(Dated: February 21, 2025)

Fermi's Golden Rule (FGR) is one of the most impactful formulas in quantum mechanics, providing a link between easy-to-measure observables – such as transition rates – and fundamental microscopic properties – such as density of states or spectral functions. Its validity relies on three key assumptions: the existence of a continuum, an appropriate time window, and a weak coupling. Understanding the regime of validity of FGR is critical for the proper interpretation of most spectroscopic experiments. While the assumptions underlying FGR are straightforward to analyze in simple models, their applicability is significantly more complex in quantum many-body systems. Here, we observe the emergence and breakdown of FGR, using a strongly interacting homogeneous spin-1/2 Fermi gas coupled to a radio-frequency (rf) field. Measuring the transition probability into an outcoupled internal state, we map the system's dynamical response diagram versus the rf-pulse duration t and Rabi frequency Ω_0 . For weak drives, we identify three regimes: an early-time regime where the transition probability takes off as t^2 , an intermediate-time FGR regime, and a long-time non-perturbative regime. Beyond a threshold Rabi frequency, Rabi oscillations appear. Our results provide a blueprint for the applicability of linear response theory to the spectroscopy of quantum many-body systems.

The framework of linear response theory is central to our understanding of how to interpret probes of complex quantum systems. For instance, connecting experimental observables to many-body quantities often relies on linear response theory via Fermi's Golden Rule (FGR) [1, 2]. FGR states that the long-time effect of a perturbation on a many-body system is given by the Fourier transform of the time correlation function of the perturbation operator with the observable. Depending on the context, this can provide crucial microscopic information on the many-body system in equilibrium, such as the spectral function [3, 4], the bulk viscosity [5], and the density susceptibility [6, 7]. The applicability of FGR is wide, ranging from scanning tunneling microscopy [8, 9], optical conductivities [10], to inelastic scattering reactions in nuclear physics [11].

The regime of validity of FGR is a problem of fundamental interest in quantum many-body physics; in strongly correlated systems, determining the validity of FGR a priori is a formidable challenge. FGR generically provides a transition rate from an initial state into a continuum under a coupling perturbation. The three underlying assumptions - a continuum to decay to, a time neither too long nor too short, and a weak coupling — are crucial. Several scenarios where these assumptions are violated have attracted theoretical interest. First, the applicability of FGR to systems with a discrete quasi-continuum was recently studied, e.g. in the context of thermalization of finite-size isolated many-body systems [12]. Secondly, at short times, it is known that FGR does not apply due to unitary time evolution [13, 14]. At long times (*i.e.* compared to the inverse level spacing of the quasi-continuum), FGR also breaks down - even if first-order perturbation theory might still apply [15]. Thirdly, in some situations, effective couplings might never be weak enough for FGR to apply, even in weakly interacting systems (see *e.g.* phonons in a weakly interacting 2D superfluid [16]).

Despite FGR's pivotal role, there is a scarcity of experimental studies of its applicability. Ultracold gases are attractive platforms to investigate such problems since their Hamiltonians are well known and coupling terms can be accurately engineered [17]. Furthermore, fast timescales associated with out-of-equilibrium many-body dynamics are often directly accessible, see *e.g.* [18–22]. Here, we map out the full dynamical response diagram of a strongly correlated quantum manybody system - here a universal spin-1/2 Fermi gas - to a timedependent momentum-independent coupling, and observe the emergence and breakdown of FGR (Fig. 1).

