premium  $\{RP_n\}$  and RNE formulation (8-14), admit also a universal economic decomposition, to be given as (18-21), provided the existence of 1) reference model-risk beliefs  $\{\pi_n^B\}$ ; 2) economically consistent *B*-sure pricing  $\{S_n^B\}$  by the same scheme under fixed *B*-values, with *B*-sure RNE measure  $\check{\mathbf{Q}}_B^{(T)} \sim \mathbf{Q}_B^{(T)}$  and *B*-sure risk-premia  $\{RP_n^B\}$ , so that:  $\forall n < T$ ,

$$S_n^B = \check{\mathbf{E}}_B[Y|\mathbf{F}_n],\tag{15}$$

$$RP_n^B = Y_n^B - S_n^B \ge 0, \text{ and}, \tag{16}$$

$$S_n^B = \lim_{\sigma_n^\pi \to 0} \hat{S}_n^B,\tag{17}$$

almost surely (under  $\pi_0^B \mathbf{Q}_B^{(T)}$ ) as  $\sigma_n^{\pi} \to 0$  for whatever reason (e.g. the data at *n* being made more and more informative, or a more and more extreme *a priori* belief  $\sigma^{\pi_0} \to 0$ ).

Given that the only additional input to asset-pricing under model-risk *B* is the reference model-risk belief<sup>4</sup> { $\pi_n^B$ }, and that viable prices { $S_n$ } are bounded by *B*-sure levels { $S_n^B$ }, we may define, at each n < T, some pricing coefficient  $A_n^B \in (0, 1)$  such that:

$$S_n = \Sigma_B A_n^B S_n^B = S_n^{\overline{b}} + A_n^b S_n^{b-\overline{b}},\tag{18}$$

$$RP_n := Y_n - S_n = \Sigma_B \pi_n^B RP_n^B + B_R P_n, \text{ with}$$
(19)

$$B\_RP_n := RP_n - \Sigma_B \pi_n^B RP_n^B = \Sigma_B \pi_n^B S_n^B - S_n = (\pi_n^b - A_n^b) S_n^{b-\overline{b}},$$
(20)

$$k_n^A = sign[b\bar{b}] \frac{\pi_n^b - A_n^b}{(\pi_n^b \pi_n^b)^{\frac{1}{2}}} \ge 0,$$
(21)

where the economic price-of-*B*-risk  $\{k_n^A\}$  must be free from explicit dependencies on *B*-sure pricing (15-16), the latter being decisions made in the absence of *B*-risk.

<sup>&</sup>lt;sup>4</sup>Economic risk-pricing amounts to recursive optimisation schemes, taking as inputs drivers of the expected preference-value chosen. Pricing with *vs* without model-risk has one extra input, the reference model-risk belief.

As such, once obtained, price-of-*B*-risk  $\{k_n^A\}$  may generate the coefficients  $\{A_n^B\}$  via (21) for asset-pricing under *B*-risk, given economically consistent but otherwise potentially arbitrary *B*-sure prices  $\{S'_n^B\} := \{Y_n^B - RP'_n^B\}$ , thus separating the pricing of model and non-model risk. This is attractive if for a useful range of risk-discounting the processes below are viable:

$$\{S'_n\} \equiv \{S^{(RP'|A)}_n\} := \{\Sigma_B A^B_n S'^B_n\} = \{S^{(0|A)}_n\} - \{\Sigma_B A^B_n RP'^B_n\}, \text{ with}$$
(22)

$$\{S_n^{(0|A)}\} := \{\Sigma_B A_n^B Y_n^B\} = \{Y_n^{\overline{b}}\} + \{A_n^b Y_n^{b-\overline{b}}\} = \{Y_n\} - \{k_n^A \sigma_n^{\pi} \cdot |Y_n^{b-\overline{b}}|\},$$
(23)

both being one way or another the sum of a martingale and a drift. All applied economic asset-pricing theories, at least for sufficiently small risk-discounting, already satisfy the above, since they are all continuous and regular with respect to perturbations near risk-neutrality.

**Remark 8.** In ambiguity-aversion/robust-control, the primary utility function (enforcing classical risk-aversion) can be dialled down continuously towards neutrality (linearity) while secondary utility or variational control continues to exert uncertainty aversion/control. In classical settings, including parameter-learning, where a single utility is to be optimised in expectation, the same can be produced by replacing the payoff variable with its up-to-date model-sure expectations subject to sufficiently small noise.

The real question of interest is then the range of viability for processes (22-23), and most relevant to us, if they have convenient RNE formulations. For this, we must characterise the economic price-of-*B*-risk  $\{k_n^A\}$  ((21)) more fully. Its origin suggests the following.

**Definition 1.** Asset-pricing under model-risk *B* and reference model-risk belief  $\{\pi_n^B\}$  is said to be *normal* if its price-of-model-risk  $\{k_n^A\}$  at  $\forall n < T$ : 1) is a *time-homogenous function* of  $\pi_n^B$  and input  $Z^n \subseteq \mathbf{D}^n$  to *B*-sure pricing (where any  $Z^n$ -dependence may be via  $\pi_n^B$ )<sup>5</sup> such that  $k_n^A$  is *continuous* in  $\pi_n^B$  and is *non-negative*; 2) satisfies  $\lim_{\sigma_n^{\pi}\to 0} k_n^A = 0$ ; 3) generates viable asset-pricing through (22-23) for an economically relevant range of risk-premium choices.

<sup>&</sup>lt;sup>5</sup>Pricing solution is measurable to the natural filtration of the pricing scheme's inputs, and so (by Proposition 4.9 of Breiman (1992)) a function of their levels to date (e.g. the toy-assets of Remark 6, where dependence on heads-count  $\{h_n\}$  is trivial if *B*-sure, and implicit, via  $\{\pi_n^B\}$ , if *B*-unsure). Any time-inhomogeneity ('same risk different price') stems from time-varying structural parameters: excluding it amounts to making our model-risk 'short-lived' relative to a potentially evolving background.

**Remark 9.** Property-1&2 are shared by most if not all existing model-risk pricing theories. Property-3 will be shown to hold in 'usual' situations. Regarding data, the standard is to set  $\{\mathbf{D}^n\} = \{Z^n\}$ , as if only inputs to model-sure pricing (e.g. null-data for Asset-1, or heads-count for Asset-2, of Remark 6) exist or matter; this, as will be seen, need not be the case.

### 2.3 Constrained RNE Formulations

#### 2.3.1 Implications of Property-1 of Normal Pricing Under Model-Risk

The following is key to if and how normal asset-pricing has tractable RNE formulations.

**Proposition 1.** For any asset-process  $(Y, \{S_n\}; (S_B^T, \{\mathbf{F}_n\}, \pi_0^B \mathbf{Q}_B^{(T)}))$  under model-risk *B*, its set of potential RNE measures whose price-of-model-risk  $\{k_n^{\hat{\pi}}\}$  ((14)) has property-1 is given by  $\mathcal{L}_S := \{\Pi_0^{(\cdot)} \mathbf{Q}_{(\cdot)}^{(T)} | \Pi_0^{(\cdot)} \in (0, 1)\}$ , which coincides with its set of model-uncertainty (Remark 2).

**Proof.** If its reference belief process  $\{\pi_n^b\}$  is regular and so resolving, it follows directly from Lemma 1 and Remark 23, Appendix B. If non-resolving, the non-negativity of risk-pricing is needed in addition, to reach the claim, as shown in Appendix C.

The above holds in continuous time, and can be verified via Ito's Lemma where applicable (Remark 22, Appendix B). The result is intuitive, as property-1 concerns the informational redundancy of pricing with respect to the belief on which it is based.

**Remark 10.** The assets of Remark 6 may serve as examples: any fixed RNE heads-probability  $\widehat{\alpha}_B \sim \alpha_B$  other than  $\alpha_B$  itself yields a price-of-B-risk that can be path-dependent or negative. Due to this, the RNE measure of Asset-2, despite its triviality, is basically unidentifiable.

**Remark 11.** Indeed the above implies that the RNE formulation of any price process with nontrivial pricing of non-model risk must violate property-1<sup>6</sup>: its RNE price-of-model-risk must be path-dependent, if not sign-inconsistent or time-inhomogeneous, under any reference modelrisk belief. This formalises Guidolin and Timmermann (2007)'s observation that parameterlearning makes RNE probabilities path-dependent and intractable.

<sup>&</sup>lt;sup>6</sup>Price process  $\{S_n\} = \{\Sigma_B A_n^B S_n^B\}$  (18) whose RNE formulation has property-1, that is,  $\{S_n\} = \{\Sigma_B \Pi_n^B Y_n^B\}$ , satisfies:  $\forall n < T$ ,  $\lim_{\sigma_n^\pi \to 0} S_n = Y_n^B$  since  $\lim_{\sigma_n^\pi \to 0} \sigma_n^\Pi = 0$ , but  $\lim_{\sigma_n^\pi \to 0} S_n = S_n^B = Y_n^B - RP_n^B$  given (16-17); thus  $\{RP_n^B\} = 0$ .

#### 2.3.2 Canonical Asset-Pricing under Model-Risk

Proposition 1 seemingly ends the prospect of having a workable RNE formulation of economic asset-pricing under model-risk (Remark 11). Recall however Definition 1 of normal pricing. By (22-23) it suffices to work with the respective RNE measure of model-risk only pricing and of model-sure pricing separately. With the latter given, we focus on the former.

One the one hand, it is undoubtedly desirable to have model-risk only processes  $\{S_n^{(0|A)}\}\$  whose RNE measures are (informationally redundant to) members of the set  $\mathcal{L}_S$  of modeluncertainty, so that its RNE formulation is tractable. On the other, theories that produce normal asset-pricing,  $\mathcal{L}_S$ -redundant or not, already have convenient forms ((22-23)) under the separately viable pricing of model and non-model risks; the (in)tractability of their RNE formulations seems irrelevant. As it turns out, shortly, under practically relevant conditions, the desirable feature of  $\mathcal{L}_S$ -redundancy is in fact necessary, for viability.

**Definition 2.** Normal asset-pricing  $\{S_n^{(RP|A)}\}$  (22-23) under model-risk *B* is said to be *canonical* if its model-risk only pricing  $\{S_n^{(0|A)}\} := \{\Sigma_B A_n^B Y_n^B\}$  has RNE measure of the form  $\Pi_0^B \mathbf{Q}_B^{(T)} \in \mathcal{L}_S$ , whose RNE model-risk beliefs  $\{\Pi_n^b\} = \{A_n^B\}$  determine asset-pricing; its RNE and economic price-of-model-risk, namely (14) and (21), coincide:  $\{k_n^\Pi\} = \{k_n^A\}$ .

Canonical pricing, with respect to the given set  $\mathcal{L}_S$  of model-uncertainty, allows the pricing of model-risk and non-model risk to have separate RNE formulations that are each by itself easy to identify and apply. However, are canonical prices, as the combination of separately viable prices, viable? Note that its overall RNE measure, even when guaranteed to exist under viability, remains elusive in general (Remark 11).

#### 2.3.3 The Base Case of Orthogonal Data Streams

The simplest yet useful situation is when model and non-model risks are intrinsically separate in the information structure itself, so that the viability of canonical pricing is trivial.

**Remark 12.** Traders often find themselves in a market that has become for a time unsettled by some model-risk that has flared up and whose economics, detection and resolution dominate, while non-model risks remain, routine, irreducible, and independently evolving.

