Maximizing Spectrum Efficiency of Data-Carrying Reference Signals via Bayesian Optimization

Taiki Kato, Graduate Student Member, IEEE, Hiroki Iimori, Member, IEEE,

Chandan Pradhan, Member, IEEE, Szabolcs Malomsoky, and Naoki Ishikawa, Senior Member, IEEE.

Abstract—Data-carrying reference signals are a type of reference signal (RS) constructed on the Grassmann manifold, which allows for simultaneous data transmission and channel estimation to achieve boosted spectral efficiency at high signal-to-noise ratios (SNRs). However, they do not improve spectral efficiency at low to middle SNRs compared with conventional RSs. To address this problem, we propose a numerical optimization-based Grassmann constellation design on the Grassmann manifold that accounts for both data transmission and channel estimation. In our numerical optimization, we derive an upper bound on the normalized mean squared error (NMSE) of estimated channel matrices and a lower bound on the noncoherent average mutual information (AMI), and these bounds are optimized simultaneously by using a Bayesian optimization technique. The proposed objective function outperforms conventional design metrics in obtaining Paretooptimal constellations for NMSE and AMI. The constellation obtained by our method achieves an NMSE comparable to conventional non-data-carrying RSs while enabling data transmission, resulting in superior AMI performance and improved spectral efficiency even at middle SNRs.

Index Terms—Channel estimation, Grassmann manifold, manifold optimization, noncoherent multiple-input multiple-output (MIMO) communication.

I. INTRODUCTION

Global mobile data traffic is on a continuous upward trend and is expected to grow approximately threefold between 2024 and 2029 [1]. Within this growth, the share of 5G new radio (NR) is expected to increase, accounting for 75% of the total by 2029 [1]. In 5G NR, five types of reference signals (RSs) are implemented, enabling accurate channel estimation and tracking. Among them, the demodulation RSs can account for up to approximately 30% of the overall transmission signals [2]. For example, in a high-mobility scenario such as a bullet train with a travel speed exceeding 300 km/h, the channel changes extremely rapidly over time [3]. In such scenarios, frequent channel estimation is required, which increases the proportion of RSs and could potentially lower spectral efficiency.

Reducing RSs is one of the main approaches to improving spectral efficiency effectively. Known methods include a semiblind method that reduces RSs through iterative channel estimation [4], a blind method that estimates the channel without RSs [5], and a superimposed pilot method that embeds RSs into data symbols [6]. All these methods detect data on the basis of the estimated channel, and such communication is referred to as coherent communication. When the channel changes rapidly, improving channel estimation accuracy is crucial for enhancing spectral efficiency [7].

Another approach to improving spectral efficiency is noncoherent communication, which does not require channel estimation. Well-known enablers include unitary space-time modulation [8, 9], differential coding [10–12], and methods based on the Grassmann manifold [13]. A key game-changer here uses reference signals derived from unitary space-time codewords [14], making it possible to perform channel estimation and data transmission simultaneously. Building on this concept, RSs on the Grassmann manifold have been proposed [15]. These data-carrying RSs (DC-RSs) can potentially replace the conventional RSs in classical training methods and boost spectral efficiency at high signal-to-noise ratios (SNRs). However, at low to middle SNRs, conventional RSs can still offer higher spectral efficiency as DC-RSs become less advantageous when the proportion of coherently detected data symbols increases. This improvement can also be achieved even in high-mobility scenarios [16].

In noncoherent communication using the Grassmann manifold, information is assigned to its subspaces. Because multiplying a space-time codeword on the manifold by a channel matrix does not change its subspace, the point on the manifold remains the same, allowing for simultaneous data and channel estimation. Designing a constellation on the Grassmann manifold is known as the Grassmann subspace packing problem [17]. Although the principle of maximizing the minimum distance between subspaces appears straightforward, this problem is highly challenging. Over the years, numerous Grassmann constellation design methods have been introduced [18–26].

Generally, construction methods fall into two categories: algebraic construction and numerical optimization. A representative algebraic approach is exponential map (Exp-Map) [18, 19]. More recently, the remarkable Cube-Split [24] and Grass-Lattice [25] constellations have been proposed for single-input multiple-output (SIMO) scenarios, achieving higher minimum distances. These algebraic methods are appealing because they enable the design of low-complexity detectors.

By contrast, numerical optimization-based approaches include methods that maximize the minimum distance between codewords [20, 23] or minimize an upper bound on the pairwise error probability (PEP) [26]. Another notable technique integrates numerical optimization with algebraic construction [22], combining the strengths of both methods. Unlike purely algebraic approaches, numerical optimization makes it possible to obtain constellations tailored to any desired objective function, allowing flexible setting of parameters such as the numbers of transmission bits and time slots, and facilitating straightforward extension to multiple-input multiple-output (MIMO) scenarios. Ideally, directly optimizing performance metrics such as channel estimation accuracy and average mutual information (AMI) would yield a desirable constellation. However, Monte Carlo simulations are required for these calculations, and it is impractical to use them as the objective in numerical optimization. Consequently, appropriate closedform objective functions are required for practical numerical optimization.

Against this background, we propose a numerical optimization approach to designing the Grassmann constellation that maximizes the total AMI in communication using DC-RSs, and its maximization leads to maximizing spectral efficiency. Here, the total AMI is defined as the sum of (1) the AMI obtained from non-coherent detection when DC-RSs are transmitted and (2) the AMI obtained from coherent detection, using the channel estimated from the DC-RSs, when data symbols are transmitted subsequently. The contributions of this paper are as follows.

- We clarify that the total AMI of communication with DC-RSs depends only on three factors: the channel estimation accuracy of DC-RSs, the noncoherent AMI, and SNR. From this relationship, it is shown that by simultaneously optimizing the channel estimation accuracy and the noncoherent AMI of DC-RSs, we can maximize the total AMI of communication, which is valid regardless of the SNR.
- 2) We propose an objective function that enables the simultaneous optimization of the channel estimation accuracy and the noncoherent AMI from DC-RSs, both of which have a fundamental trade-off. In this process, a Bayesian optimization technique is used to efficiently search for good parameters. We demonstrate that the standard design metric is not suitable for optimizing the total AMI of communication. To address this problem, we derive an upper bound for the normalized mean squared error (NMSE) of estimated channel matrices, and a lower bound for the noncoherent AMI, proposing a new objective function that optimizes these bounds.
- 3) We demonstrate that constellations on the Pareto front for NMSE and noncoherent AMI can be obtained efficiently by using the proposed objective function, and the constellation obtained through the proposed optimization method achieves better performance in terms of channel estimation accuracy and total AMI than all the conventional Grassmann constellations. Moreover, the results show that the proposed method achieves performance equal to or better than that of the classical training method using conventional RSs across all SNRs, indicating the effectiveness of using DC-RSs for all SNRs.

The remainder of this paper is organized as follows. In section II, we review conventional channel estimation methods and evaluation metrics of coherent communication. In section III, we introduce conventional construction methods for Grassmann constellations, evaluation metrics of noncoherent communication, and conventional DC-RSs. In section IV, we present the proposed objective functions and optimization method. Then, in section V, we evaluate the performance of the constellation obtained using the proposed optimization method. Finally, in section VI, we conclude this paper.