Conventionally, FGR arises from a linear-response analysis on a system governed by a Hamiltonian $\hat{H}_{\rm S}$ (which includes both the kinetic and interaction energies) perturbed by a probing term $V_{\rm pr}$. We assume that $V_{\rm pr}$ outcouples particles in spin state $\left|\downarrow\right\rangle$ into a noninteracting state $\left|o\right\rangle$ with driving frequency $\omega_{\rm pr}$, *i.e.* $\hat{V}_{\rm pr} = \frac{\hbar\Omega_0}{2} e^{-i\omega_{\rm pr}t} \sum_{\mathbf{k}} \hat{c}^{\dagger}_{o,\mathbf{k}} \hat{c}_{\downarrow,\mathbf{k}} + \text{h.c.}$, where Ω_0 is the bare-transition Rabi frequency characterizing the coupling strength and $\hat{c}_{\sigma,\mathbf{k}}$ (resp. $\hat{c}_{\sigma,\mathbf{k}}^{\dagger}$) is the annihilation (resp. creation) operator for particles with spin state σ and momentum $\hbar \mathbf{k}$; \hat{V}_{pr} does not couple to spin state $|\uparrow\rangle$. The main observable for studying the dynamics induced by \hat{V}_{pr} is the transition rate $R(\omega, t) \equiv d\alpha/dt$ of the fraction of outcoupled particles $\alpha \equiv N_{\rm o}(\omega, t)/N_{\downarrow}$, where N_{\downarrow} is the initial number of particles in state $|\downarrow\rangle$, t is the coupling pulse duration, and $\omega = \omega_{\rm pr} - \omega_0$ is the detuning to the bare internal-state transition. In a suitable time window, FGR provides a powerful expression for (a time-independent) R [23, 24]:

$$R(\omega, t) \to R_{\rm FGR}(\omega) = \frac{\Omega_0^2}{4N_{\downarrow}} \sum_{\mathbf{k}} A(\mathbf{k}, \xi_{k\downarrow}/\hbar - \omega) n_{\rm F}(\xi_{k\downarrow} - \hbar\omega)$$
(1)

FIG. 1. Probing a quantum many-body system: the system considered here is a homogeneous universal spin-1/2 Fermi gas, prepared in equilibrium of the Hamiltonian $\hat{H}_{\rm S}$, in the two internal states $|\uparrow\rangle$ and $|\downarrow\rangle$ (green and red circles). A probe $\hat{V}_{\rm pr}$ is turned on for a duration *t*, which couples $|\downarrow\rangle$ to the initially unoccupied state $|\circ\rangle$ (blue circles), with a (momentum-independent) bare-transition Rabi frequency Ω_0 and a detuning ω from the bare transition. The transfer fraction α is then measured, see typical absorption images of ⁶Li atoms in a box trap in the bottom right (the color is associated to the corresponding spin state, encoded in different Zeeman sublevels). A cartoon spectrum is shown in the top right, characterized by a peak frequency shift $\omega_{\rm p}$ and width Γ .

where $\xi_{k\downarrow} = \hbar^2 k^2 / (2m) - \mu_{\downarrow}$, $k = |\mathbf{k}|$, *m* is the atom's mass, μ_{\downarrow} is the chemical potential, and $n_{\rm F}(\epsilon)$ is the Fermi-Dirac distribution at energy ϵ . The most interesting quantity in Eq. (1) is the spectral function $A(\mathbf{k}, \omega') \equiv -2 {\rm Im}[G_{\rm ret}(\mathbf{k}, \omega')]$, where $G_{\rm ret}(\mathbf{k}, \omega')$ is the Fourier transform ($\omega' \leftrightarrow t$) of the retarded Green's function $G_{\rm ret}(\mathbf{k}, t) \equiv -i\Theta(t) \langle \{\hat{c}_{\downarrow,\mathbf{k}}(t), \hat{c}^{\dagger}_{\downarrow,\mathbf{k}}(0)\} \rangle$, and Θ is the Heaviside function [25]. It is typically unfeasible to determine *a priori* the range of Ω_0 and *t* over which Eq. (1) applies in a strongly correlated system.

Our platform for exploring this problem is a homogeneous unitary Fermi gas in a spin-population balanced mixture of $|\downarrow\rangle$ and $|\uparrow\rangle$. In the energy diagram of ⁶Li, the internal states $\{ |\downarrow\rangle, |o\rangle, |\uparrow\rangle \}$ correspond respectively to the three lowest Zeeman sublevels. We work at a bias magnetic field $B \approx 690$ G, for which the s-wave scattering length $a_{\rm s}$ between $|\downarrow\rangle$ and $|\uparrow\rangle$ is infinite, $1/a_s = 0$ [26]. We typically have spin populations of $N_{\downarrow} \approx N_{\uparrow} \approx 2 \times 10^5$ atoms, and a temperature $T \approx 0.15 E_{\rm F}/k_{\rm B}$, where the Fermi energy is $E_{\rm F} \approx h \times 4$ kHz. The coupling $\hat{V}_{\rm pr}$ is realized with a radiofrequency (rf) field [27]; we verified that the trapping is uniform both for the initial spin states and for $|0\rangle$ [28]. We measure α as a function of the control parameters Ω_0 and t, fixing the rf detuning to $\omega = 0.63(2)E_{\rm F}/\hbar$; this value corresponds to the peak frequency shift in the weak-drive limit, *i.e.* $\omega_{\rm p}$ for small Ω_0 (see cartoon of the spectrum in Fig. 1 [29]).