Consider the case of *B*-sure risks that are independent to *B*-informative data. That is, data  $\{\mathbf{D}^n\}$ , with  $\mathbf{D}^T(T) \equiv Y$  regardless (Item-1, Section 1.4), split into two streams  $\{(D^n, Z^n)\}$  up to time T-1 such that  $\{D^n\}$  informs only on *B*-value, and  $\{Z^n\}$ , only on a *B*-independent part of the asset payoff. As such, dataflow  $\{D^n\}$  and its law  $Q_B^{T-1}$  are surplus to *B*-sure pricing. It is useful to make this important feature of the governing law  $\pi_0^B \mathbf{Q}_B^{(T)}$  explicit:

$$\pi_0^B \mathbf{Q}_B^{(T)} \equiv \pi_0^B Q_B^{(T-1)}(D^{T-1} \in \cdot) \times W^{(T-1)}(Z^{T-1} \in \cdot) W_B^Y(Y \in \cdot | Z^{T-1} \in \cdot), \text{ with}$$
(24)

$$Q_B^{(T-1)}(D^{T-1} \in \cdot) := \mathbf{Q}_B^{(T)}|_{T-1}(D^{T-1} \in \cdot),$$
(25)

$$W^{(T-1)}(Z^{T-1} \in \cdot) := \mathbf{Q}_{B}^{(T)}|_{T-1}(Z^{T-1} \in \cdot) \text{ (so no } B\text{-dependence)},$$
(26)

$$W_{B}^{Y}(Y \in \cdot) := \mathbf{Q}_{B}^{(T)}(Y \in \cdot) = \sum_{\delta Z^{T-1}} W_{B}^{Y}(Y \in \cdot | \delta Z^{T-1}) W^{(T-1)}(\delta Z^{T-1}).$$
(27)

**Remark 13.** For the coin-toss based Asset-1 of Remark 6, heads-count record  $\{h_n\}$  informs only on model-risk, unlike for Asset-2, where it affects model and non-model risks alike.

Under the above conditional independence of model and non-model risks, economic assetpricing has the following obvious canonical RNE measure and formulation:

$$\Pi_{0}^{B} Q_{B}^{(T-1)}(D^{T-1} \in \cdot) \times \check{W}^{(T-1)}(Z^{T-1} \in \cdot) \check{W}_{B}^{Y}(Y \in \cdot | Z^{T-1} \in \cdot),$$
(28)

$$\{S_n\} = \{S_n^{(RP|\Pi)}\} = \{\Sigma_B \Pi_n^B S_n^B\},\tag{29}$$

where  $\check{W}^{(T-1)} \sim W^{(T-1)}$  and  $\check{W}_B^Y \sim W_B^Y$  provide *B*-sure pricing  $\{S_n^B\}$ , free from *B*-risk pricing, and RNE belief  $\{\Pi_n^B\}$ , *B*-risk pricing, free from *B*-sure pricing, with initial level  $\Pi_0^B \sim \pi_0^B$  and driven by the same log-LRP  $\{l_n^{b\overline{b}}(\mathbf{D}^n)\} := \{\log \frac{Q_b^{(T-1)}|_n(D^n)}{Q_{\overline{b}}^{(T-1)}|_n(D^n)}\}$  as the reference model-risk belief  $\{\pi_n^B\}$ .

#### 2.3.4 The General Case of 'Usual' Assets

This category includes most if not all applied asset processes. They are Ito processes (standard or discretised) of the underlying data and/or the log-LRPs, where the data structure is non-orthogonal (e.g. containing interim payouts, which impact both model and non-model risks). We shall proceed from first principles, so as to expose the role of model-risk clearly.

**Remark 14.** Usual model-sure asset-pricing is quite simple, a deterministic drift discounting a static noise. Without interim payout news, such model-sure pricing is noiseless (constant), so asset valuation becomes a simple orthogonal case, driven entirely by model-risk.

Under model-risk and standard conditions, usual asset-prices exhibit two distinct types of drifts, one from excess ('unpriced') realised values, one from risk-inference based on said excess. It will be seen that the Ito process dynamic is such that under any equivalent measure the expected sum of the two cannot vanish unless they each vanish separately, which occurs only under canonical pricing.

**Definition 3.** An usual-case asset-process  $(Y, \{S_n\}; (S_B^T, \{\mathbf{F}_n\}, \pi_0^B \mathbf{Q}_B^{(T)}))$  is one whose dataflow  $\{\mathbf{D}^n\} = \{(D^n, Z^n)\}$  has a record  $\{Z^n\}$  of realised incremental change, if any, to bullet-payoff Y such that  $\{Z^n\}$  has independent small increments under its *B*-sure law  $\mathbf{Q}_B^{(T)}$  and its RNE law  $\check{\mathbf{Q}}_B^{(T)} \sim \mathbf{Q}_B^{(T)}$  for *B*-sure pricing  $\{S_n^B\}$ . Cumulations  $z_n := \sum_{j=0}^n Z^n(j)$ , with  $Z^n(0) \equiv 0 =: z_0$  and  $z_T \equiv Y$ , form the firmed-up component  $\{z_n\}$  of the ('cum-div') asset value. The *B*-sure payoff expectation  $Y_j^B$  and *B*-sure price  $S_j^B$  at any j = 0, 1, 2, ..., T - 1 are of the form:

$$Y_j^B = z_j + \mathbf{E}_B[Y - z_j | \mathbf{F}_j] = z_j + \mathbf{E}_B[Y - z_j] = z_j + y_B(T - j, j),$$
(30)

$$S_j^B = z_j + \check{\mathbf{E}}_B[Y - z_j | \mathbf{F}_j] = z_j + \check{y}_B(T - j, j),$$
(31)

$$RP_{j}^{B} = y_{B}(T - j, j) - \check{y}_{B}(T - j, j) = : RP^{B}(j) \ge 0,$$
(32)

where  $y_B(T-j,j)$  is deterministic and satisfies,  $\{Y_j^B\}$  being a martingale, for any i = 1, ..., T-j,  $y_B(i,j) = y_B(T-j,j) - y_B(T-j-i,j+i) = \mathbf{E}_B[\Delta_{(i,j)}z]$ , with  $\Delta_{(i,j)}(\cdot) := (\cdot)_{j+i} - (\cdot)_j$ , and likewise for  $\check{y}_B(i,j)$  and  $\check{\mathbf{E}}_B[\Delta_{(i,j)}z]$ . Absolute *B*-impact  $|Y_j^{b-\overline{b}}| = y_+(T-j,j) - y_-(T-j,j) = :Y^{\Delta}(j) > 0$ , with the economic significance of *B*-outcomes labelled,  $B \in \mathcal{B} = \{+, -\}$ , is also deterministic.

Expected payoff  $\{Y_j^-\}$  and price process  $\{S_j^-\}$  may be written in terms of firmed-up values  $\{z_j^-\} := \{z_j(B = -)\}$ , whose martingale measure  $W_-^{(T)}$  is Wiener and generated by i.i.d standard Normals  $\{\epsilon_n^Z\}$  and some spot-volatility process  $\{\sigma_j^Z\}$ : so  $\Delta z_{j+1}^- = \sigma_j^Z \epsilon_{j+1}^Z$ ,  $0 \le j < T$ , and,

$$\Delta Y_{j+1}^{-}(B) = \mathbf{1}_{\{B=+\}} \cdot r(j) + \Delta z_{j+1}^{-}, \tag{33}$$

$$\Delta S_{j+1}^{-}(B) = \mathbf{1}_{\{B=+\}} \cdot r(j) + R^{-}(j) + \Delta z_{j+1}^{-},$$
(34)

where *B*-sure drift  $R^B(j) := -\Delta_{(1,j)}RP^B \equiv \mathbf{E}_B[\Delta_{(1,j)}z] - \check{\mathbf{E}}_B[\Delta_{(1,j)}z] \ge 0$  stems from *B*-sure pricing, and *model-drift*  $r(j) := -\Delta_{(1,j)}Y^{\Delta} \equiv \mathbf{E}_{+}[\Delta_{(1,j)}z] - \mathbf{E}_{-}[\Delta_{(1,j)}z] > 0$ , from *B*-impact. Our scenario is essentially one of standard sequential testing of Wiener processes differing by a drift (e.g. Peskir and Shirayev (2006) or Shiryaev (1967)), which reads as (33) in discrete time. The governing law of usual-case assets, in the convention of (24), now with Wiener measure  $W_B^{(T)}$  for the paths  $\{Z^n\}$  to ultimate payoff Y, is:

$$\pi_0^B Q_B^{(T-1)}(D^{T-1} \in \cdot) \times W_B^{(T)}(Z^T \in \cdot).$$
(35)

Data  $\{D^n\}$  are redundant to *B*-sure pricing:  $\mathbf{Q}_B^{(T)}(Y \in \cdot) \equiv W_B^{(T)}(Y \in \cdot) \sim \check{W}_B^{(T)}(Y \in \cdot) \equiv \check{\mathbf{Q}}_B^{(T)}(Y \in \cdot)$ , as in the orthogonal case. Data  $\{Z^n\}$  however impact model and non-model risks alike.

**Proposition 2.** For usual-case assets under model-risk *B*, normal pricing that is 2-differentiable with respect to the reference model-risk belief process  $\{\pi_i^B\}$  must be canonical to be viable:

$$S_j = S_j^{(RP|\Pi)} = \Sigma_B \Pi_j^B S_j^B = S_j^{(0|\Pi)} - \Sigma_B R P^B(j) \Pi_j^B, \ j = 0, 1, 2, ..., T - 1,$$
(36)

where model-risk only pricing  $\{S_{j}^{(0|\Pi)}\} = \{\Sigma_{B}\Pi_{j}^{B}Y_{j}^{B}\}$  has RNE measure  $\Pi_{0}^{B}Q_{B}^{(T-1)}W_{B}^{(T)}$  and is given by the associated RNE model-risk inference process  $\{\Pi_{j}^{B}\}$ .

**Proof.** See continuous-time proof in Appendix D, applicable here under small increments. Briefly, for any viable  $\{S_j^{(0|A)}\} = \{\Sigma_B A_j^B Y_j^B\} = \{Y_j^-\} + \{A_j^+ Y_j^{\Delta}\}$  ((23)), drift  $\{\Delta Y_{j+1}^- - r(j)A_j^+\}$  must offset drift  $\{\Delta A_{j+1}^+ Y_j^{\Delta}\}$  in expectation under some RNE measure, possible *iff.* it has canonical form  $\Pi_0^B Q_B^{(T-1)} W_B^{(T)}$ , under which the two drifts separately vanish in expectation, thanks to  $\{A_j^+\}$  being a 2-differentiable function of model-risk inference  $\{\pi_j^+\}$  that is based essentially on  $\{\Delta Y_{j+1}^-(B)\}$ . The viability of (36), as a martingale plus a well-behaved drift, follows<sup>7</sup>.