II. SYSTEM MODEL

In this section, we describe the channel model assumed in this paper as well as a conventional channel estimation method. NMSE is used as a metric of channel estimation accuracy, and AMI as a metric of maximum information rate that can be conveyed successfully in channel-coded scenarios. We also review the NMSE of estimated channel matrices and the coherent AMI assuming channel estimation errors.

A. Channel Model

We consider a MIMO system with M transmit antennas and N receive antennas. The channel model is quasi-static Rayleigh fading, where the channel matrix $\mathbf{H} \in \mathbb{C}^{M \times N}$ remains constant for T time slots and each element of \mathbf{H} follows $\mathcal{CN}(0,1)$. A space-time block code (STBC), $\mathbf{S} \in \mathbb{C}^{T \times M}$, satisfies the power constraint $\mathrm{E}[\|\mathbf{S}\|_{\mathrm{F}}^2] = T$. The received symbol $\mathbf{Y} \in \mathbb{C}^{T \times N}$ is given by

$$\mathbf{Y} = \mathbf{S}\mathbf{H} + \sigma_{\mathbf{v}}\mathbf{V},\tag{1}$$

where each element of $\mathbf{V} \in \mathbb{C}^{T \times N}$ follows $\mathcal{CN}(0,1)$, and the SNR is defined as SNR = $10 \cdot \log_{10}(1/\sigma_v^2)$ [dB].

B. Conventional Channel Estimation and Data Detection

In coherent scenarios, the channel matrix is estimated by using known RS, and data is detected on the basis of the estimated channel. Owing to its low complexity nature, the training method is used in typical communication standards. Let $T = T_p$ denote the number of time slots for the RS, and assume that the RS $\mathbf{P} \in \mathbb{C}^{T_p \times M}$ is known at both the receiver and the transmitter. At the receiver, the channel is estimated using the known RS \mathbf{P} and the received signal \mathbf{Y} . In the zeroforcing (ZF) case, the estimated channel $\hat{\mathbf{H}}$ is obtained using the pseudo-inverse matrix $\mathbf{P}^+ = (\mathbf{P}^H \mathbf{P})^{-1} \mathbf{P}^H$, whereas in the case of minimum mean square error (MMSE) estimation, it is obtained using a weight matrix, i.e., [15]

$$\hat{\mathbf{H}} = \begin{cases} \mathbf{P}^{+}\mathbf{Y} & (\mathbf{ZF}) \\ (\mathbf{P}^{\mathrm{H}}\mathbf{P} + \sigma_{\mathrm{v}}^{2}\mathbf{I}_{M})^{-1}\mathbf{P}^{\mathrm{H}}\mathbf{Y} & (\mathrm{MMSE}) \end{cases}.$$
(2)

The receiver performs maximum likelihood detection using \hat{H} , and the estimated symbol \hat{S} is given by

$$\hat{\mathbf{S}} = \underset{\mathbf{S} \in \mathcal{S}}{\operatorname{argmin}} \|\mathbf{Y} - \mathbf{S}\hat{\mathbf{H}}\|_{\mathrm{F}}^{2},$$
(3)

where S represents a codebook of space-time codewords. Although maximum likelihood detection enables optimal symbol estimation, the computational complexity increases exponentially with the number of transmission bits. In practice, MMSE equalization is a standard method to detect symbols independently because of its low computational complexity.

C. Channel Estimation Accuracy

Channel estimation accuracy is evaluated from the difference between the actual channel and estimated channel matrices, with NMSE used as the metric. To prevent the increase in NMSE at low SNRs, the estimated channel $\hat{\mathbf{H}}$ is normalized as $\bar{\mathbf{H}} = \hat{\mathbf{H}}/\alpha_c$, where $\alpha_c = \sqrt{\mathbf{E}[\|\hat{\mathbf{H}}\|_{\mathrm{F}}^2]/(N \cdot M)}$. Using this normalized estimated channel $\bar{\mathbf{H}}$, we express NMSE as

$$\text{NMSE} = 10 \cdot \log_{10}(\sigma_{\rm e}^2) \text{ [dB]},\tag{4}$$

and

$$\sigma_{\rm e}^2 = \frac{\mathrm{E}[\|\mathbf{H} - \mathbf{H}\|_{\rm F}^2]}{\mathrm{E}[\|\mathbf{H}\|_{\rm F}^2]}.$$
(5)

Here, we model the channel estimation error by using the Gauss-Markov uncertainty model from [27]. The estimated channel $\overline{\mathbf{H}}'$, which includes an error, is given by [15]

$$\bar{\mathbf{H}}' = \sqrt{1 - \beta_{\rm c}^2} \mathbf{H} + \beta_{\rm c} \mathbf{E},\tag{6}$$

where $\mathbf{E} \in \mathbb{C}^{M \times N}$ is an error matrix with each element following $\mathcal{CN}(0, 1)$. The parameter $0 \leq \beta_c \leq 1$ represents the uncertainty of $\mathbf{\bar{H}}'$, where $\beta_c = 0$ means that the estimated channel and the actual channel are completely identical. From (5) and (6), the relationship between NMSE and β_c can be respectively written as

$$\sigma_{\rm e}^2 = \frac{{\rm E}[\|\mathbf{H}' - \mathbf{H}\|_{\rm F}^2]}{{\rm E}[\|\mathbf{H}\|_{\rm F}^2]} = 2 \cdot (1 - \sqrt{1 - \beta_c^2}), \qquad (7)$$

and

$$\beta_{\rm c} = \sqrt{1 - \left(1 - \frac{\sigma_{\rm e}^2}{2}\right)^2}.\tag{8}$$

D. Coherent AMI with Channel Estimation Errors

Let us consider a codebook S with the cardinality $|S| = 2^{B_d}$, and each codeword $\mathbf{S}_i \in \mathbb{C}^{T_d \times M}$ of S conveys B_d bits. According to the system model (1), the received symbol is represented as $\mathbf{Y}_i = \mathbf{S}_i \mathbf{H} + \sigma_v \mathbf{V}$. Here, the coherent AMI with channel estimation errors is given by [15, 28]

$$R_{\rm d} = \frac{B_{\rm d}}{T_{\rm d}} - \frac{1}{T_{\rm d}|\mathcal{S}|} \mathbb{E}_{\bar{\mathbf{H}}',\mathbf{V}} \left[\sum_{i=1}^{|\mathcal{S}|} \log_2 \left(\frac{\sum_{j=1}^{|\mathcal{S}|} p(\mathbf{Y}_i | \mathbf{S}_j, \bar{\mathbf{H}}')}{p(\mathbf{Y}_i | \mathbf{S}_i, \bar{\mathbf{H}}')} \right) \right]$$
(9)

where [15]

$$p(\mathbf{Y}|\mathbf{S}, \bar{\mathbf{H}}') = \frac{1}{(\pi(\sigma_{\mathrm{v}}^2 + \sigma_{\mathrm{e}}^2))^{NT_{\mathrm{d}}}} \exp\left(-\frac{\|\mathbf{Y} - \mathbf{S}\bar{\mathbf{H}}'\|_{\mathrm{F}}^2}{\sigma_{\mathrm{v}}^2 + \sigma_{\mathrm{e}}^2}\right),\tag{10}$$

and [15]

$$\frac{p(\mathbf{Y}_i|\mathbf{S}_j, \bar{\mathbf{H}}')}{p(\mathbf{Y}_i|\mathbf{S}_i, \bar{\mathbf{H}}')} = \exp\left(\frac{-z_{i,j} + z_{i,i}}{\sigma_v^2 + \sigma_e^2}\right).$$
(11)