We first map the boundary where the linear response framework breaks down. Since perturbation theory generically predicts a linear relationship of R with driving power, the key signature of the nonlinear response regime is that the transfer

FIG. 2. Boundary between the linear and nonlinear response regimes. (a) Transfer fraction α versus $\hbar\Omega_0/E_{\rm F}$ for various $tE_{\rm F}/\hbar$. The dashdotted lines are fits $(\Omega_0/\Omega_{\rm C})^2$ to the data points restricted to $\alpha < 0.1$ (solid markers). The gray dashed line is the large- Ω_0 limit $\alpha = 1/2$. The dotted error bars in the bottom left are for points for which the transfer fraction is not statistically distinguished from 0. (b) Boundary $\Omega_{\rm C}$ versus t. The nonlinear (resp. linear) response regime is marked as the blue-shaded (resp. white) area. The blue dotted lines are power-law fits in the low- $\Omega_{\rm C}$ and high- $\Omega_{\rm C}$ limits; the extracted exponents are shown in adjacent legends. The red dashed lines are the theoretical predictions, see text. The red, orange, and light orange points correspond to the data sets in (a).

fraction is $\alpha \not\propto \Omega_0^2$. In Fig. 2a, we show α as a function of Ω_0 for a few selected t; here and wherever relevant, we normalize quantities relative to $E_{\rm F}$, the natural energy scale of this system. While at large Ω_0 , all transfer fractions approach the asymptotic value of 1/2 (see the gray dashed line), for small enough Ω_0 , all series feature a clear region where $\alpha \propto \Omega_0^2$. We determine this (smooth) boundary by fitting the small- α data with $\alpha = (\Omega_0 / \Omega_C)^2$. The adjustable parameter Ω_C is a convenient parameter that characterizes the crossover from the perturbative (linear response) to the non-perturbative (nonlinear response) regimes. The extracted $\Omega_{\rm C}$ for various pulse durations is shown in Fig. 2b. Notably, we observe power laws for both weak and strong drives. At strong drives, a power-law fit gives $t \propto \Omega_{\rm C}^{-1.2(1)}$; this agrees with the expectation that $\Omega_{\rm C} t \sim 1$ in the large- Ω_0 regime where the quantum dynamics would be dominated by Rabi oscillations between the internal states $|\downarrow\rangle$ - $|o\rangle$. For weak drives, we find instead $t \propto \Omega_{\rm C}^{-2.1(4)}$, which agrees with the expectation that $\alpha \propto \Omega_0^2 t$ in FGR's regime.

FIG. 3. Dynamics in the linear response regime and emergence of FGR. Time series of the transfer fraction $\alpha(t)$ are shown for various Ω_0 and postselected such that $\alpha < 0.1$ and t < 12 ms [28]. Both in the main panel and the lower inset, the red (resp. gray) dash-dotted line is the universal quadratic $\alpha = \frac{1}{4}\Omega_0^2 t^2$ at early times (resp. a fit $\alpha = \frac{Z}{4}\Omega_0^2 t^2$, where Z = 0.70(4) and the band represents the uncertainty). Upper inset: spectral response $I_{FGR}(\omega)$ measured in FGR's regime (see text). Near the peak, we use $\Omega_0 = 2\pi \times 45(3)$ Hz for t =5 ms. Away from the peak, we typically use $\Omega_0 = 2\pi \times 140(5)$ Hz, for t = 1.5 ms to improve the signal [28]. The solid line is an interpolation used to determine α via Eq. (2); see the corresponding solid black lines in the main panel and lower inset. As the short-time behavior of α is dictated by the high- ω part of the rf spectrum, the solid black lines are limited by the range of ω over which I_{FGR} was measured (see [28] for a discussion of extrapolations). The dotted blue line in the main panel is determined from the peak spectral response Ipeak. Lower inset: Early-time dynamics. The ideal-gas data (in practice, a single-component Fermi gas) is shown as red points and a fit gives $\alpha/\Omega_0^2 = 0.26(2) \times t^{2.02(5)}$ in excellent agreement with the theoretical limit.