### 2.4 Properties of Canonical Model-Risk Pricing

#### 2.4.1 The 1-Parameter Price-of-Model-Risk

**Corollary 1.** Model-risk premia  $\{B\_RP_n\}$  ((20)) under canonical pricing (Definition 2),

$$B\_RP_n = (\pi_n^b - \Pi_n^b)S_n^{b-\overline{b}}, \ \forall n < T,$$
(37)

imply the following economic price-of-model-risk  $k_n^{\Pi}$  ((21)): with  $\sigma_n^{\Pi} := (\Pi_n^b \underline{\Pi}_n^b)^{\frac{1}{2}}$ ,

$$k_n^{\Pi} = (K^{\frac{1}{2}} - K^{-\frac{1}{2}})\sigma_n^{\Pi}, \ \forall n < T,$$
(38)

where  $K := \left(\frac{O_f[\pi_0^b]}{O_f[\Pi_0^b]}\right)^{sign[b\overline{b}]} = \left(\frac{O_f[\pi_n^b]}{O_f[\Pi_n^b]}\right)^{sign[b\overline{b}]}$  is conserved by the risk-inference processes ((4)).

<sup>&</sup>lt;sup>7</sup>Note its obvious viability if  $\{RP^B(j)\}$  is *B*-indifferent and pseudo-constant, as in many practical tasks.

**Remark 15.** Price-of-model-risk  $k_n^{\Pi}$  is positive iff. K > 1. It takes value  $k_{\frac{1}{2}} := (K-1)/(K+1)$  at peak B-risk ( $\sigma_n^{\pi} = \frac{1}{2}$ ), where the asset-price offers a risk-premium of  $\frac{1}{2}k_{\frac{1}{2}}|S_n^{b-\overline{b}}|$  and a gain-loss ratio of  $(1 + k_{\frac{1}{2}})/(1 - k_{\frac{1}{2}}) \equiv K$  exactly <sup>8</sup>.

**Remark 16.** To buyers (sellers), the bigger (smaller) K is, the better. In theory and practice, condition  $K \in (1,2)$  seems sensible for competitive markets, with  $K-1 \gg 1$  in general.

#### 2.4.2 Connection with Familiar Price Dynamics

To avoid clutter, consider henceforth usual-case assets with *B*-indifferent *B*-sure risk-premia, denoted  $\check{rp}(j) > 0$ ,  $0 \le j < T$ , and so  $Y^{\Delta}(j) = S^{\Delta}(j)$ , with *B*-sure drift  $\check{R}(j) := \check{rp}(j) - \check{rp}(j+1) > 0$ . Under canonical pricing (36), we then have: for any n < T and  $0 \le j < T$ ,

$$S_n = S_n^{(r\check{p}|\Pi)} = S_n^{(0|\Pi)} - r\check{p}(n) = Y_n^- - r\check{p}(n) + S^{\Delta}(n)\Pi_n^+,$$
(39)

$$\Delta S_{j+1}(B) = \Delta Y_{j+1}^{-}(B) + \check{R}(j) + S^{\Delta}(j) \Delta \Pi_{j+1}^{+}(B) - r(j) \Pi_{j}^{+}(B).$$
(40)

Given (33-34) and generic inference dynamics (A.6), we have  $\{\Delta \Pi_{j+1}^+\}$  as below, with two sources of noise, one from  $\{Z^n\}$ , given by  $\{\sigma_j^{lZ} \epsilon_{j+1}^Z\}$ , with  $\sigma_j^{lZ} := r(j)/\sigma_j^Z$  (Peskir and Shirayev (2006)), one from *independent B*-informative data  $\{D^n\}$ , modelled likewise, given by  $\{\sigma_j^{lD} \epsilon_{j+1}^D\}$ , which can be absorbed via  $\{\sigma_j^l \epsilon_{j+1}'\} = \{\sigma_j^{lZ} \epsilon_{j+1}^Z + \sigma_j^{lD} \epsilon_{j+1}^D\}$ , with  $(\sigma_j^l)^2 = (\sigma_j^{lZ})^2 + (\sigma_j^{lD})^2$ :

$$\Delta \Pi_{j+1}^+(B) = \mu_j^{\Pi,B} + \sigma_j^{\Pi,l} \cdot \epsilon'_{j+1}, \qquad (41)$$

$$\mu_j^{\Pi,B} := \sigma_j^{\Pi,l} \sigma_j^l \Big( \mathbf{1}_{\{B=+\}} - \Pi_j^+(B) \Big), \tag{42}$$

$$\sigma_j^{\Pi,l} := (\sigma_j^{\Pi})^2 \sigma_j^l. \tag{43}$$

The above reduces to the standard case of Peskir and Shirayev (2006) under trivial  $\{D^n\}$ . It has a drift by design relative to reference belief  $\{\pi_i^+\}$  (same dynamics differing initial level):

$$\mu_j^{\Pi,\pi} := \Sigma_B \pi_j^B \mu_j^{\Pi,B} = \sigma_j^{\Pi,l} \sigma_j^l \cdot (\pi_j^+ - \Pi_j^+) = \sigma_j^{\Pi,l} \sigma_j^l \cdot k_j^\Pi \sigma_j^\pi \ge 0.$$
(44)

Note  $\mu_j^{\Pi,\Pi} \equiv 0 \equiv \mu_j^{\pi,\pi}$ , making explicit the martingale property of inference and pricing. Further, as its volatility  $\sigma_j^{\Pi,l}$  (43) drives price volatility via  $\sigma_j^{\Pi,l}S^{\Delta}(j)$  ((40)), the price-of-*B*-risk (38) peaks exactly when model-risk generated price-volatility does (*ceteris paribus*).

<sup>&</sup>lt;sup>8</sup>Gain-to-loss with respect to *B*-outcomes is always  $O_f[\Pi_n^b]^{-sign[b\overline{b}]}$ , and  $O_f[\pi_n^b] = 1$  at peak *B*-risk.

Pulling it together, the full asset-price dynamic under model-risk *B* reads as follows:

$$\Delta S_{j+1}(B) = \left[\check{R}(j) + \sigma_j^Z \epsilon_{j+1}^Z\right] \tag{45}$$

$$+r(j)(\mathbf{1}_{\{B=+\}} - \Pi_{j}^{+}(B))$$
(46)

$$+S^{\Delta}(j)(\sigma_{j}^{\Pi})^{2} \left[ (\sigma_{j}^{l})^{2} \left( \mathbf{1}_{\{B=+\}} - \Pi_{j}^{+}(B) \right) + \sigma_{j}^{l} \epsilon_{j+1}^{\prime} \right].$$
(47)

It is a  $(\Pi_0^B Q_B^{(T)} W_B^{(T)})$ -martingale plus drift { $\check{R}(j)$ }.

**Remark 17.** Practical situations are often characterised by  $\check{R}(j) \ll r(j) \ll S^{\Delta}(j)$ : the B-sure dynamic (45) dominated by model-drift (46), dominated in turn by model-inference (47). Consequently, dispersion among assets tends to be driven by model-risk and model-risk inference. Moreover, it is often the case  $F_j^{D/Z} := (\sigma_j^{ID})^2/(\sigma_j^{IZ})^2 \gg 1$ , so  $(\sigma_j^I)^2 = (\sigma_j^{IZ})^2(1 + F_j^{D/Z}) \approx (\sigma_j^{ID})^2$ , that is, asset dynamics mostly reflect data other than those on tangible (firmed-up) payouts.

If averaged with respect to model-risk, given reference model-risk belief  $\{\pi_n^+\}$ , dominant dynamic (47) takes on the following classical form:

$$\sigma_j \left( \frac{\mu_j}{\sigma_j} + \epsilon'_{j+1} \right), \tag{48}$$

with volatility  $\sigma_j := \sigma_j^{\Pi,l} S^{\Delta}(j)$ , drift  $\mu_j := \mu_j^{\Pi,\pi} S^{\Delta}(j)$ , and price-of-diffusion-risk  $\mu_j / \sigma_j$  (by (38)):

$$\frac{\mu_j}{\sigma_j} = (K^{\frac{1}{2}} - K^{-\frac{1}{2}})\sigma_j^{\Pi}\sigma_j^{\pi}\sigma_j^l = \frac{K^{\frac{1}{2}} - K^{-\frac{1}{2}}}{S^{\Delta}(j)} \left(\frac{\sigma_j^{\pi}}{\sigma_j^{\Pi}}\right)\sigma_j.$$
(49)

Expansion in (K-1) (see Remark 16) makes the classical relationship more explicit:

$$\frac{\mu_j}{\sigma_j} \approx \frac{K-1}{S^{\Delta}(j)} \sigma_j \text{ and } \mu_j \approx \frac{K-1}{S^{\Delta}(j)} \sigma_j^2.$$
(50)

**Remark 18.** The proportionality factor characterises ex-ante pricing through an intuitive and direct metric (Remark 15). How its level comes about is a matter of economic theory (e.g. risk-aversion). Regardless, our derivation links it firmly to ex-ante beliefs, making the above relevant to bias studies and measurements under model-uncertainty.

# 3 Bias and Risk-Pricing Measurement via Price Anomalies

### 3.1 The Joint-Hypothesis Issue

Consider the asset of section 2.4.2. For focus, let its *B*-sure reference beliefs be not only free of model-uncertainty but also of error, at least enough for its effects on any *B*-sure *ex-post* drift to be minor. Then the asset's *ex-post* drift under model-risk,  $\{rp_n\} := \{\Sigma_B \mathbf{p}_n^B Y_n^B\} - \{S_n\}$ , given objective conditional probabilities  $\{\mathbf{p}_n^B\}$  of *B*-outcomes, all adapted to  $\{\mathbf{F}_n\}$ , satisfies:

$$rp_n - \check{rp}(n) = B_RP_n + (\mathbf{p}_n^b - \pi_n^b)S^{b-b}(n), \ n < T.$$

$$(51)$$

The LHS collects the known or directly observable terms. For the RHS terms, no estimate of one can be made without the other; conclusions about risk-pricing,  $\{B\_RP_n\}$ , and bias,  $\{\mathbf{p}_n^b\}$ - $\{\pi_n^b\}$ , are entangled. The issue is acute for our model-risk: any observed process corresponds to one realised *B*-outcome, that is, its *ex-post* patterns reflect not (51) but one run of the dynamic as if  $\mathbf{p}_n^b \equiv 1$  or 0, so that many 'like' incidences are needed for estimates. Yet, given 'one-off' and often heterogeneous sources of model-uncertainties, how can this be done?

### 3.2 Assets Facing Potential Model-Change

When model-sure, usual-case asset is a simple drift with a static noise. Upon some trigger, it may face an objective chance  $\mathbf{p}_0^{(\cdot)}$  of entering a new state (e.g. from  $\{B = b\}$  to  $\{B = \overline{b}\}$ ). Denote any new state by '1', any status quo, '**0**', and status quo model-sure pricing,  $\{S_n^{\mathbf{0}}\}$ .

Change triggers may or may not follow a known law (e.g. Poisson). Our interest lies in what ensues after a triggering event. Such an approach amounts to treating model-risk as a compound process and ignoring the part governing how/when model-risk arises (considering it known, valued and reflected in model-sure prices). Further, the average time between one model-crisis and next, say  $\lambda^{-1}$ , is presumed long enough for our one-off methodology to apply. Further, set  $n \ll \lambda^{-1}$  and  $n \ll T$  from now on.