Here, $z_{i,j}$ can be calculated as [15]

$$z_{i,j} \simeq \| (\mathbf{S}_i - \sqrt{1 - \beta_c^2} \mathbf{S}_j) \mathbf{H} + \sqrt{\sigma_v^2 + \beta_c^2} \mathbf{V} \|_{\mathrm{F}}^2.$$
(12)

III. NONCOHERENT COMMUNICATION BASED ON GRASSMANN CONSTELLATION

In this section, we describe communication based on Grassmann constellation. First, we define the Grassmann manifold and introduce representative Grassmann constellations. Next, we explain noncoherent detection using the representative Grassmann constellation and review the method for calculating AMI in noncoherent communication. Finally, we describe the conventional DC-RSs, which use noncoherent communication for channel estimation, and methods to improve its channel estimation accuracy.

A. Grassmann Manifold

For nonnegative integers k and $n \ge k$, the Grassmann manifold $\mathcal{G}(n, k)$ represents the set of all k-dimensional subspaces in an n-dimensional space. In this paper, we define the Grassmann manifold as a quotient space of the Stiefel manifold by the $k \times k$ unitary group:

$$\mathcal{U}(k) = \{ \mathbf{U} \in \mathbb{C}^{k \times k} \mid \mathbf{U}^{\mathrm{H}} \mathbf{U} = \mathbf{I}_k \}.$$
(13)

The Stiefel manifold S(n, k) is the set of all $n \times k$ orthonormal basis matrices and is represented by

$$\mathcal{S}(n,k) = \{ \mathbf{S} \in \mathbb{C}^{n \times k} \mid \mathbf{S}^{\mathrm{H}} \mathbf{S} = \mathbf{I}_k \}.$$
(14)

Here, let the equivalence relation \sim signify that subspaces are equal. In the Stiefel manifold, the set of matrices that are equivalent under this relation is denoted by

$$[\mathbf{S}] = \{ \mathbf{S}_1 \in \mathcal{S}(T, M) \mid \mathbf{S}_1 \sim \mathbf{S} \}.$$

$$(15)$$

Operations on the Stiefel manifold that leave the subspace unchanged are equivalent to multiplication by a unitary matrix from the right. Thus, when represents the subspace of the Grassmann manifold with an orthonormal basis, the Grassmann manifold can be defined as

$$\mathcal{G}(n,k) = \mathcal{S}(n,k) / \mathcal{U}(k) = \{ [\mathbf{S}] \mid \mathbf{S} \in \mathcal{S}(n,k) \}.$$
(16)

When using points on the Grassmann manifold as codewords, we set n = T and k = M, i.e., each subspace representing a codeword. Later, a Grassmann codebook is denoted by $\mathcal{X} = \{\mathbf{X}_i \in \mathcal{G}(T, M) \mid i = 1, \dots, 2^{B_g}\}.$

B. Conventional Grassmann Constellation

We introduce conventional construction methods for the Grassmann constellation, including Exp-Map, which is based on exponential mapping, Grass-Lattice, an algebraic construction for SIMO, and a method for maximizing the minimum distance through numerical optimization.

1) Exp-Map [18, 19]: Using the matrix exponential, we can represent any point on the Grassmann manifold as

$$\mathbf{X} = \begin{bmatrix} \exp\begin{pmatrix} \mathbf{0} & \mathbf{C}_i \\ -\mathbf{C}_i^{\mathrm{H}} & \mathbf{0} \end{bmatrix} \mathbf{I}_{T,M}, \tag{17}$$

where $\mathbf{I}_{T,M} = [\mathbf{I}_{M \times M} \ \mathbf{0}_{M \times (T-M)}]^{\mathrm{T}}$ and $\mathbf{C}_i \in \mathbb{C}^{M \times (T-M)}$ is an arbitrary matrix. One method for constructing the constellation is to map QAM symbols to \mathbf{C}_i , for example. The constellation generated by exponential mapping is characterized by its high channel estimation accuracy [15]. 2) Grass-Lattice [25]: The construction of Grass-Lattice in SIMO is based on a mapping \mathcal{M} from a unit hypercube to the Grassmann constellation. The unit hypercube is the Cartesian product of the interval (0, 1) taken 2(T - 1) times, and the interval (0, 1) is evenly divided into 2^{B_1} equal segments. Thus, the bit length of Grass-Lattice is $B_g = 2(T - 1)B_1$. The mapping \mathcal{M} consists of three mappings, written as

$$\mathcal{M} = \mathcal{M}_3 \circ \mathcal{M}_2 \circ \mathcal{M}_1. \tag{18}$$

First, in \mathcal{M}_1 , points on the unit hypercube are mapped to the complex Gaussian distribution $\mathcal{CN}(0,1)$. Next, \mathcal{M}_2 maps points following a complex Gaussian distribution to the unit sphere. Finally, the points on the unit sphere are mapped onto the Grassmann manifold through \mathcal{M}_3 . For the open interval (0,1), it is necessary to define a lower bound α_1 and an upper bound $1 - \alpha_1$. It can be optimized for performance, and [25] provides the optimal α_1 for specific parameters.

3) Manifold Optimization for Maximizing Minimum Chordal Distance (Mopt-MCD) [20, 24]: Maximizing the minimum distance between symbols can improve the symbol error rate (SER) in coherent codes. By appropriately defining the distance, we can also improve the SER of noncoherent codes [20]. Here, we consider chordal distance as a distance metric for the Grassmann constellation [24]. The chordal distance $d_c(\mathbf{X}_i, \mathbf{X}_j)$ between two codewords is given by [24]

$$d_{\mathbf{c}}(\mathbf{X}_i, \mathbf{X}_j) := \sqrt{M - \|\mathbf{X}_i^{\mathrm{H}} \mathbf{X}_j\|_{\mathrm{F}}^2}.$$
 (19)

The constellation obtained by maximizing the minimum chordal distance (MCD) demonstrates the best performance in terms of noncoherent AMI [15]. From (19), the MCD can be maximized by minimizing the maximum value of $\|\mathbf{X}_i^{\mathrm{H}}\mathbf{X}_j\|_{\mathrm{F}}^2$. The max function can be approximated by using the log-sum-exp function to make it a differentiable function, enabling continuous optimization on the manifold [29]. Thus, the problem of maximizing MCD can be represented as minimizing the metric f_{MCD} , written as [15]

$$f_{\text{MCD}} := \log \sum_{i=1}^{|\mathcal{X}|-1} \sum_{j=i+1}^{|\mathcal{X}|} \exp\left(\frac{\|\mathbf{X}_i^{\text{H}}\mathbf{X}_j\|_{\text{F}}^2}{\epsilon}\right), \quad (20)$$

where ϵ is a smoothing constant.

C. Noncoherent Detection

Noncoherent detection can be performed without using channel state information (CSI). The Grassmann constellation satisfies orthonormality, and each subspace is distinct. Utilizing this property in communication allows for codewords that are invariant under multiplication by the channel matrix.