We now use this boundary to focus on the time dynamics within the linear response regime. In Fig. 3, we show the transfer fraction $\alpha \cdot (E_{\rm F}/\hbar\Omega_0)^2$ - the normalization is chosen for the perturbative regime - as a function of the normalized time $E_{\rm F}t/\hbar$ for various Ω_0 . We only display data such that $\alpha < 0.1$ and observe that all data sets collapse onto a unique curve.

At long times $(E_{\rm F}t/\hbar \gtrsim 70)$, the normalized α approaches a scaling $\propto t$ characteristic of FGR's regime (see the dotted blue line in Fig. 3), irrespective of Ω_0 . In the regime where $\alpha \propto \Omega_0^2 t$, we measure the dimensionless linear response spectrum $I_{\rm FGR} \equiv \alpha \cdot (E_{\rm F}/\hbar\Omega_0^2 t) = R_{\rm FGR}(\omega) \cdot (E_{\rm F}/\hbar\Omega_0^2)$ as a function of the normalized detuning $\hbar\omega/E_{\rm F}$, see upper inset of Fig. 3 [30].

At short times $(E_{\rm F}t/\hbar \lesssim 3)$, the transfer fraction exhibits a t^2 scaling. At extremely short times, we expect the universal limit $\alpha \cdot (E_{\rm F}/\hbar\Omega_0)^2 \approx (E_{\rm F}t/\hbar)^2/4$, which reflects the normalization of the spectral function [28] (red dot-dashed line). In the lower inset, we show the data taken for the ideal gas

(red points), which closely follows that expectation (red dotdashed line). However, for the shortest times accessed in our work, we find that the interacting-gas measurements are well described by $Z \cdot (E_{\rm F}t/\hbar)^2/4$, with Z = 0.70(4) (gray dotdashed line and band). A well-defined value of Z at intermediate times is indicative of a separation of scales in the spectral response, with a well-defined peak of area Z [31].

More generally, linear response theory implies a powerful link between FGR's spectrum of Eq. (1) - presumably valid only at long times - and the dynamics of the transfer fraction $\alpha(\omega, t)$ at all times t [28]:

$$\alpha(\omega, t) = t^2 \int_{-\infty}^{\infty} \frac{\mathrm{d}\omega'}{2\pi} \operatorname{sinc}^2\left(\frac{\omega' - \omega}{2}t\right) R_{\mathrm{FGR}}(\omega'), \quad (2)$$

where $\operatorname{sinc}(x) \equiv \operatorname{sin}(x)/x$. This result is the many-body counterpart of the textbook finite-time form of FGR [32]. Based on a generic form for R_{FGR} of typical width Γ (inset of Fig. 3 and cartoon of Fig. 1), we can qualitatively discuss the various spectroscopic regimes, at a fixed detuning ω . In this work, we focus on the near-resonant case $\omega \approx \omega_{\text{p}}$.

When $t \gg \Gamma^{-1}$, the sinc² becomes much narrower than $R_{\rm FGR}$. This is *FGR's regime*, for which Eq. (2) implies that the transfer fraction $\alpha = \lambda t$, where $\lambda \equiv R_{\rm FGR} \propto \Omega_0^2$ is FGR's transition rate. Note that Ω_0 has to remain low enough for Eq. (2) to be valid (especially $\alpha \ll 1$ so that $\lambda t \ll 1$). Secondly, in the limit $t \ll \Gamma^{-1}$, one finds $\alpha = \Omega_0^2 t^2/4$, the (*time-)quadratic regime*, which is the early-time behavior expected for a driven two-level system; in the strong drive limit, the criterion of small transfer fraction is $\Omega_0 t \ll 1$. Both these regimes, characterized by the scaling $\alpha \propto \Omega_0^2$, are described by linear response theory.