With the economic direction sign[10] of potential change explicit, ignoring time-dependence of model-risk impact  $S^{\Delta}(n)$  given  $n \ll T$  and  $r(n) \ll S^{\Delta}(n)$ , asset-pricing ((39)) becomes:

$$S_n = S_n^{\mathbf{0}} + sign[\mathbf{10}]S^{\Delta} \cdot \Pi_n^1, \ n \ll T.$$
(52)

### 3.3 The Representation of Status Quo Bias

Given canonical pricing (36), with reference and RNE belief processes,  $\{\pi_n^1\} \sim \{\Pi_n^1\}$  respectively, of *ex-ante* risk-pricing parameter  $K := (\frac{O_f[\pi_0^1]}{O_f[\Pi_0^1]})^{sign[10]}, K-1 \gg 1$ , let the market for our usual-case assets be in addition competitive in the sense of Remark 15 so that  $K \in (1,2)$ .

The objective conditional probability process  $\{\mathbf{p}_n^1\}$  governing change-risk is determined by the objective but unknown unconditional law  $\mathbf{p}_0^1$  of model-risk. Its relationship against the RNE  $\{\Pi_n^1\}$  and reference belief process  $\{\pi_n^1\}$  can be characterised through the following:

$$\rho K^{sign[10]} \equiv \frac{O_f[\mathbf{p}_0^1]}{O_f[\Pi_0^1]},\tag{53}$$

$$\rho := \frac{O_f[\mathbf{p}_0^1]}{O_f[\pi_0^1]}; \tag{54}$$

for instance, if a change-risk is unpriced, then K = 1; or if it is classical, with its law  $\mathbf{p}_0^1$  known and so without model-uncertainty, then  $\rho = 1$ .

Parameter  $\rho$  is by definition not part of any economic risk-discounting. The joint-hypothesis issue takes a concrete form here: what observable prices reflect is the product (53); to split it into 'intention' *K* and 'mistake'  $\rho$  seems to require external criteria. It will be shown that this need not be so. Indeed, a high apparent bias under model-uncertainty may not be irrational either (Discussion). The case of interest is when change is rare,  $\mathbf{p}_0^1 < \frac{1}{2}$ , but priced as even *rarer*, such that (53-54) are both sizeable ( $\rho \gg 1$ ). This 'justified strong status quo' provides a clear baseline against which to assess change. 'Unjustified strong status quo' ( $\mathbf{p}_0^1 > \frac{1}{2}$ ) offers easy gains to 'bets on change' and so cannot persist.

### 3.4 Unconditional Model-Risk Symmetry, Dominance and Uniformity

Consider now a market of a large number of usual-assets, each subject to some change-risk (e.g. new CEO, tort, war, recession) as characterised. Let these risks command economic pricing (Remark 1) in this market, presumably due to their ability to affect relevant aggregate factors (e.g. market value/volatility/dispersion<sup>9</sup>).

<sup>&</sup>lt;sup>9</sup>Dispersion is particularly intriguing in our context. As a priced factor it has been linked to market uncertainty, the business cycle and 'structural shifts' (e.g. Demirer and Jategaonkar (2013), Kolari et al. (2021)).

For clarity, let the unconditional *all-cause* probability of positive/negative economic change be *even*: at any time half of all *potential* changes (if any) in the market are positive/negative; any particular cause (e.g. war) may still be economically one-sided. Unconditional unevenness is addressed in footnote-12 and Remark 27. Let 'pricing intention' K ((53)) and 'apparent bias'  $\rho$  ((54)) be indifferent to the economic nature and direction of potential change.

Further, let parameter K,  $\rho$  and change-impacts  $S^{\Delta}$  be uniform across the market. Such uniformity amounts in practice to requiring asset dispersions to be driven by differences in risk-inference progression, rather than anything else (Remark 17). In the same vein, let all risk-inference be based on i.i.d data, that is, have log-LRPs of constant and uniform volatility. Note that we still treat each individual change-outcome as random and independent; while this may be a stretch for model-risk triggers such as war, it is a sensible start.

### 3.5 Conditional Cross-Sectional Trading

Pair-trading sorts assets into cohorts by cross-sectional statistics to build long *vs* short positions. It amounts in our setup to conditioning by *B*-inference metrics, the driver of dispersion. Consider events  $\{\Pi_n^1 = v\}$ ,  $v \in (0, 1)$ ,  $n \ll T$ . By Bayes' Rule (4) and definition (53), the  $\{\Pi_n^1 = v\}$ -conditioned mean-excess  $rp(\pm, v) := \pm (\mathbf{p}_n^1(v) - v)S^{\Delta}$  to be realised, with  $sign[1\mathbf{0}]$  explicit, reads:

$$rp(\pm,v) = \pm (\sigma^{v})^{2} \frac{1 - (\rho K^{\pm 1})^{-1}}{v + \underline{v}(\rho K^{\pm 1})^{-1}} S^{\Delta},$$
(55)

where  $(\sigma^v)^2 := v\underline{v}$ , making price-volatility the driver of excess ((43) and (48)). Note that the above is invariant under label-switching  $1 \leftrightarrow \mathbf{0}$  (i.e.  $v \leftrightarrow \underline{v}$ ,  $+ \leftrightarrow -$  and  $\rho \leftrightarrow \rho^{-1}$ ).

**Remark 19.** With no uncertainty,  $\rho = 1$ , the above is the ex-ante risk-premium when  $\{\Pi_n^1 = v\}$  ((38)): in classical markets, all the 'strategising' merely earns what the market deems fair.

Despite excess (55) being driven by price-volatility, conditioning by  $\{\Pi_n^1 = v\}$ ,  $v \in (0, 1)$ , mainly amounts to conditioning by *momentum* (past performance):  $\{\Pi_n^1 = v\}$  means an excess-to-date of  $\pm (v - \Pi_0^1)S^{\Delta}$  due to  $\{\Pi_n^1\}$  going from  $\Pi_0^1 \ll \frac{1}{2}$  to v ((52)). Sorting assets by past performance to buy/sell winners/losers exploits this excess. Under strong status quo, price-implied modeluncertainty ( $\propto (\sigma^v)^2$ ) is a priori low. It may rise and then fall with dataflow. The window of opportunity for pair-trading is given by (E.8), Appendix E.2. Drifts are hard to measure (e.g. Merton (1980)). Volatility trading is a good practical alternative. Volatility events, by (40-43), take the form  $\{\Pi_n^1 = v\} \bigcup \{\Pi_n^1 = v\}$ ,  $v \in (0, \frac{1}{2}]$ , and the  $\{\sigma_n^{\Pi} = vv\}$ -conditioned *ex-post* mean-excess  $rp_n^{\sigma}(v)$  averages over the sign[10] of any potential change and over the  $\{\Pi_n^1 = v\}$ - and  $\{\Pi_n^1 = v\}$ -events in the volatility cohort:

$$rp_n^{\sigma}(v) := \frac{\sum_{\pm} \mathbb{P}_n(\pm, v) rp(\pm, v) + \sum_{\pm} \mathbb{P}_n(\pm, \underline{v}) rp(\pm, \underline{v})}{\mathbb{P}_n(v) + \mathbb{P}_n(\underline{v})},$$
(56)

where  $\mathbb{P}_n(\cdot) := \sum_{\pm} \mathbb{P}_n(\pm, \cdot)$ , with  $\mathbb{P}_n(\pm, \cdot)$  being the joint-probability of  $\{sign[1\mathbf{0}] = \pm\}$  and  $\{\Pi_n^1 = \cdot\}$ .

The relevant likelihoods, or more to the point, their ratios, can be determined by the underlying log-LRP dynamics, whose cumulative cross-sectional distributions are Normal, making closed expressions possible (Appendix E.3). As a by-product, the likelihood-ratio functions predict an association of volatility with 'negative momentum' (Remark 26 of Appendix E.3), a well-documented empirical phenomenon (e.g. Ang et al. (2006) and Wang and Xu (2015)).

Both sets of conditional risk-reward curves, of momentum (55) and of volatility (56), are concave as a function of  $v \in (0, 1)$ , vanishing whenever  $v\underline{v} \rightarrow 0$ , with a unique positive maximum.

#### 3.5.1 Momentum Effect and Status Quo Bias

Conditional excess (55) exhibits Momentum, a key price-anomaly (Jegadeesh and Titman (1993)): if  $\rho K^{\pm 1} \gg 1$ , excess-to-date  $(v - \Pi_0^1)S^{\Delta}$ , by RNE beliefs  $\{\Pi_n^1\}$  rising from  $\Pi_0^1 \ll \frac{1}{2}$  to  $v > \Pi_0^1$ , persists on average in the same direction. The effect applies to  $\rho K^{\pm 1} \ll 1$  also: past excess due to RNE beliefs  $\{\Pi_n^1\}$  falling from  $\Pi_0^1 \approx 1$  to  $v < \Pi_0^1$  means an average future excess of the same sign; indeed, label-switching here defines a new parameter  $\rho^{-1} > 1$ .

**Remark 20.** Momentum thus vanishes only if  $\rho \approx 1$ , that is, if there is little model-uncertainty. The effect grows with  $\rho$ , which by definition (54) is a bias against change.

From (55), momentum trading has at  $v_{max}^{\pm mo}$  its best realisable excess  $rp_{max}^{\pm mo}$ :

$$v_{max}^{\pm mo} := \frac{1}{(\rho K^{\pm 1})^{\frac{1}{2}} + 1}, \ r p_{max}^{\pm mo} := \pm \frac{(\rho K^{\pm})^{\frac{1}{2}} - 1}{(\rho K^{\pm})^{\frac{1}{2}} + 1} S^{\Delta};$$
(57)

peak-profitability is then  $\frac{1}{2}(rp_{max}^{+mo}-rp_{max}^{-mo})$ , by pairing cohorts of conditioning-momentum  $v_{max}^{\pm mo}$ . As a function of bias  $\rho$ , risk-reward curve (55) and its peak (57) imply rising rewards from rising momentum up to a point, beyond which profitability falls, as seen in Ang et al. (2006).

#### 3.5.2 Low-Risk Effect and Status Quo Bias

Low-Risk Effect (e.g. Ang et al. (2006)) turns the classical dictum 'high risk high reward' on its head. Momentum risk-reward (55) already hints at it: peak-reward (57) is in low-volatility regions under sizeable bias  $\rho$ . The effect is clearer under volatility-conditioning (56), whose peak-location and -size can be found by similar, standard, methods (Appendix E).

The solution at  $\rho = 1$  (no bias) and leading-order solutions at  $\rho \gg 1$  (high bias) are revealing and may be given by the same expression; the peak-location  $v_{max}^{\sigma}$  and -size  $rp_{max}^{\sigma}$  are:

$$v_{max}^{\sigma} := \frac{1}{\rho+1}, \ rp_{max}^{\sigma} := \frac{1}{2} \frac{K-1}{K+1} S^{\Delta}.$$
 (58)

At  $\rho = 1$  the above is an exact solution, by which  $v_{max}^{\sigma} = \frac{1}{2}$ , where price-volatility peaks, thus agreeing with 'high risk high reward' in the absence of model-uncertainty or bias.

There is otherwise a low-risk effect: peak-reward occurs at  $v_{max}^{\sigma} \approx \rho^{-1}$ , corresponding to low risk if  $\rho \gg 1$ ; maximum volatility,  $v = \frac{1}{2}$ , is rewarded poorly *ex-post*:  $rp^{\sigma}(\frac{1}{2}) = \frac{S^{\Delta}}{2}\mathcal{O}(\frac{K-1}{\rho}-1)$ . Note the natural separation of risk-pricing K and bias  $\rho$ : the latter is revealed by peak-location  $v_{max}^{\sigma}$ , while the former, by peak-reward  $rp_{max}^{\sigma}$ , which remains that set *ex-ante* for peak-risk (Remark 15). No external rules are needed to tell 'intended pricing' from 'unintended bias'.