A Grassmann codeword **X** with time slot length $T = T_g$ is transmitted according to the system model (1), where **X** satisfies $\mathbf{X}^{H}\mathbf{X} = \mathbf{I}_M$. Since $\mathbb{E}[\|\mathbf{X}\|_F^2] = M$, to satisfy $\mathbb{E}[\|\mathbf{S}\|_F^2] = T_g$, we set $\mathbf{S} = \sqrt{T_g/M}\mathbf{X}$. The generalized likelihood ratio test (GLRT) receiver can estimate the codeword by maximizing the likelihood without CSI and is given by [30]

$$\hat{\mathbf{X}} = \underset{\mathbf{X} \in \mathcal{X}}{\operatorname{argmax}} \|\mathbf{Y}^{\mathrm{H}} \mathbf{X}\|_{\mathrm{F}}^{2},$$
(21)

where $\hat{\mathbf{X}}$ denotes an estimated symbol.

Fig. 1. Example of conventional RS and DC-RS structures [15].

D. Noncoherent AMI of Grassmann Communication

Let B_g be the number of transmission bits of a Grassmann constellation, and noncoherent AMI is calculated by the Monte Carlo simulation of [24]:

$$R_{\rm g} = \frac{B_{\rm g}}{T_{\rm g}} - \frac{1}{T_{\rm g}|\mathcal{X}|} \mathbf{E}_{\mathbf{H},\mathbf{V}} \left[\sum_{i=1}^{|\mathcal{X}|} \log_2 \left(\frac{\sum_{j=1}^{|\mathcal{X}|} p(\mathbf{Y}_i | \mathbf{X}_j)}{p(\mathbf{Y}_i | \mathbf{X}_i)} \right) \right].$$
(22)

In multi-antenna scenarios, the conditional probability $p(\mathbf{Y}_i|\mathbf{X}_i)$ in (22) can be calculated as [15, 20]

$$p(\mathbf{Y}|\mathbf{X}) = \frac{\exp(-\|\mathbf{Y}\|_{\mathrm{F}}^{2}/\sigma_{\mathrm{v}}^{2} + \|\mathbf{Y}^{\mathrm{H}}\mathbf{X}\|_{\mathrm{F}}^{2}/\sigma_{\mathrm{v}}^{2}/\left(1 + \sigma_{\mathrm{v}}^{2}M/T_{\mathrm{g}}\right))}{\pi^{T_{\mathrm{g}}N}\sigma_{\mathrm{v}}^{2T_{\mathrm{g}}N}\left(1 + 1/\sigma_{\mathrm{v}}^{2}/M \cdot T_{\mathrm{g}}\right)^{MN}}.$$
(23)

Then, we express $p(\mathbf{Y}_i|\mathbf{X}_j)/p(\mathbf{Y}_i|\mathbf{X}_i) = \exp(\eta_{i,j})$ in (22). Here, $\eta_{i,j}$ can be expressed as [15]

$$\eta_{i,j} = \frac{\|\mathbf{Y}_{i}^{\mathrm{H}}\mathbf{X}_{j}\|_{\mathrm{F}}^{2} - \|\mathbf{Y}_{i}^{\mathrm{H}}\mathbf{X}_{i}\|_{\mathrm{F}}^{2}}{\sigma_{\mathrm{v}}^{2}\left(1 + \sigma_{\mathrm{v}}^{2}M/T_{\mathrm{g}}\right)}.$$
(24)

Using $\eta_{i,j}$, we can write (22) as

$$R_{\rm g} = \frac{B_{\rm g}}{T_{\rm g}} - \frac{1}{T_{\rm g}|\mathcal{X}|} \mathbf{E}_{\mathbf{H},\mathbf{V}} \left[\sum_{i=1}^{|\mathcal{X}|} \log_2 \sum_{j=1}^{|\mathcal{X}|} \exp(\eta_{i,j}) \right].$$
(25)

E. Data-Carrying Reference Signal

The channel can be estimated from the estimated symbol $\hat{\mathbf{X}}$ obtained through noncoherent communication using DC-RS. Assuming $\mathbf{X} = \hat{\mathbf{X}}$, we can obtain the estimated channel $\hat{\mathbf{H}}$ by multiplying $\sqrt{M/T_g}\hat{\mathbf{X}}^{\mathrm{H}}$ from the left side of the received symbol \mathbf{Y} , written as [15]

$$\hat{\mathbf{H}} = \sqrt{\frac{M}{T_g}} \hat{\mathbf{X}}^{\mathrm{H}} \mathbf{Y} = \hat{\mathbf{X}}^{\mathrm{H}} \mathbf{X} \mathbf{H} + \sigma_{\mathrm{v}} \mathbf{V}' = \mathbf{H} + \sigma_{\mathrm{v}} \mathbf{V}', \quad (26)$$

where $\mathbf{V}' = \sqrt{M/T_g} \hat{\mathbf{X}}^{H} \mathbf{V}$. This enables DC-RS to estimate the channel while simultaneously transmitting data. When $\hat{\mathbf{X}} \neq \mathbf{X}$, DC-RS cannot estimate the channel accurately, leading to a degradation in channel estimation accuracy compared with conventional RS. An example of communication using conventional RS and DC-RS is shown in Fig. 1 [15]. In this example, an RS is transmitted for T_p or T_g time slots, followed by coherent symbols transmitted for T_d time slots. The transmitted B_d bits of coherent symbols are detected on the basis of the channel estimated by the RS. Although conventional RS carries no information, DC-RS conveys an additional B_g of information. Therefore, it is possible to increase the amount of information accuracy of conventional RS is superior, an evaluation of the actually conveyed information is necessary.

F. NMSE Minimization by Unitary Matrices

In [15], a method was proposed to minimize the NMSE of DC-RSs. By considering symbol estimation errors, we can expand $E[||\hat{\mathbf{H}} - \mathbf{H}||_{F}^{2}]$ as [15]

$$\mathbf{E}[\|\hat{\mathbf{H}} - \mathbf{H}\|_{\mathrm{F}}^{2}] = \sigma_{\mathrm{v}}^{2} \frac{M^{2}N}{T_{\mathrm{g}}} + \frac{2}{|\mathcal{X}|} \sum_{i=1}^{|\mathcal{X}|} \sum_{j=i+1}^{|\mathcal{X}|} p_{i,j} \mathbf{E}[\|\mathbf{D}_{i,j}\|_{\mathrm{F}}^{2}],$$
(27)

where $\mathbf{D}_{i,j} = (\mathbf{X}_j^{\mathrm{H}} \mathbf{X}_i - \mathbf{I}_M) \mathbf{H}$ and $p_{i,j}$ denotes the PEP. The multiplication of the Grassmann constellation by a unitary matrix does not change their subspace, thus having no effect on the average power or the chordal distance between codewords. Using this property, we can formulate the NMSE minimization problem as [15]

$$\begin{array}{ll} \underset{\{\mathbf{U}_{1},\cdots,\mathbf{U}_{|\mathcal{X}|}\}}{\text{minimize}} & \sum_{i=1}^{|\mathcal{X}|-1} \sum_{j=i+1}^{|\mathcal{X}|} \frac{\left\|\mathbf{I}_{M}-\mathbf{U}_{i}^{\mathrm{H}}\mathbf{X}_{i}^{\mathrm{H}}\mathbf{X}_{j}\mathbf{U}_{j}\right\|_{\mathrm{F}}^{2}}{\mathrm{Re}[\det(\mathbf{I}_{M}-\mathbf{X}_{i}^{\mathrm{H}}\mathbf{X}_{j}\mathbf{X}_{j}^{\mathrm{H}}\mathbf{X}_{i})]} \\ \text{s.t.} & \mathbf{U}_{i} \in \mathcal{U}(M), \ \forall \ i = \{1,\cdots,|\mathcal{X}|\}. \end{array}$$

$$(28)$$

IV. PROPOSED TOTAL AMI OPTIMIZATION METHOD

In this section, we propose an optimization method for the total AMI of communication with DC-RSs. We derive objective functions for optimizing the NMSE of estimated channel matrices and noncoherent AMI, and we propose a method that uses a convex combination to optimize these functions simultaneously.