Using the experimentally measured $R_{\rm FGR}$ (the solid black line interpolation in the upper inset of Fig. 3), we can compute $\alpha(\omega, t)$ via Eq. (2). The result, shown as the solid black line in the main panel agrees very well with the data, even away from FGR's regime $E_{\rm F}t/\hbar \lesssim 70$.

The applicability of FGR has important implications for the interpretation of rf spectra measurements [4, 33]. Therefore, we now focus on a more careful examination of the boundary of FGR, in the low- Ω_0 regime. We take spectra analogous to the upper inset of Fig. 3 for various Ω_0 , with a pulse duration $t \approx 2\pi/(5\Omega_0)$; since we remain close to FGR's regime, we also normalize the more general spectra to $I \equiv \alpha \cdot (E_{\rm F}/\hbar\Omega_0^2 t)$. From each of those spectra, we extract the peak frequency shift $\omega_{\rm p}$, the (full width at half-maximum) width $\Gamma_{\rm fit}$ and peak spectral response $I_{\rm peak}$ using a smooth interpolation of the data [28]; we show the results in Fig. 4. Two examples of spectra are shown in the inset of Fig. 4, one within (light red points) and one beyond (dark red points) FGR's regime for $\omega \approx \omega_{\rm p}$.

The measured $\omega_{\rm p}$ is largely insensitive to $\hbar\Omega_0/E_{\rm F}$; this justifies *a posteriori* our choice of fixing the rf detuning to the low- Ω_0 value of $\omega_{\rm p}$. On the other hand, $\Gamma_{\rm fit}$ and $I_{\rm peak}$ vary significantly, even down to surprisingly low $\hbar\Omega_0/E_{\rm F}$. It is only for $\hbar\Omega_0/E_{\rm F} \lesssim 10^{-2}$ that $\Gamma_{\rm fit}$ and $I_{\rm peak}$ level off and

one reaches the Ω_0 -independent regime. The gray lines correspond to the same spectral properties calculated from Eq. (2)(see caption). The good agreement indicates that the variation of the spectral properties even in the linear response regime can be understood by a finite pulse area effect. In particular, we find in the low-power limit that the spectral width is $\hbar\Gamma_0/E_{\rm F} = 0.24(6)$. Under typical weak drives used before [4, 33], $\Gamma_{\rm fit}$ can be 50% larger - or more - than Γ_0 . Furthermore, we verify the scaling in time by extracting I_{linfit} , defined as a linear fit to $\alpha(\omega_{\rm p}, t) \cdot \frac{E_{\rm F}}{\hbar\Omega_0^2}$ up to a pulse duration $t = 2\pi/(5\Omega_0)$, see light orange points in Fig. 4. The agreement with I_{peak} is very good, which highlights that a clean linear-response-like scaling $\alpha \propto t$ does not guarantee the validity of FGR. This shows that even with seemingly reasonable choices of Rabi frequencies and pulse areas, systematic errors can arise from deviations to FGR.

FIG. 4. Spectral properties near FGR's regime. The normalized peak frequency shift $\hbar \omega_{\rm p}/E_{\rm F}$, spectral width $\hbar \Gamma_{\rm fit}/E_{\rm F}$, and peak spectral response $I_{\rm peak}$ are determined from the spectra $I(\omega)$ for various Ω_0 (for a pulse area $\Omega_0 t \approx 2\pi/5$); see examples in the inset. The transfer rate $I_{\rm linfit}$ is determined from a linear fit to the time series $\alpha(\omega_{\rm p}, t) \cdot \frac{E_{\rm F}}{\hbar\Omega_0^2}$. The dashed gray lines are calculated from Eq. (2) using as input FGR's spectrum of the upper inset of Fig. 3, and $t = 2\pi/(5\Omega_0)$. Inset: Examples of spectra within (light red) and beyond (dark red) FGR's regime. Dotted lines show the smooth interpolation [28] used for extracting spectral properties. The corresponding Ω_0 of the spectrum can be read from the matching marker color in the main plot.