### 4 Summary, Conclusion and Discussion

The study concerns the risk-neutral equivalent formulation of asset-pricing under model-risk when the model-risk is binary and governed by a law that may be unknown. Explicit price dynamics are derived given information structures and data hierarchies typical of practice, exposing model-risk as a dominant driver of prices and excess, with a key role in Status Quo Bias and well-known anomalies such as Momentum and Low-Risk. It provides an integrated and concrete framework to approach these highly relevant and interconnected topics.

It makes use of an overlooked feature (Lemma 1) of hypothesis testing, namely, regular tests (Section 1.1) that are informationally redundant to one another (Definition 4) are essentially identical. An immediate effect of this is to make any risk-neutral equivalent measure of non-trivial asset-pricing under model-risk intractable (Proposition 1), even in simple cases.

However, in practically relevant situations (Section 2.3.3-2.3.4) and for economically consistent model-risks (Item-3&4, Section 1.4, and Corollary 2, Appendix C), it also limits viable economic asset-pricing (Remark 1) to just one form (Proposition 2). This leads to an intuitive 1-parameter model-risk pricing formula with familiar properties (Corollary 1). The parameter is associated with a conservation law of inference and is a product of 'intention' (preference) and 'mistake' (difference between objective and subjective laws).

*Ex-ante* ('intended') model-risk pricing, arrived at through classical theories or those with ambiguity-aversion/robust-control, can be captured by our parameter  $K \in (1, \infty)$  (53), with K = 1 corresponding to 'no model-risk discounting'. Its derivation reveals that it equals the intended gain-loss ratio of the asset at peak model-risk (Remark 15), suggesting  $K \in (1, 2)$  in competitive markets (Remark 16), or at least  $K - 1 \gg 1$  in general.

The difference between true model-risk law and the reference model-risk belief on which asset-pricing is based can be captured by our parameter  $\rho \in (0, \infty)$  (54), with  $\rho = 1$  meaning 'no difference' (as in classical settings), and  $\rho \neq 1$  meaning 'bias'. It gives expression to Status Quo Bias and allows its effects to be disentangled from risk-pricing (Section 3.5.1-3.5.2).

The above is interesting also in light of *the inertia axiom* of Bewley (2002), which says, in effect, that to update an existing decision by incorporating a new state that is subject to Knightian uncertainty, the status quo is kept *unless* an alternative that is better under all circumstances exists. For our model-risk, it suggests *inertial pricing*, one that is *piece-wise free of model-risk discounting*, jumping between alternative models when appropriate, despite (or because of) the facility to resolve model-risk under regular inference. The maxmin utility pricing solution already has this characteristic, but there is *no* built-in pessimism in inertial pricing. Both are viable in our setup, as model alternatives are given by probability measures that are equivalent prior to risk-resolution. This subject and its implications to theory and practice will be examined in a follow-up study.

Our approach should apply to model-risks of any finite number of outcomes. The price-ofmodel-risk and its properties generalise straightforwardly. Lemma 1 can be extended through repeat applications of the binary original to arbitrary binary partitions. Results parallel to Proposition 1-2 may then follow.

# **APPENDIX**

# A Properties of Inferential Hypothesis Testing

Under *small increments*, so that above-second-order change due to incremental data can be discarded, the defining properties of log-LRP (2) are as follows:  $\forall m < n \in \mathbb{N}$  finite,

$$\mathbf{E}_{Q_b}[\Delta l_n^{b\overline{b}}|F_m] = \frac{1}{2} \mathbf{E}_{Q_b}[(\Delta l_n^{b\overline{b}})^2|F_m] = \frac{1}{2} \mathbf{E}_{Q_b}[(\Delta l_n^{\overline{b}b})^2|F_m] > 0,$$
(A.1)

$$-\mathbf{E}_{Q_{\overline{b}}}[\Delta l_{n}^{b\overline{b}}|F_{m}] = \frac{1}{2}\mathbf{E}_{Q_{\overline{b}}}[(\Delta l_{n}^{b\overline{b}})^{2}|F_{m}] = \frac{1}{2}\mathbf{E}_{Q_{\overline{b}}}[(\Delta l_{n}^{\overline{b}b})^{2}|F_{m}] > 0, \tag{A.2}$$

$$\mathbf{E}_{Q_B}[l_n^{b\overline{b}}|F_m] = \frac{(-1)^{1_{\{B=\overline{b}\}}}}{2} \mathbf{Var}_{Q_B}[l_n^{b\overline{b}}|F_m], \tag{A.3}$$

where  $\mathbf{E}_{Q_B}[\cdot|\cdot]$  and  $\mathbf{Var}_{Q_B}[\cdot|\cdot]$  denote expectations and variance respectively under  $Q_B$ . Under either of its defining measures, *expected log-LRP* coincides with *relative entropy*; it equals, up to a factor of  $\pm \frac{1}{2}$ , the cumulative variance of the log-LRP. The above explicitly demonstrates how i.i.d data guarantee the divergence of (A.3) and so *B*-resolution as  $n \to \infty$ .

Standard log-LRPs, those of independent and small increments, have the dynamics below:

$$\Delta l_{j+1}^{b\overline{b}}(B) := l_{j+1}^{b\overline{b}}(B) - l_{j}^{b\overline{b}}(B) = (-1)^{\mathbf{1}_{\{B=\overline{b}\}}} \frac{(\sigma_{j}^{l})^{2}}{2} + \sigma_{j}^{l} \cdot \epsilon_{j+1}, \ j = 0, 1, 2, ...,$$
(A.4)

$$l_{n}^{b\overline{b}}(B) \sim \mathcal{N}\left((-1)^{\mathbf{1}_{\{B=\overline{b}\}}} \frac{(\sigma_{[n]}^{l})^{2}}{2}, \ \sigma_{[n]}^{l}\right), \ n = 1, 2, 3...,$$
(A.5)

where  $(\sigma_{[n]}^l)^2 := \sum_{j=0}^{n-1} (\sigma_j^l)^2$  is its cumulative variance, and  $\{\epsilon_{j+1}\}$ , i.i.d standard Normal variables  $\sim \mathcal{N}(0,1)$ . The exponentiation of the above yields the dynamics of inferential odds (4), from which the dynamics of inferential beliefs  $\{\pi_n^b\}$  derive via Ito-Taylor expansion:

$$\frac{\Delta \pi_{j+1}^b(B)}{(\sigma_j^\pi)^2} = \left(\mathbf{1}_{\{B=b\}} - \pi_j^b(B)\right)(\sigma_j^l)^2 + \sigma_j^l \cdot \epsilon_{j+1}, \ j = 0, 1, 2, ...,$$
(A.6)

with  $\Delta \pi_{j+1}^b := \pi_{j+1}^b - \pi_j^b$  and  $(\sigma_j^\pi)^2 := \pi_j^b \underline{\pi}_j^b$ , all adapted to  $\{F_j\}$ .

Passing into Continuous Time. Taking small-increment to its limit, with t ∈ ℝ<sup>+</sup> replacing n ∈ ℕ, continuous-time log-LRPs are well-defined. Under independent increments, they become Lévy processes, and, if predictable and so continuous, they are Wiener. For i.i.d data, they are also uniform: with {w<sub>τ</sub>} denoting standard Wiener noise,

$$dl_{\tau}^{b\overline{b}}(B) = (-1)^{\mathbf{1}_{\{B=\overline{b}\}}} \frac{(\sigma^{l})^{2}}{2} d\tau + \sigma^{l} dw_{\tau}.$$
 (A.7)

Time-varying data obtain as i.i.d data under an absolutely continuous *clock-change*  $t \mapsto \tau(t)$ , leading to an image log-LRP  $\{l_t^{b\overline{b}}\} := \{l_{\tau(t)}^{b\overline{b}}\}$  that is Wiener, with absolutely continuous time-varying parameters (see e.g. Kallsen (2006)); inferential odds and beliefs, via (4), are the associated Ito processes. That is, in exact parallel to (A.1-A.6),

$$dl_t^{b\overline{b}}(B) = \mu_t^{l,b}(B)dt + \sigma_t^l dw_t, \text{ with } \mu_t^{l,b}(B) := (-1)^{\mathbf{1}_{\{B=\overline{b}\}}} \frac{(\sigma_t^l)^2}{2};$$
(A.8)

$$d\pi_t^b(B) = \left(\mathbf{1}_{\{B=b\}} - \pi_t^b(B)\right) (\sigma_t^{\pi})^2 (\sigma_t^l)^2 dt + (\sigma_t^{\pi})^2 \sigma_t^l dw_t.$$
(A.9)

- 2. Regular Inference. Its defining feature is predictability (of the risky outcome concerned). In discrete time, this requires the time of risk-resolution to be 'pre-declared' or at infinity. Clock-change allows continuous-time regular inference to have finite resolution-times, by compactifying uniform regular inference to bring resolution  $T_{\tau}(B) = \infty$  forward to some  $T(B) := T_t(B) < \infty$ . The resulting log-LRPs diverge as  $t \to T(B)$ , but the associated beliefs and so asset-pricing remain finite and continuous, thanks to Bayes' Rule (4).
- Complete Markets and Unhedgeable Model-Risks. Market completeness excludes unpredictable risk-resolutions (price-jumps) and so demands regular inference. In such a setting, to be unhedgeable and thus priced economically (Remark 1), model-risk B may be unresolvable or resolvable but with T(B) > T; this is the default case for model-risk studies. The mixed case of probabilistic resolution, P({T(B) ≤ t + s}|F<sub>t</sub>) ∈ (0,1), ∀t < T, ∀s ∈ (0,T-t], which may occur in continuous-time complete markets so long as T(B) is predictable, involves treating the unhedgeable part of the model-risk only.</li>
- 4. Non-Resolution and Novikov's Condition. For any discrete-time log-LRP that is based on equivalent measures on the space  $S^{\mathbb{N}}$  of total data, written as  $\hat{Q}_b \sim Q_b$  in the financial context, one being some RNE version of the other, the Radon-Nikodym Theorem ensures  $\lim_{n\to\infty} \log \frac{\hat{Q}_b|_n(\cdot)}{Q_b|_n(\cdot)} < \infty$  almost surely, and hence a finite total variance (A.3) and the non-resolution of *B*-values. In continuous time, the same principle is at play: nonresolution implies that inferential beliefs, Ito processes as in (A.8-A.9), satisfy Novikov's Condition, and vice versa.

5. Adjacency. Given any pair of log-LRPs  $\{l_n^{b\overline{b}}\}$  and  $\{\hat{l}_n^{b\overline{b}}\}$  of respective defining laws  $\{Q_b, Q_{\overline{b}}\}$  and  $\{\hat{Q}_b, \hat{Q}_{\overline{b}}\}$  such that equivalence  $\hat{Q}_B \sim Q_B$  holds on the space  $S^{\mathbb{N}}$  of total data, they almost surely can differ at most by a random constant as  $n \to \infty$ , since  $\forall n \in \mathbb{N}$  we have:

$$\hat{l}_{n}^{b\overline{b}} - l_{n}^{b\overline{b}} = \log \frac{\hat{Q}_{b|n}}{Q_{b|n}} - \log \frac{\hat{Q}_{\overline{b}|n}}{Q_{\overline{b}|n}},\tag{A.10}$$

where the RHS is convergent under equivalence. The same holds in continuous time.