A. Problem Formulation

We assess the achievable spectral efficiency of communication with DC-RSs, referred to as the total AMI, which is composed of coherent AMI and noncoherent AMI. According to (9) - (12), coherent AMI depends solely on SNR and the NMSE of estimated channel matrices. Hence, the total AMI depends only on a constructed Grassmann codebook \mathcal{X} and SNR. Here, we define the total AMI as

$$R_{\rm T}(\mathcal{X}, \sigma_{\rm v}^2) = T_{\rm g}R_{\rm g} + T_{\rm d}R_{\rm d}, \qquad (29)$$

and its maximization problem can be formulated as

$$\begin{array}{l} \underset{\mathcal{X}=\{\mathbf{X}_{1},\cdots,\mathbf{X}_{|\mathcal{X}|}\}}{\text{maximize}} & R_{\mathrm{T}}(\mathcal{X},\sigma_{\mathrm{v}}^{2}) \\ \text{s.t.} & \mathbf{X}_{i} \in \mathcal{G}(T_{\mathrm{g}},M), \ \forall \ i = \{1,\cdots,|\mathcal{X}|\}. \end{array}$$
(30)

To maximize the total AMI, DC-RSs should be optimized for both noncoherent AMI and NMSE. However, Monte Carlo simulations are computationally intensive, making it challenging to directly optimize performance metrics such as AMI and NMSE themselves. Additionally, there is a tradeoff between noncoherent AMI and NMSE, and optimizing the total AMI requires a dedicated simultaneous optimization of both metrics.

B. New Upper Bound for NMSE

As given in (28), the NMSE of estimated channel matrices can be minimized via a unitary transformation without changing the subspace. That is, the optimization of (28) does not change the chordal distance, implying that AMI and SER are maintained. In contrast, this article optimizes the constellation itself to maximize the total AMI. By optimizing the relationship between subspaces, it is possible to achieve a lower NMSE. If we use (28) as an objective function to minimize the NMSE of estimated channel matrices by optimizing the constellation itself, the minimization problem can be reformulated into

$$\underset{\mathcal{X} = \{\mathbf{X}_{1}, \cdots, \mathbf{X}_{|\mathcal{X}|}\}}{\text{minimize}} \sum_{i=1}^{|\mathcal{X}|-1} \sum_{j=i+1}^{|\mathcal{X}|} \frac{\left\|\mathbf{I}_{M} - \mathbf{X}_{i}^{\mathrm{H}}\mathbf{X}_{j}\right\|_{\mathrm{F}}^{2}}{\operatorname{Re}[\det(\mathbf{I}_{M} - \mathbf{X}_{i}^{\mathrm{H}}\mathbf{X}_{j}\mathbf{X}_{j}^{\mathrm{H}}\mathbf{X}_{i})]}$$
s.t. $\mathbf{X}_{i} \in \mathcal{G}(T_{\mathrm{g}}, M), \ \forall \ i = \{1, \cdots, |\mathcal{X}|\}.$

$$(31)$$

If we were to use (31) as an objective function, the PEP would be minimized at the same time because (31) includes weighted coefficients of PEPs. This is not an issue if only NMSE minimization is considered, but our method simultaneously maximize noncoherent AMI. The problem here is that there is a positive correlation between PEP and noncoherent AMI, whereas NMSE and noncoherent AMI have a negative correlation. Hence, the PEP minimization leads to improvements in both NMSE and noncoherent AMI within the convex combination, thereby reducing the degrees of freedom for optimization. By excluding the weighted coefficients of PEPs from the NMSE objective function, we can optimize NMSE with greater freedom, yielding a constellation that has better total AMI.

To avoid the above issue, we instead use an upper bound of PEP. The upper bound of (27) is transformed into

$$E[\|\hat{\mathbf{H}} - \mathbf{H}\|_{\rm F}^2]$$

$$\leq \sigma_{\rm v}^2 \frac{M^2 N}{T_{\rm g}} + \frac{2}{|\mathcal{X}|} \left(\max_{i \neq j} p_{i,j} \right) \sum_{i=1}^{|\mathcal{X}|-1} \sum_{j=i+1}^{|\mathcal{X}|} E[\|\mathbf{D}_{i,j}\|_{\rm F}^2].$$
(32)

Thus, we can define a new objective function f_{NMSE} as

$$f_{\text{NMSE}} := \sum_{i=1}^{|\mathcal{X}|-1} \sum_{j=i+1}^{|\mathcal{X}|} \|\mathbf{I}_{M} - \mathbf{X}_{i}^{\text{H}} \mathbf{X}_{j}\|_{\text{F}}^{2}, \qquad (33)$$

where the minimization of f_{NMSE} is equivalent to that of (32). In this paper, we propose f_{NMSE} as the objective function for minimizing NMSE in the problem of maximizing the total AMI.

When only f_{NMSE} is minimized, the NMSE performance of the optimized constellation is equivalent to that of the training method. However, this occurs only when all codewords satisfy $\mathbf{X}_i^{\text{H}}\mathbf{X}_j = \mathbf{I}_M$, meaning that all codewords are identical. This is equivalent to the receiver having prior knowledge of the transmitted codeword, resulting in no information. Therefore, to maximize the total AMI of DC-RSs, it is necessary to consider not only the NMSE but also the noncoherent AMI.

C. New Lower Bound for Noncoherent AMI

Maximizing the MCD leads to the maximization of noncoherent AMI. However, in this paper, we consider the simultaneous optimization of two performance metrics in a trade-off relationship, namely, NMSE and noncoherent AMI; in other words, we attempt to optimize both objectives. Accordingly, we derive a new objective function that is related to the noncoherent AMI, leading to a flexible maximization of the total AMI.