For large enough drives, the non-perturbative dynamics will ultimately consist of Rabi oscillations, which can exhibit many-body effects [22, 34, 35]. We now examine the emergence of those oscillations. In Fig. 5a we show a map of the dynamics of $\alpha(t)$ as a function of t and Ω_0 . At low Ω_0 , $\alpha(t)$ is mostly monotonically increasing. For Ω_0 larger than a threshold Ω_{thres} , Rabi oscillations appear, with an oscillation frequency $\Omega_{\text{R}} \sim \Omega_0$; we determine that $\hbar \Omega_{\text{thres}}/E_{\text{F}} = 0.17(2)$

FIG. 5. Threshold for Rabi oscillations. (a) Time series $\alpha(t)$ for various $\hbar\Omega_0/E_{\rm F}$. The dash-dotted line and the six-point star indicate the threshold Rabi frequency $\hbar\Omega_{\rm thres}/E_{\rm F}$. (b) Oscillation frequency $\Omega_{\rm R}$ (red points) and decay rate $\Gamma_{\rm R}$ (blue points) extracted from fits to the time series (see text and [28] for details). The open symbols correspond to $\Omega_0 \lesssim \Omega_{\rm thres}$.

(see time series in [28]). Calculating this threshold theoretically is a complex out-of-equilibrium many-body problem. However, we remark that $\Omega_{\text{thres}}/\Gamma_0 = 0.7(2)$, which suggests, somewhat analogously to the atom-photon case [32], that this transition occurs in a many-body system when the Rabi frequency is comparable to the continuum width. Recent measurements on the highly spin-imbalanced Fermi gas [22] (*i.e.* $N_{\downarrow} \ll N_{\uparrow}$) also support this idea; indeed, from the data in [22], we extract $\Omega_{\text{thres}}/\Gamma_0 = 0.8(2)$.

For $\Omega_0 > \Omega_{thres}$, we extract the oscillation frequency Ω_R and the decay rate Γ_R from a fit, see Fig. 5b. The renormalized oscillation frequency $(\Omega_R/\Omega_0)^2$ shows a plateau at low Ω_0 , down to $\Omega_0 \approx \Omega_{thres}$. Its plateau value $(\Omega_R/\Omega_0)^2 =$ 0.73(5) is close to an analogous measurement in the highly-

FIG. 6. Dynamical response diagram of the universal spin-1/2 Fermi gas versus the coupling control parameters Ω_0 and t. The dotted lines denote the (non-sharp) boundaries between regimes; λ and Γ_0 are FGR's transition rate and spectral width. The stars represent the rescaled data from Fig. 2, illustrating the condition where $\alpha = 10\%$. Diamond and square markers, which correspond to various measurements from Figs. 3-4, with matching colors, highlight the boundaries between different regimes. The dash-dotted line and six-point star indicate the threshold frequency for Rabi oscillations as in Fig. 5, and the band represents the uncertainty.

imbalanced Fermi gas, 0.63(3) [22, 36]. For $\hbar\Omega_0 \gtrsim E_{\rm F}$, $\Omega_{\rm R}/\Omega_0$ rises rapidly. At high Ω_0 , $\Omega_{\rm R}$ approaches Ω_0 ; in that regime, $\Omega_0/\Gamma_0 \gtrsim 15$, so that the many-body system can be approximated as a two-level system [32, 37]. At low Ω_0 , $\Gamma_{\rm R}$ decreases with Ω_0 , without reaching a nonzero limit. At $\Omega_0 \approx 4E_{\rm F}/\hbar$, $\Gamma_{\rm R}$ approaches a maximum, $\hbar\Gamma_{\rm R} \approx 4E_{\rm F}$. The analogous measurements in the highly-imbalanced system were connected to many-body properties of the dressed (Fermi polaron) impurity, *e.g.* the quasiparticle residue and its lifetime [22]. Intriguingly, even though such simple interpretations are elusive in this spin-balanced system (as there is no small parameter, and no well-defined quasiparticles in the normal phase), the results are qualitatively similar [28, 38].