## **B** The Informational Integrity of Inference

Consider two inferential tests about binary variable *B* based on cumulative data process  $\{D^n\}$  of natural filtration  $\{F_n\}$  satisfying usual conditions (Section 1.1). Denote their respective *a* posteriori odds processes by  $\{O_f[\pi_n^b]\}, O_f[\pi_0^b] \in \mathbb{R}^+$ , and  $\{O_f[\hat{\pi}_n^b]\}, O_f[\hat{\pi}_0^b] \in \mathbb{R}^+$ , with respective log-LRPs  $\{I_n^{b\bar{b}}\} := \{\log \frac{Q_b|_n}{Q_{\bar{b}}|_n}\}$  and  $\{\hat{l}_n^{b\bar{b}}\} := \{\log \frac{\hat{Q}_b|_n}{\hat{Q}_{\bar{b}}|_n}\}$ , where  $Q_B$  and  $\hat{Q}_B$  are the respective *B*-sure beliefs underpinning the two inferential tests and determining the respective inferential odds via Bayes' Rule (4).

**Definition 4.** An inference process  $\{\hat{\pi}_n^b\}$  is said to be *informationally redundant* to another,  $\{\pi_n^b\}$ , if 1)  $\exists C > 0$  finite such that  $\forall n \in \mathbb{N}$  on all non-null data-to-date (under  $Q_B|_n$  or  $\hat{Q}_B|_n$ )<sup>10</sup>,

$$|\hat{l}_n^{b\overline{b}} - l_n^{b\overline{b}}| < C; \tag{B.1}$$

2) there is a set  $\{g_n : \mathbb{R}^+ \mapsto \mathbb{R}^+\}$  of non-trivial continuous functions, one for each  $n \in \mathbb{N}$ , such that  $\forall O_f[\pi_0^b] \in \mathbb{R}^+$ ,  $\forall O_f[\hat{\pi}_0^b] \in \mathbb{R}^+$ , and on all non-null data-to-date (under  $Q_B|_n$  or  $\hat{Q}_B|_n$ ),

$$O_f[\hat{\pi}_n^b] = g_n \big( O_f[\pi_n^b] \big); \tag{B.2}$$

3) the redundancy maps above are time-homogeneous:  $\forall n \in \mathbb{N}$ ,  $g_n = g$  and  $O_f[\hat{\pi}_n^b] = g(O_f[\pi_n^b])$ .

**Remark 21.** Condition (B.1) means 'like speed of resolution', and (B.2), the measurability of  $\{\hat{\pi}_n^b\}$  to the natural filtration  $\{F_n^\pi\} \subseteq \{F_n\}$  of  $\{\pi_n^b\}$ . Time-homogeneity means: whenever  $\pi_n^b = \pi_{n'}^b$  we have  $\hat{\pi}_n^b = \hat{\pi}_{n'}^b$  regardless.

<sup>&</sup>lt;sup>10</sup>Define the likelihood ratio of null-events as 1.

**Lemma 1.** No regular inference about a given binary variable *B* can be informationally redundant with respect to another without being identical to it, except at the a priori level.

**Proof.** Consider two regular inference processes in odds terms:  $\{O_f[\pi_n^b]\}$  with  $O_f[\pi_0^b] \in (0, \infty)$ , and  $\{O_f[\hat{\pi}_n^b]\}$  with  $O_f[\hat{\pi}_0^b] \in (0, \infty)$ , on filtered space  $(S^{\mathbb{N}}, \{F_n\})$ , based on cumulative data process  $\{D^n\}$ , under respective *B*-sure beliefs  $Q_B$  and  $\hat{Q}_B$  and likelihood ratios,  $\{L_n^{b\bar{b}}\} := \{\frac{Q_b|_n}{Q_{\bar{b}}|_n}\}$ and  $\{\hat{L}_n^{b\bar{b}}\} := \{\frac{\hat{Q}_b|_n}{\hat{Q}_{\bar{b}}|_n}\}$ . Let them be linked by redundancy maps, the collection  $\{g_n\}$  of non-trivial continuous functions  $g_n : (0, \infty) \mapsto (0, \infty)$ , one for each  $n \in \mathbb{N}$ .

Part I. At any  $m \ge 1$  and n > m, the following must hold almost surely for maps  $g_m$  and  $g_n$ , on positive random variables  $O_f[\pi_m^b]$ ,  $O_f[\hat{\pi}_m^b]$ ,  $O_f[\pi_n^b]$  and  $O_f[\hat{\pi}_n^b] \in (0,\infty)$ :

$$g_n(O_f[\pi_n^b]) = g_n(O_f[\pi_0^b]L_n^{b\overline{b}}) = g_n(O_f[\pi_m^b]L_{n|m}^{b\overline{b}}) = O_f[\hat{\pi}_0^b]\hat{L}_n^{b\overline{b}} = O_f[\hat{\pi}_m^b]\hat{L}_{n|m}^{b\overline{b}} = g_m(O_f[\pi_m^b])\hat{L}_{n|m}^{b\overline{b}},$$
(B.3)

where  $L_{n|m}^{b\overline{b}}$  and  $\hat{L}_{n|m}^{b\overline{b}}$  are the respective likelihood ratios of any realisable data between m and n given the data at m. Setting  $O_f[\pi_m^b] = 1$  in (B.3) reveals:  $\forall L_{n|m}^{b\overline{b}} \in (0,\infty)$ ,

$$\hat{L}_{n|m}^{b\overline{b}} = g_m(1)^{-1} g_n \left( L_{n|m}^{b\overline{b}} \right).$$
(B.4)

Alternatively, setting  $L_{n|m}^{b\overline{b}} = 1$  in (B.3), and in (B.4), reveals:  $\forall O_f[\pi_m^b] \in (0, \infty)$ ,

$$g_n(1)^{-1}g_n(O_f[\pi_m^b]) = g_m(1)^{-1}g_m(O_f[\pi_m^b]).$$
(B.5)

Combining these with (B.3), we have, for arbitrary  $m \ge 0$ , n > m,  $L_{n|m}^{b\overline{b}}$  and  $O_f[\pi_m^b]$ ,

$$g_n\left(O_f[\pi_m^b]L_{n|m}^{b\overline{b}}\right) = g_n(1)^{-1}g_n\left(O_f[\pi_m^b]\right) \cdot g_n\left(L_{n|m}^{b\overline{b}}\right),\tag{B.6}$$

and thus the functional equation at each  $n \in \mathbb{N}$ :  $\forall X, X' \in (0, \infty)$ ,

$$g_n(XX') = g_n(1)^{-1}g_n(X)g_n(X').$$
 (B.7)

It has non-trivial continuous real solutions  $g_n(\cdot) = (\cdot)^{\gamma_n} c_n$ , with  $c_n \equiv g_n(1) \in (0, \infty)$ , and  $\gamma_n$ , a real constant. By (B.5) however,  $\gamma_n = \gamma_{n'} = \gamma$  must hold for some  $\gamma$  for arbitrary n and n' in  $\mathbb{N}$ .

*Part II.* Condition (B.1) rules out  $\gamma \neq 1$  for regular inference. Hence  $O_f[\hat{\pi}_n^b] = g_n(1)O_f[\pi_n^b]$ and  $\hat{L}_n^{b\overline{b}} = \frac{g_n(1)}{g_0(1)}L_n^{b\overline{b}}$ ,  $\forall n \in \mathbb{N}$ , with  $c_0 \equiv g_0(1) := \frac{O_f[\hat{\pi}_0^b]}{O_f[\pi_0^b]}$ . That is, at any  $n \in \mathbb{N}$ , the map required is of the form  $g_n = c_n \cdot \mathbf{Id}$ , with  $c_n > 0$  and  $\lim_{n \to \infty} c_n < \infty$ .

Part III. By time-homogeneity:  $\forall n \in \mathbb{N}$ ,  $\hat{L}_n^{b\overline{b}} = L_n^{b\overline{b}}$  and  $O_f[\hat{\pi}_n^b] = \frac{O_f[\hat{\pi}_0^b]}{O_f[\pi_0^b]}O_f[\pi_n^b] = O_f[\hat{\pi}_0^b]L_n^{b\overline{b}}$ .

**Remark 22.** Lemma 1 applies to continuous-time inference. All may be stated unchanged, but for 'N' becoming 'R<sup>+</sup>', and ' $\rightarrow \infty$ ', ' $\rightarrow$  T(B)' (Item-2). The proof proceeds identically, as all arguments involve only discrete moments. Indeed, in continuous time, the additional tool of Ito's Lemma may be applied to 2-differentiable maps between continuous log-LRPs of independent increments, each following dynamics (A.8-A.9). Any such redundancy map (excluding label-switch)  $g : \mathbb{R} \mapsto \mathbb{R}$  with  $\hat{l}_t^{b\overline{b}} = g(l_t^{b\overline{b}}), t \in (0,T(B))$ , must satisfy:

$$g'' = -(-1)^{\mathbf{1}_{\{B=b\}}}(g'-1)g'.$$
(B.8)

For B = b and where  $g' \neq 0$ , we have  $g' = g'(0)e^{-g(0)}e^{g-Id}$ ,  $g'e^{-g} = g'(0)e^{-g(0)}e^{-Id}$ , so,

$$g = -\log\left(g'(0)e^{-\mathrm{Id}} + (1 - g'(0))e^{-g(0)}\right);\tag{B.9}$$

by divergence (5) as  $t \to T(b)$  (the log-LRPs being resolving) we must have g'(0) = 1; likewise for  $B = \overline{b}$  when (B.9) becomes  $g = \log (g'(0)e^{Id} + (1 - g'(0))e^{-g(0)})$  and  $\lim_{t\to T(\overline{b})} l_t^{b\overline{b}} = -\infty$ . Note that the above argument does not use condition (B.1); it works with the weaker condition of common resolution-time T(B), finite or infinite.

**Remark 23.** The redundant inferential process  $\{\hat{\pi}_n^b\}$ , already a  $(\hat{\pi}_0^B \hat{Q}_B)$ -martingale by definition, is also a  $(\hat{\pi}_0^B Q_B)$ -martingale (see Part III). That is, process  $\{\hat{\pi}_n^b\}$ , as the price of an asset of value 1 in case of  $\{B = b\}$  and 0 otherwise, has equivalent martingale measure  $\hat{\pi}_0^B Q_B$  as well as  $\hat{\pi}_0^B \hat{Q}_B$ . We thus have  $\hat{Q}_B = Q_B$ , as such a market under regular inference is complete. This implication of redundancy is relevant to Proposition 1. The same applies in continuous time.

# C PROPOSITION 1 FOR NON-RESOLVING PROCESSES

The proof for Proposition 1 is identical to that of Lemma 1, with Remark 23 securing the claim at the end, *except* non-resolving asset-processes (caused by finite horizon  $T < \infty$  or otherwise), to which the 'like speed' condition (B.1) is either trivial or irrelevant. The argument for  $\gamma = 1$  (Part II of the proof) instead relies on the non-negativity of risk-pricing. This is laid out below; it applies identically to discrete or continuous time.