The noncoherent AMI can be obtained from (25), but transforming the Monte Carlo integration in closed form is a challenging task. Here, we instead derive a lower bound for the noncoherent AMI and maximize it. First, by applying Jensen's inequality to (25), we obtain the lower bound of the noncoherent AMI that requires Monte Carlo simulations, which is given by

$$R_{\rm g} \ge \frac{B_{\rm g}}{T_{\rm g}} - \frac{1}{T_{\rm g}|\mathcal{X}|} \log_2 \sum_{i=1}^{|\mathcal{X}|} \sum_{j=1}^{|\mathcal{X}|} \mathrm{E}_{\mathbf{H},\mathbf{V}} \left[\exp(\eta_{i,j}) \right].$$
(34)

In particular, by using the Maclaurin expansion at low SNRs, we can expand $E_{\mathbf{H},\mathbf{V}}[\exp(\eta_{i,j})]$ as

$$\mathbf{E}_{\mathbf{H},\mathbf{V}}\left[\exp(\eta_{i,j})\right] \simeq \mathbf{E}_{\mathbf{H},\mathbf{V}}\left[1+\eta_{i,j}\right],\tag{35}$$

where

$$\mathbf{E}_{\mathbf{H},\mathbf{V}}\left[\eta_{i,j}\right] = \frac{\mathbf{E}_{\mathbf{H},\mathbf{V}}\left[\|\mathbf{Y}_{i}^{\mathrm{H}}\mathbf{X}_{j}\|_{\mathrm{F}}^{2}\right] - \mathbf{E}_{\mathbf{H},\mathbf{V}}\left[\|\mathbf{Y}_{i}^{\mathrm{H}}\mathbf{X}_{i}\|_{\mathrm{F}}^{2}\right]}{\sigma_{\mathrm{v}}^{2}\left(1 + \sigma_{\mathrm{v}}^{2}M/T_{\mathrm{g}}\right)},$$
(36)

and $E_{\mathbf{H},\mathbf{V}}\left[\|\mathbf{Y}_{i}^{\mathrm{H}}\mathbf{X}_{j}\|_{\mathrm{F}}^{2}\right]$ can be written as

$$\begin{split} \mathbf{E}_{\mathbf{H},\mathbf{V}} \left[\|\mathbf{Y}_{i}^{\mathrm{H}}\mathbf{X}_{j}\|_{\mathrm{F}}^{2} \right] \\ &= \mathbf{E}_{\mathbf{H},\mathbf{V}} \left[\|(\mathbf{X}_{i}\mathbf{H} + \mathbf{V})^{\mathrm{H}}\mathbf{X}_{j}\|_{\mathrm{F}}^{2} \right] \\ &= \mathbf{E}_{\mathbf{H},\mathbf{V}} \left[\mathrm{Tr} \left\{ \left((\mathbf{X}_{i}\mathbf{H} + \mathbf{V})^{\mathrm{H}}\mathbf{X}_{j} \right) \left((\mathbf{X}_{i}\mathbf{H} + \mathbf{V})^{\mathrm{H}}\mathbf{X}_{j} \right)^{\mathrm{H}} \right\} \right] \\ &= \mathbf{E}_{\mathbf{H},\mathbf{V}} \left[\mathrm{Tr} \left\{ (\mathbf{X}_{i}\mathbf{H} + \mathbf{V})^{\mathrm{H}}\mathbf{X}_{j}\mathbf{X}_{j}^{\mathrm{H}}(\mathbf{X}_{i}\mathbf{H} + \mathbf{V}) \right\} \right] \\ &\quad + \mathbf{V}^{\mathrm{H}}\mathbf{X}_{j}\mathbf{X}_{j}^{\mathrm{H}}\mathbf{X}_{i}\mathbf{H} + \mathbf{V}^{\mathrm{H}}\mathbf{X}_{j}\mathbf{X}_{j}^{\mathrm{H}}\mathbf{V} \right\} \right] \\ &= E_{1} + E_{2} + E_{3} + E_{4}. \end{split}$$
(37)

We calculate the expectation of each term. For the first term, since the expectation of each element of \mathbf{HH}^{H} is 1 under the assumption of Rayleigh fading, E_1 is given by

$$E_{1} = E_{\mathbf{H},\mathbf{V}} \left[\operatorname{Tr} \left\{ \mathbf{H}^{\mathrm{H}} \mathbf{X}_{i}^{\mathrm{H}} \mathbf{X}_{j} \mathbf{X}_{j}^{\mathrm{H}} \mathbf{X}_{i} \mathbf{H} \right\} \right]$$

= Tr $\left\{ \mathbf{X}_{i}^{\mathrm{H}} \mathbf{X}_{j} \mathbf{X}_{j}^{\mathrm{H}} \mathbf{X}_{i} \right\}$
= $\| \mathbf{X}_{i}^{\mathrm{H}} \mathbf{X}_{j} \|_{\mathrm{F}}^{2}$. (38)

Fig. 2. Relationships between noncoherent AMI and objective functions.

12.00

Next, for the second and third terms, since V and H are independent, E_2 and E_3 are respectively given by

$$E_2 = \mathcal{E}_{\mathbf{H},\mathbf{V}} \left[\operatorname{Tr} \left\{ \mathbf{H}^{\mathrm{H}} \mathbf{X}_i^{\mathrm{H}} \mathbf{X}_j \mathbf{X}_j^{\mathrm{H}} \mathbf{V} \right\} \right] = 0, \qquad (39)$$

noncoherent AMI [bit/symbol]

$$E_3 = \mathcal{E}_{\mathbf{H},\mathbf{V}} \left[\operatorname{Tr} \left\{ \mathbf{V}^{\mathrm{H}} \mathbf{X}_j \mathbf{X}_j^{\mathrm{H}} \mathbf{X}_i \mathbf{H} \right\} \right] = 0.$$
 (40)

Finally, for the fourth term, since the expectation of each element of $\mathbf{V}\mathbf{V}^{\mathrm{H}}$ is σ_{v}^{2} , E_{4} is given by

$$E_4 = \mathbb{E}_{\mathbf{H},\mathbf{V}} \left[\operatorname{Tr} \left\{ \mathbf{V}^{\mathrm{H}} \mathbf{X}_j \mathbf{X}_j^{\mathrm{H}} \mathbf{V} \right\} \right]$$
$$= \sigma_{\mathrm{v}}^2 \|\mathbf{X}_j\|_{\mathrm{F}}^2$$
$$= M \sigma_{\mathrm{v}}^2. \tag{41}$$

Consequently, $E_{\mathbf{H},\mathbf{V}}[\eta_{i,j}]$ of (36) can be simplified into

$$E_{\mathbf{H},\mathbf{V}}[\eta_{i,j}] = \frac{\|\mathbf{X}_{i}^{\mathrm{H}}\mathbf{X}_{j}\|_{\mathrm{F}}^{2} + M\sigma_{\mathrm{v}}^{2} - (\|\mathbf{X}_{i}^{\mathrm{H}}\mathbf{X}_{i}\|_{\mathrm{F}}^{2} + M\sigma_{\mathrm{v}}^{2})}{\sigma_{\mathrm{v}}^{2}(1 + \sigma_{\mathrm{v}}^{2}M/T_{\mathrm{g}})} \\ = \frac{\|\mathbf{X}_{i}^{\mathrm{H}}\mathbf{X}_{j}\|_{\mathrm{F}}^{2} - \|\mathbf{X}_{i}^{\mathrm{H}}\mathbf{X}_{i}\|_{\mathrm{F}}^{2}}{\sigma_{\mathrm{v}}^{2}(1 + \sigma_{\mathrm{v}}^{2}M/T_{\mathrm{g}})} \\ = \frac{\|\mathbf{X}_{i}^{\mathrm{H}}\mathbf{X}_{j}\|_{\mathrm{F}}^{2} - M}{\sigma_{\mathrm{v}}^{2}(1 + \sigma_{\mathrm{v}}^{2}M/T_{\mathrm{g}})},$$
(42)

and the lower bound of noncoherent AMI is written as

$$R_{\rm g} \ge \frac{B_{\rm g}}{T_{\rm g}} - \frac{1}{T_{\rm g}|\mathcal{X}|} \log_2 \left(|\mathcal{X}|^2 + \sum_{i=1}^{|\mathcal{X}|} \sum_{j=1}^{|\mathcal{X}|} \frac{\|\mathbf{X}_i^{\rm H}\mathbf{X}_j\|_{\rm F}^2 - M}{\sigma_{\rm v}^2 \left(1 + \sigma_{\rm v}^2 M/T_{\rm g}\right)} \right)$$
(43)

Therefore, by using the symmetric relationship of X_i and X_j , maximizing this lower bound is equivalent to minimizing a new objective function:

$$f_{\rm SCD} := \sum_{i=1}^{|\mathcal{X}|-1} \sum_{j=i+1}^{|\mathcal{X}|} \|\mathbf{X}_i^{\rm H} \mathbf{X}_j\|_{\rm F}^2,$$
(44)

which is referred to as the sum of chordal distances (SCD).

The relationship between the noncoherent AMI and the objective functions $f_{\rm MCD}$ and $f_{\rm SCD}$ is shown in Fig. 2. Here, we set parameters as $(M, T_{\rm g}, B_{\rm g}) = (1, 4, 8)$, and SNRs as -10, 0, 10 and 20 dB. As shown in Fig. 2, both objective functions are sharply correlated with the noncoherent AMI in a wide range of SNRs. Although $f_{\rm MCD}$ has conventionally been used as a standard objective function to maximize the noncoherent AMI, we combine $f_{\rm NMSE}$ to maximize not only the noncoherent AMI but the total AMI. Thus, we demonstrate the advantages of using $f_{\rm SCD}$ over $f_{\rm MCD}$ via the performance comparisons in Section V.

D. Total AMI Optimization Method

In the previous sections, the new objective functions f_{NMSE} and f_{SCD} were obtained. As mentioned earlier, there is a trade-off between the NMSE of estimated channel matrices and noncoherent AMI. Thus, to maximize the total AMI, these objective functions must be optimized in a dedicated manner. For this multi-objective optimization problem, we propose optimizing a convex combination of objective functions to obtain constellations on the Pareto front for the NMSE and noncoherent AMI. Letting f_{C} and f_{R} be the objective functions for the NMSE of estimated channel matrices and noncoherent AMI, which is an upper bound for effective data rate, respectively, the total AMI maximization problem for a given ratio $\alpha \in [0, 1]$ can be represented by the minimization problem as follows:

$$\mathcal{X}^* = \underset{\mathcal{X}}{\operatorname{argmin}} \quad \alpha f_{\rm C} + (1 - \alpha) f_{\rm R}. \tag{45}$$

In our comparisons, we use $f_{\rm C}$ as $f_{\rm NMSE}$ and evaluate the difference between $f_{\rm R} = f_{\rm MCD}$ and $f_{\rm R} = f_{\rm SCD}$. In this minimization problem, the optimal value of α depends on parameters such as the number of time slots $T_{\rm g}$ and transmission bits $B_{\rm g}$. For example, in the slot configuration given in Fig. 1, when the proportion of bits in the coherent code is larger than that in the noncoherent code, the contribution of NMSE to the total AMI becomes greater, making a relatively large α optimal. Therefore, we also have to optimize α for a parameter set. For each α , we perform manifold optimization on (45) using Mopt. The total AMI is then calculated for the constellation obtained through optimization, and this serves as the score for each α . Hence, the problem of maximizing the total AMI with respect to α at a given SNR is expressed by

$$\begin{array}{ll} \underset{\alpha}{\text{maximize}} & R_{\mathrm{T}}(\mathcal{X}^*, \sigma_{\mathrm{v}}^2) \\ \text{s.t.} & \alpha \in [0, 1]. \end{array}$$
(46)

To efficiently search for the optimal α , we employ an algorithm known as the tree-structured Parzen estimator (TPE) [31], a type of Bayesian optimization. In TPE, the results of the objective function are divided into a set \mathcal{L} of α that yield good scores and a set \mathcal{G} of those that do not, then the probability density functions $l(\alpha)$ for \mathcal{L} and $g(\alpha)$ for \mathcal{G} are constructed by kernel density estimation. From these probability density functions, the α of the next trial is selected as follows:

$$\alpha = \operatorname*{argmax}_{\alpha} \frac{l(\alpha)}{g(\alpha)}.$$
(47)

Algorithm 1 Proposed total AMI optimization algorithm.

- 8: **return** α and corresponding \mathcal{X}^* that maximizes $R_{\mathrm{T}}(\mathcal{X}^*, \sigma_{\mathrm{v}}^2)$.

Output: Optimal α and \mathcal{X}^*

The optimization algorithm is summarized in Algorithm 1. In line 2, the probability density functions are constructed by kernel density estimation. In line 3, for the first few trials, random values of $\alpha \in [0, 1]$ are selected to construct the probability density functions. For each trial, (45) is optimized on selected α , and the total AMI of the obtained constellation is the score. By repeating this trial, we can obtain the optimal α using the TPE algorithm.

V. PERFORMANCE COMPARISONS

In this section, we demonstrate the performance advantage of the constellation obtained through the proposed optimization method. Here, the numbers of time slots and bits for the Grassmann constellation were set to $T_{\rm g} = 4$ and $B_{\rm g} = 8$, respectively. In the calculation of the total AMI for the optimization, SNR was set to 10 dB and the number of time slots for the data symbols was set to $T_{\rm d} = 10$ where each data symbol is 16QAM. For the construction by using our proposed optimization method, we used Optuna [32], which supports TPE, to search for the optimal value of α .

A. Advantages of $f_{\rm SCD}$ over $f_{\rm MCD}$

First, we compare the optimization objective functions $f_{\rm R} = f_{\rm MCD}$ and $f_{\rm SCD}$ in (45). For the optimization of the constellation in this comparison, the numbers of transmit and receive antennas were set to (M, N) = (1, 1). Accordingly, $B_{\rm d} = 40$, resulting in a total of $B_{\rm g} + B_{\rm d} = 48$ bits transmitted. Here, in the case of $(f_{\rm C}, f_{\rm R}) = (f_{\rm NMSE}, f_{\rm MCD})$, we set ϵ of (20) as 10^{-4} to ensure that the contributions of each objective function are balanced, as there is a large difference between the maximum values of $f_{\rm NMSE}$ and $f_{\rm MCD}$.

First, Fig. 3 shows the results of the total AMI comparison of the constellations, which were obtained through each trial of the proposed algorithm. An upper bound, which was obtained using the constellations optimized over a sufficient time by selecting α at equal intervals, is shown in the figure. As shown in Fig. 3, the results obtained using $f_{\rm SCD}$ were better than those obtained using $f_{\rm MCD}$ in terms of the total AMI. Furthermore, the search using $f_{\rm SCD}$ was stable and demonstrated the effective exploration of α . The reason why optimization using $f_{\rm MCD}$ was less effective is demonstrated in the next performance comparison.

Fig. 3. Results of total AMI optimization with respect to α .

Fig. 4. Optimization progress of noncoherent AMI and NMSE.