**Proof.** Consider the sign of risk-pricing (13-14), that is, of  $\pi_n^b - \hat{\pi}_n^b$ . Under redundancy map  $c_n X^{\gamma}$  (Part I of the proof), with  $X_n := O_f[\pi_n^b] \in (0, \infty)$ , we have, at any given n < T,

$$\pi_n^b - \hat{\pi}_n^b = \frac{c_n X_n^{\gamma} - X_n}{(1 + c_n X_n^{\gamma})(1 + X_n)}, \ c_n > 0, \ \gamma \in \mathbb{R}.$$
 (C.1)

It vanishes at  $X_n = 0$  and  $X_n = \infty$ , as price-of-risk must do under certainty. However, it can have another vanishing point  $x_{n,0} := c_n^{\frac{1}{1-\gamma}}$  (e.g. for  $c_n = 1$ ,  $x_{n,0} = 1$ ), across which the sign of (C.1) flips. Such forbidden price-of-risk behaviour can be avoided *iff*.  $\gamma = 1$ .

Note that the property of (C.1) also allows the following statement:

**Corollary 2.** Given any asset and binary risk with respect to which it is decomposed (as in Section 1.4), economically interpretable risk-pricing (in the sense of property-1, Definition 1) is possible only if the risk is economically consistent (in the sense of Item-3, Section 1.4).

# D PROOF OF PROPOSITION 2 ON THE CANONICAL PRICING OF USUAL-CASE ASSETS

The result is a feature of the price and inference dynamics under Ito-Taylor expansion. To avoid clutter, we proceed in continuous time and write  $\mathbf{1}_+$  for  $\mathbf{1}_{\{B=+\}}$ ,  $B \in \{+, -\}$ .

**Proof.** Part I. Viable model-risk only pricing  $\{S_t^{(0|A)}\} := \{\Sigma_B A_t^B Y_t^B\} = \{Y_t^-\} + \{A_t^+ Y_t^{\Delta}\}, \text{ given 2-differentiable coefficients } \{A_t^+(\pi_t^+,...)\}, \text{ must be canonical.}$ 

Under reference belief  $\pi_0^B Q_B^{(T)} W_B^{(T)}$ , with  $dW_{-,t}^{(T)} = \sigma_t^Z dw_t^Z$  as our reference Wiener measure,  $\{dw_t^Z\}$  being a standard Wiener process, given model-drift  $r(t)dt = -dY^{\Delta}(t)$ , we have:

$$dS_t^{(0|A)} = \left[ (\mathbf{1}_+ - A_t^+) r(t) dt + \sigma_t^Z dw_t^Z \right] +$$
(D.1)

$$(\sigma_t^{\pi})^2 Y^{\Delta}(t) \partial_{\pi} A_t^+ \cdot \left[ (\mathbf{1}_+ - \pi_t^+) (\sigma_t^l)^2 dt + (\sigma_t^{\pi})^2 \frac{\partial_{\pi}^2 A_t^+}{2\partial_{\pi} A_t^+} (\sigma_t^l)^2 dt + \sigma_t^l dw_t' \right], \tag{D.2}$$

with  $(\sigma_t^l)^2 := (\sigma_t^{lZ})^2 + (\sigma_t^{lD})^2$ , where  $\sigma_t^{lZ} := r(t)/\sigma_t^Z$  stems from data  $\{Z^t(B)\}$  (Peskir and Shirayev (2006)), and  $(\sigma_t^{lD})^2$ , from *B*-conditionally independent data  $\{D^t(B)\}$  modelled likewise, and so  $\sigma_t^l dw_t' := \sigma_t^{lZ} dw_t^Z + \sigma_t^{lD} dw_t^D$ .

Without risk-pricing,  $\{A_t^+\} = \{\pi_t^+\}$ , we have trivial viability under reference belief  $\pi_0^B Q_B^{(T)} W_B^{(T)}$ :

$$dS_t^{(0|\pi)} = \left[ (\mathbf{1}_+ - \pi_t^+) r(t) dt + \sigma_t^Z dw_t^Z \right] + (\sigma_t^\pi)^2 Y^\Delta(t) \left[ (\mathbf{1}_+ - \pi_t^+) (\sigma_t^l)^2 dt + \sigma_t^l dw_t' \right].$$
(D.3)

With viable model-risk only pricing, under some RNE measure  $\hat{\pi}_0^B \hat{Q}_B^{(T)} \hat{W}_B^{(T)} \sim \pi_0^B Q_B^{(T)} W_B^{(T)}$ : we have  $\{S_t^{(0|A)}\} = \{\Sigma_B \hat{\pi}_t^B \hat{S}_t^B\}$  and the following relationship, by (11-14) and (21),

$$\pi_t^+ - A_t^+ = k_t^A \sigma_t^\pi = k_t^{\hat{\pi}} \sigma_t^\pi + \frac{\Sigma_B \hat{\pi}_t^B \hat{R} \hat{P}_t^B}{Y_t^\Delta} = (\pi_t^+ - \hat{\pi}_t^+) + \frac{\Sigma_B \hat{\pi}_t^B \hat{R} \hat{P}_t^B}{Y_t^\Delta}.$$
 (D.4)

**Remark 24.** The reference model-risk inference process  $\{\pi_t^B\}$  and any of its RNE version  $\{\hat{\pi}_t^B\}$  infer B at 'like speed' (ltem-5, Appendix A.1), implying  $\mathcal{O}(\pi_t^B - \hat{\pi}_t^B) = \mathcal{O}((\sigma_t^\pi)^2)$ ,  $\sigma_t^\pi \ll \frac{1}{2}$ , at any t < T, and so  $\mathcal{O}(k_t^{\hat{\pi}}) = \mathcal{O}(\sigma_t^\pi)$  for any RNE price-of-model-risk  $k_t^{\hat{\pi}}$  ((14)); see (37-38) when  $\{\hat{\pi}_t^B\} = \{\Pi_t^B\}$ . In turn, given (D.4) and Proposition 1:  $\mathcal{O}(\hat{RP}_t^B) = \mathcal{O}((\sigma_t^\pi)^2)$  and  $\mathcal{O}(k_t^A) = \mathcal{O}(\sigma_t^\pi)$ , as well as  $\mathcal{O}(\partial_\pi A_t^B) = \mathcal{O}(\partial_\pi^2 A_t^B) = \mathcal{O}(1)$  and  $\mathcal{O}(d\hat{RP}_t^B) = \mathcal{O}(d(\sigma_t^\pi)^2) = \mathcal{O}((\sigma_t^\pi)^4)$ ,  $\sigma_t^\pi \ll \frac{1}{2}$ .

Consider first the case of trivial  $\{D^t\}$ . The drift of  $\{dS_t^{(0|A)}\}$  is nil in expectation under some RNE measure  $\hat{\pi}_0^B \hat{W}_B^{(T)}$ , where  $d\hat{W}_{B,t}^{(T)} = \hat{r}_{B,t} dt + \sigma_t^Z dw_t^Z$ ,  $\hat{r}_{B,t} dt = -d\hat{R}\hat{P}_t^B$ . That is, (D.1) must offset (D.2) in expectation. With that of (D.1) written as  $v_t := (\hat{\pi}_t^+ - A_t^+)r(t) - \Sigma_B \hat{\pi}_t^B \hat{r}_{B,t}$  and noting  $\hat{\pi}_t^+ - \pi_t^+ = (\hat{\pi}_t^+ - A_t^+) - (\pi_t^+ - A_t^+)$ , viability requires:

$$\frac{-\nu_t}{r(t)} = (\sigma_t^{\pi})^2 Y^{\Delta}(t) \partial_{\pi} A_t^+ \cdot \frac{(\sigma_t^{lZ})^2}{r(t)} \left[ (\sigma_t^{\pi})^2 \frac{\partial_{\pi}^2 A_t^+}{2\partial_{\pi} A_t^+} - (\pi_t^+ - A_t^+) - \frac{-\nu_t}{r(t)} \right].$$
(D.5)

By Remark 24, we have  $\mathcal{O}(RHS) = \mathcal{O}((\sigma_t^{\pi})^4)$  and  $\mathcal{O}(LHS) = \mathcal{O}((\sigma_t^{\pi})^2)$ ,  $\forall \sigma_t^{\pi} \ll \frac{1}{2}$ , so nil-drift is possible only if each side of the above vanishes on its own, meaning:

$$\frac{\partial_{\pi}^{2} A_{t}^{+}}{2 \partial_{\pi} A_{t}^{+}} = \frac{\pi_{t}^{+} - A_{t}^{+}}{(\sigma_{t}^{\pi})^{2}}.$$
 (D.6)

This has solutions of the form  $\{A_t^+\} = \{\Pi_t^+\}$  only, where  $\{\Pi_t^+\}$  is any model-risk inference based on any measure  $\Pi_0^B W_B^{(T)}$ ,  $\Pi_0^B \sim \pi_0^B$ . The same can be obtained from the LHS of (D.5).

Adding *B*-conditionally independent data  $\{D^t\}$  under *B*-sure law  $Q_B^{(T)}$ , the dynamics of  $\{dS_t^{(0|A)}\}$  have an additional independent noise term  $(\sigma_t^{\pi})^2 Y^{\Delta}(t) \partial_{\pi} A_t^+ \cdot \sigma_t^{ID} dw_t^D$  ((D.2)), and the new martingale measure (unique) can be read of  $f^{11}$ :  $\Pi_0^B W_B^{(T)} Q_B^{(T)}$ ,  $\Pi_0^B \sim \pi_0^B$ .

<sup>&</sup>lt;sup>11</sup>Alternatively, by writing  $(\sigma_t^l)^2 = (\sigma_t^{lZ})^2(1 + F_t^{D/Z})$ ,  $F_t^{D/Z} := (\sigma_t^{lD})^2/(\sigma_t^{lZ})^2$ , a viability requirement parallel to (D.5) albeit with an extra drift contribution from  $\{D^t\}$  on the RHS can be derived; the same argument and an application of Proposition 1 then lead to the same condition (D.6) and conclusion.

Part II. Viability of canonical normal pricing  $\{S_t^{(RP|\Pi)}\} = \{S_t^{(0|\Pi)}\} - \{\Sigma_B R P^B(t) \Pi_t^B\}.$ 

Under the martingale measure  $\Pi_0^B Q_B^{(T)} W_B^{(T)}$  of  $\{S_t^{(0|\Pi)}\}$ , the equation of motion of  $\{S_t^{(RP|\Pi)}(B)\}$  has form (D.3), but with an extra drift  $R^B(t)dt = -dRP^B(t)$ :

$$dS_t^{(RP|\Pi)} = \left[ (\mathbf{1}_+ - \Pi_t^+)\check{r}(t)dt + \sigma_t^Z dw_t^Z \right] + S^{\Delta}(t)(\sigma_t^{\Pi})^2 \left[ (\mathbf{1}_+ - \Pi_t^+)(\sigma_t^l)^2 dt + \sigma_t^l dw_t' \right] + R^{(\cdot)}(t)dt, \quad (\mathsf{D}.7)$$

where  $S^{\Delta}(t) \equiv Y^{\Delta}(t) - [RP^+(t) - RP^-(t)]$  and  $\check{r}(t)dt := -dS^{\Delta}(t)$ . As such, it is viable whenever  $\frac{R^{\pm}(t)\sigma_t^Z}{(\sigma_t^Z)^2 + r(t)S^{\Delta}(t)(\sigma_t^{\Pi})^2}$  is square-integrable up to any pre-horizon point (Novikov's Condition).