In Fig. 4, we compared the progress of optimization in terms of noncoherent AMI and the NMSE of the estimated channel matrices. For each constellation, the optimization was performed using random α values, and the optimization trajectories and convergence points were plotted. For optimization using $f_{\rm SCD}$, it can be observed that constellations were obtained on the Pareto front with respect to the trade-off between noncoherent AMI and NMSE. In contrast, with $f_{\rm MCD}$, the optimization either barely progressed or became excessively biased towards NMSE, resulting in a polarized outcome. Thus, Pareto-optimal constellations were rarely obtained, making $f_{\rm MCD}$ unsuitable as an optimization objective function.

B. Comparisons of Chordal Distances

On the basis of the above results, we will now present the performance of the proposed constellation, which was obtained through optimization using the proposed objective function f_{SCD} . Here, we compare the chordal distance of the proposed constellation with those of the conventional Grassmann constellations, such as Exp-Map, Cube-Split, and Mopt-MCD, which maximizes the MCD. The chordal distance distributions of the proposed constellation and conventional constellations for $(M, T_g, B_g) = (1, 4, 8)$ are shown in Fig. 5, where Exp-Map was constructed by combining different bits such as $B_g = 4 + 2 + 2$. Although algebraically constructed constellations, the other constellations, which were obtained through numerical optimization, exhibited continuous distributions. The proposed constellation, although inferior to Cube-Split and Mopt-MCD in terms of the minimum chordal distance, showed similar peaks to Exp-Map, which excels in channel estimation accuracy, suggesting that optimization including NMSE had been achieved.

We also evaluated the MCD for each $B_{\rm g}$ with the number of time slots fixed at $T_{\rm g} = 4$, as shown in Fig. 6. Here, we compared the constellations obtained through algebraic constructions: Exp-Map, Cube-Split, and Grass-Lattice. For Exp-Map and Grass-Lattice, $B_{g} = 6$ and 12 are the original configurations, whereas for Cube-Split, $B_{g} = 8$ is the original configuration; the other constellations were constructed by combining different bits. Thus, for $(M, T_g, B_g) = (1, 4, 8)$, Cube-Split achieved good MCD. Grass-Lattice is expected to perform better with larger values of $T_{\rm g}$. As shown in the figure, the constellations derived through algebraic constructions varied in MCD performance based on parameters, with the corresponding performance changed. By contrast, Mopt-MCD, which maximizes MCD through numerical optimization, consistently achieved optimal performance, suggesting flexibility across parameters. As a reference, we also plotted the MCD of the proposed constellation for $B_{\rm g} = 8$. It performed bad in terms of MCD than the others because it was optimized to maximize the total AMI rather than MCD. To investigate the advantages of the proposed constellation, we evaluated how much channel estimation accuracy and total AMI were improved in the following simulations.

C. Comparisons of NMSE and total AMI

Here, we compare the NMSE of estimated channel matrices and the total AMI of the constellation obtained by the proposed optimization method with those of the conventional Grassmann constellations and training method. The parameters were set to $(T_g, B_g) = (4, 8)$, and comparisons were made for (M, N) = (1, 1) and (M, N) = (2, 2). In addition to Mopt-MCD, we also compared a constellation further optimized using unitary matrices, as described in (28). We refer to this conventionally optimized constellation [15] as Mopt-NMSE. For the training method, we set $T_p = 4$, used QPSK symbols for the RS, and calculated the total AMI as T_dR_d . Additionally, in the case of (M, N) = (2, 2), the number of bits for the coherent codes was $B_d = 80$, meaning that the proportion of information contained in the coherent codes became larger than that of (M, N) = (1, 1).

First, the NMSE comparison results are shown in Fig. 7. The results indicated that the proposed constellation significantly reduced NMSE compared with the conventional constellations.

Fig. 5. Distribution of chordal distances with $(M, T_g, B_g) = (1, 4, 8)$.

Fig. 6. MCD comparison for increasing $B_{\mathbf{g}}$ with $(M, T_{\mathbf{g}}) = (1, 4)$.

Unlike conventional unitary matrix optimization, the proposed method optimized the subspace itself, achieving a higher channel estimation accuracy than any of the conventional constellations. Total AMI requires both channel estimation accuracy and noncoherent AMI, and we next show the extent to which this NMSE optimization improves the total AMI.

Next, the total AMI comparison results are shown in Fig. 8. These results indicated that the proposed constellation achieved superior performance across all SNRs compared with the conventional constellations. Although the conventional constellations failed to achieve improved spectral efficiency over training methods at middle SNRs, the proposed constellation surpassed the performance of the training method. Moreover, the proposed constellation achieved performance equal to or better than the conventional constellations at high SNRs. In particular, for (M, N) = (2, 2), the improvement at middle SNRs was substantial. With an increased number of antennas, the contribution of coherent AMI to the total AMI increased, which heightened the impact of NMSE and resulted in a better total AMI than those obtained using the conventional constellations. Therefore, the proposed method can be considered an effective approach to improving spectral efficiency, especially when the proportion of the coherent codes increases.

Finally, Fig. 9 shows the comparison results of the total AMI in the Rician channel model $\mathbf{Y} = \mathbf{H}'\mathbf{X} + \sigma_{v}\mathbf{V}$, where

Fig. 7. NMSE comparison with $(T_g, B_g) = (4, 8)$.

 $\mathbf{H}' = \sqrt{K/(K+1)} \cdot \exp(-2\pi j \cdot d/\lambda) + \sqrt{1/(K+1)}\mathbf{H}$ in the case of 5GHz carrier frequency. Here, we set d = 100m and $\lambda = 0.06$ m, and the K-factor of the Rician channel model is varied from -10 to 30 dB. The parameters were set as (M, N) = (1, 1) for simplicity, and the constellation obtained by the proposed method is the one optimized in the Rayleigh

Fig. 8. Total AMI comparison with $(T_g, B_g) = (4, 8)$.

fading channel model. The comparison was performed with an SNR of 10 dB. This figure shows that the proposed constellation showed the best performance regardless of the *K*-factor of the Rician channel model, whereas the performance of the other constellations and training method varies with the *K*-factor. We confirmed that the same trends were observed for the parameters of M, N, and SNR. Therefore, our proposed constellation can be effective for any channel model in general.

VI. CONCLUSIONS

In this paper, we proposed a design method for the Grassmann constellation via a numerical optimization, which simultaneously optimizes channel estimation accuracy and data transmission. In the numerical optimization, we derived an upper bound for the NMSE of estimated channel matrices and a lower bound for noncoherent AMI, and simultaneously optimized them by using a Bayesian optimization technique. The proposed objective functions demonstrate an advantage in

Fig. 9. Total AMI comparison upon increasing K-factor in Rician channel.

total AMI optimization over conventional functions in terms of enabling the acquisition of constellations on the Pareto front of NMSE and noncoherent AMI. The constellation obtained using the proposed objective function significantly outperforms conventional Grassmann constellations in terms of channel estimation accuracy, thereby achieving superior performance in terms of the total AMI and allowing for improved spectral efficiency at middle SNRs compared with conventional RS.

ACKNOWLEDGMENT

The authors would like to thank Dr. Yuto Hama from Ericsson Research, Japan, for providing valuable comments.