# E THE MOMENTUM AND LOW-RISK FORMULAE

Under the assumptions of Section 3.2-3.4, all the probabilities required derive from the uniform random-walk that is the RNE log-LRP  $\{l_n^{10}\}$ , with constant volatility  $\sigma^l$ . The distributions of RNE beliefs  $\{\Pi_n^1\}$  and so of prices ((52)) obtain by a change of variable.

The log-LRP level  $l_n^{10}$  itself at any time *n* has the following Normal distribution:

$$\mathcal{N}\left(\mu_{[n]}^{l}(B) = \frac{(-1)^{B+1}}{2} (\sigma^{l})^{2} n, \ (\sigma_{[n]}^{l})^{2} = (\sigma^{l})^{2} n\right), \ B \in \{0, 1\}.$$
(E.1)

Distributions for prices, i.e. RNE beliefs  $\{\Pi_n^1 = v\}$ , given  $\{l_n^{10} = l\}$ , derive from Bayes' Rule (4):

$$l = H_{\Pi \pm} + \log \circ O_f[v], \text{ with}$$
(E.2)

$$H_{\Pi\pm} := \log \circ O_f[\underline{\Pi}_{0\pm}^1] = H_p + \log(\rho K^{\pm 1}), \tag{E.3}$$

$$H_{\mathbf{p}} := \log \circ O_f[\underline{\mathbf{p}}_0^1], \tag{E.4}$$

where  $O_f[\Pi_{0\pm}^1] = O_f[\mathbf{p}_0^1]/(\rho K^{\pm 1})$  ((53)), with  $sign[1\mathbf{0}] = \pm$ ; note  $dl = (v\underline{v})^{-1}dv$ . The *H*-variables are inferential milestones:  $H_{\Pi\pm}$  is the log-LRP hurdle for event  $\{\Pi_n^1 \ge \frac{1}{2}\}$ , and  $H_p$ , for  $\{\mathbf{p}_n^1 \ge \frac{1}{2}\}$ .

### E.1 Tracking Inferential Progress and Bias Dominance

The degree of *B*-certainty as data accumulate may be assessed as usual, given Normal distribution. The objective degree is tracked by some  $|C_n^{\mathbf{p}}|$ , where, with  $t_{\mathbf{p}} := 2H_{\mathbf{p}}/(\sigma^l)^2$ ,

$$C_{n}^{\mathbf{p}}(B) := \frac{H_{\mathbf{p}} - \mu_{[n]}^{l}(B)}{\sigma_{[n]}^{l}} = \frac{1}{2}\sigma_{[n]}^{l} \cdot \left((-1)^{B} + \frac{t_{\mathbf{p}}}{n}\right).$$
(E.5)

The above is high for  $\sigma_{[n]}^l \ll 1$  (little data) or  $\sigma_{[n]}^l \gg 1$  (lots of data), with  $|C_n^{\mathbf{p}}|$  bottoming at 0 if and when  $H_{\mathbf{p}} = \mu_{[n]}^l(B)$ , that is, if and when  $n = (-1)^{B+1} t_{\mathbf{p}}$  has a solution.

For the price-implied RNE inference process  $\{\Pi_n^1\}$ , the same indicator, denoted  $|C_{n\pm}^{\Pi}|$ , reads:

$$C_{n\pm}^{\Pi}(B) := \frac{H_{\Pi\pm} - \mu_{[n]}^{l}(B)}{\sigma_{[n]}^{l}} = \frac{1}{2}\sigma_{[n]}^{l} \cdot \left((-1)^{B} + \frac{t_{\Pi\pm}}{n}\right)$$
(E.6)

$$=\frac{1}{2}\sigma_{[n]}^{l}\cdot(\frac{t_{\rho}}{n}\pm\frac{t_{K}}{n})+C_{n}^{\mathbf{p}}(B), \qquad (\mathsf{E}.7)$$

where  $t_{\Pi\pm} = t_{\rho} \pm t_K + t_p$ , with  $t_{\rho} := 2\log(\rho)/(\sigma^l)^2 > 0$  and  $t_K := 2\log K/(\sigma^l)^2 > 0$  (recall  $K - 1 \gg 1$  in general and  $K \in (1, 2)$  in competitive markets).

The pattern of  $|C_{n\pm}^{\Pi}|$  parallels that of  $|C_n^{\mathbf{p}}|$ ; it has 0 as a minimum if and when  $n = (-1)^{B+1}t_{\Pi\pm}$ holds. Note that  $t_{\rho}$  is the 'burden of proof' due to bias, and  $t_{\rho}/n$  tracks how it is overcome. Recall that we consider situations of positive objective hurdle  $H_{\mathbf{p}} > 0$  and bias domination  $H_{\Pi\pm} - H_{\mathbf{p}} \gg 0$ , that is,  $t_{\mathbf{p}} > 0$  and  $t_{\rho} \gg t_K$ , where 'objective burden'  $t_{\mathbf{p}}$  can be arbitrary but presumed 'non-extreme' for non-trivial inference/excess.

### E.2 The Window of Opportunity

Excess-profit opportunities occur when data become sufficient for the conditional probabilities of change to be meaningful but insufficient for subjective inference to overcome bias:

$$\left\{\frac{t_{\mathbf{p}}}{n} \ll 1\right\} \bigcap \left\{\frac{t_{\rho}}{n} \gg 1\right\};\tag{E.8}$$

the first demand means data dominance over objective hurdle and the second, bias over data.

**Remark 25.** Consider for example profitable events  $\{O_f[\Pi_n^1] = \rho^{-1}\}$  or  $\{O_f[\Pi_{n\pm u}^1] = \rho^{-1}\}$  ((58)), with n fixed and inside the above window, and u > 0 sufficient to take the event outside. Their respective probability densities are  $\propto (n)^{-1/2}e^{-|C_n^p|^2/2}$  and  $\propto (n \pm u)^{-1/2}e^{-|C_{n\pm u}^p|^2/2}$ . Thus, in-window events dominate, with a likelihood ratio of  $\sqrt{1 \pm u/n} \cdot e^{|C_{(n\pm u)}^p|^2/2 - |C_n^p|^2/2} \gg 1$ , diverging as  $(1 - u/n) \rightarrow 0$  or  $(1 + u/n) \rightarrow \infty$ , with n fixed.

### E.3 Momentum and Volatility Mixtures

To the probabilities relevant to volatility-conditioned mean-excess (56), the following applies:

$$\mathbb{P}_n(\Pi_n^1 = v)\mathbb{P}_n(\pm | \Pi_n^1 = v) \equiv \mathbb{P}_n(\pm)\mathbb{P}_n(\Pi_n^1 = v | \pm).$$
(E.9)

Note that  $\mathbb{P}_n(\Pi_n^1 = v | \pm)$  comes from Normal distribution (E.1) via (E.2), so the likelihood ratio, given  $sign[1\mathbf{0}] = \pm$ , of event  $\{\Pi_n^1 = \underline{v}\}$  vs  $\{\Pi_n^1 = v\}$ ,  $v \in (0, \frac{1}{2}]$  is:

$$R_{n|\pm}(\underline{v}/v) := \frac{\mathbb{P}_n(\underline{v}|\pm)}{\mathbb{P}_n(v|\pm)} = (\frac{v}{\underline{v}})^{(t_{\Pi\pm}/n)-1}.$$
 (E.10)

Thus,  $\{\Pi_n^1 = v\}$ -events dominate while bias still does (i.e.  $t_\rho/n \gg 1$ ).

We also need the ratio  $M_{n|v} := \mathbb{P}_n(+|v)/\mathbb{P}_n(-|v)$  of assets with  $\{sign[1\mathbf{0}] = +\} vs$  those with  $\{sign[1\mathbf{0}] = -\}$  among all assets in the event-set  $\{\Pi_n^1 = v\}, v \in (0, 1)$ , to compute (56).

By (E.9) we have mix-ratio  $M_{n|v} = \mathbb{P}_n(v|+)/\mathbb{P}_n(v|-)$ , since  $\mathbb{P}_n(\pm) = \frac{1}{2}$  by setup<sup>12</sup>. Hence:

$$M_{n|v} = \left(\frac{\rho v}{\underline{v}}\right)^{-t_K/n} \cdot K^{1-(t_p/n)}.$$
(E.11)

Likewise, for the volatility-conditioned mix-ratio  $M_{n|vv} := \mathbb{P}_n(+|vv|)/\mathbb{P}_n(-|vv|), v \in (0, \frac{1}{2}]$ :

$$M_{n|v\underline{v}} = M_{n|v} \frac{1 + R_{n|+}(\underline{v}/v)}{1 + R_{n|-}(\underline{v}/v)}.$$
(E.12)

Note the source of conditionality: risk-pricing. For K = 1, conditional mixes equal the unconditional mix regardless; for  $K \in (1, 2)$ , they are perturbations of the unconditional one.

**Remark 26.** Both momentum-mix functions (E.11-E.12) above are monotone declining, and peak-volatility  $(v = \frac{1}{2})$  means  $M_{n|\frac{1}{2}} = M_{n|\frac{1}{2}\frac{1}{2}} = \rho^{-t_K/n}K^{1-(t_p/n)} \approx \exp[-(t_\rho/n)\log K]$ . Hence, in the window (E.8) of opportunity, when trading events are most abundant, the observed mix at high volatility can be highly negative vs the unconditional background, given sizeable bias  $\rho$ . This mix returns to its unconditional state as  $n \to \infty$  when model-risk resolves.

<sup>&</sup>lt;sup>12</sup>Deviation from  $\frac{1}{2}$  puts a *constant factor* in (E.11-E.12). The negative mix-effect of Remark 26 remains, relative to the unconditional mix. See also Remark 27.

### E.4 Peak-Reward Location and Size for Volatility-Conditioned Trading

Focusing first on the  $\{\Pi_n^1 = v\}$ -contributions to the volatility-conditioned mean-excess (56), given mix-function (E.11) and condition (E.8), it has a unique optimum, (58), with  $\mathcal{O}(\frac{(K-1)H_p}{(\sigma^l)^2 n})$ -errors. Note that the accuracy of solution (58) improves with data accumulation.

Further, given (E.10) and under condition (E.8), the  $\{\Pi_n^1 = \underline{v}\}$ -contributions to (56) are no more than  $\mathcal{O}(\rho^{-t_\rho/n})$ . That is, the leading order solution (58) is not affected significantly by these contributions while  $t_\rho/n \gg 1$ , i.e. while bias dominates.

**Remark 27.** For uneven unconditional-mix,  $\mathbb{P}_n(\pm) \neq \frac{1}{2}$ , the same applies. Compared to the even-case (58), the peak moves left (right), and its size, down (up), if the unevenness tilts negatively (positively); peak-location is capped by  $v_{max}^{+mo}$  ((57)), and peak-size, by  $rp_{max}^{+mo}$  ((57)).

Without uncertainty or bias,  $\rho = 1$ , both halves of (56), the  $\{\Pi_n^1 = v\}$ - and  $\{\Pi_n^1 = \underline{v}\}$ contributions, are invariant under  $v \leftrightarrow \underline{v}$  switching ((55) and (E.10-E.12)), so their derivatives both vanish at  $v = \frac{1}{2}$ , thus confirming 'peak-reward for peak-risk' under classical conditions.