Finally, we gather all the above results to sketch the dynamical response diagram versus the control parameters t and Ω_0 , for $\omega \approx \omega_p$, see Fig. 6 [39]. The stars mark the boundary between the linear and non-perturbative (nonlinear) response regimes. The diamonds mark on the low-t end the border of the quadratic regime $\alpha \propto t^2$ (red area) and on the hight end the border to FGR's regime (golden area). The typical timescale that separates the two is $1/\Gamma_0$, although the prefactors are quite large, *e.g.* the onset time for FGR's regime is $t^* \approx 20\Gamma_0^{-1}$. The square marks Ω_0^* , the largest Ω_0 for which an FGR regime exists; we find $\Omega_0^* \approx 0.05\Gamma_0$. Finally, the sixpointed star indicates the location of Ω_{thres} , the threshold for Rabi oscillations (white hatched region) [40].

In summary, we mapped out the various dynamical regimes

of a strongly correlated quantum many-body system coupled to a probe, revealing the emergence of FGR's regime. The surprisingly low driving power (in natural units) that marks the boundary of FGR's regime serves as a cautionary tale: it shows the importance of careful examination of scalings with time and coupling strength in order to apply FGR's interpretation for the spectroscopy of a complex system.

The mapping achieved in this work is generic, as it applies to a system with a spectrum consisting of a peak (of spectral weight < 1) of width Γ . In the future, it would be interesting to explore the analogous diagram for a system with a more complex spectrum, *e.g.* multiple peaks (for instance, on the BEC side, $a_s > 0$). Furthermore, exotic early time behaviors, such as two distinct quadratic regimes, could be observed if the spectral response exhibits a scale separation.

Another interesting avenue is the weak-drive long-time dynamics of this system. While the simpler case of discrete level-to-continuum is amenable to the non-perturbative Wigner-Weisskopf approach [32, 41], our many-body setting is more complex as the long-time spin populations generally tend to a nontrivial mixture of $\{|\downarrow\rangle, |o\rangle, |\uparrow\rangle\}$. However, preliminary measurements suggest that even in this situation, long-time dynamics are nearly exponential-like.

On the theoretical side, it is a challenge to interpret and calculate the threshold power for Rabi oscillations. Furthermore, the qualitative similarities between the Rabi oscillations of the Fermi polaron and the much more complex spin-balanced unitary gas might point to intriguing opportunities to understand many-body systems without small parameters from a (seemingly unrelated) impurity limit [42, 43].

- [27] Final-state interactions between atoms in state $|o\rangle$ and the atoms in $|\uparrow\rangle$ and $|\downarrow\rangle$ are small, with $k_{\rm F}a_{{\rm s},o\sigma} \lesssim 0.2$ where $\hbar k_{\rm F} = \sqrt{2mE_{\rm F}}$ is the Fermi momentum and $a_{{\rm s},o\sigma}$ is the s-wave scattering length between the atoms in outcoupled state and the initial states, $a_{{\rm s},o\uparrow} \approx 1200a_0$ and $a_{{\rm s},o\downarrow} \approx 1400a_0$ (a_0 is the Bohr radius) [44].
- [28] See Supplementary Material.
- [29] Note that the validity range of FGR (with respect to Ω_0) is most restricted at the peak frequency shift [28].
- [30] Interestingly, the numerical integral of the spectrum shown is ≈ 1 when the upper cutoff is $\hbar\omega/E_{\rm F} \approx 1.5$. The expected normalization $\pi/2$ is achieved by complementing it with an extrapolated high- ω tail that corresponds to a Tan's contact of $C/(Nk_{\rm F}) \approx 3$ [4, 45, 46].
- [31] Suppose that the spectrum has a well-defined peak of width Γ immersed in a wider incoherent background of width $\Gamma_{\rm inc} \gg \Gamma$. At the earliest time, $t \ll \Gamma_{\rm inc}^{-1}$, we still expect $\alpha(t) = \Omega_0^2 t^2/4$ due to the normalization $\int_{-\infty}^{\infty} R_{\rm FGR} d\omega' = \frac{\pi}{2} \Omega_0^2$. In the intermediate regime $\Gamma_{\rm inc}^{-1} \ll t \ll \Gamma^{-1}$, one expects $\alpha(t) = Z \Omega_0^2 t^2/4$, where $Z = \frac{2}{\pi \Omega_0^2} \int_{\mathcal{C}} R_{\rm FGR} d\omega'$ is the spectral weight

under the peak and C is an interval of size $\sim \Gamma$ around the peak; this situation typically encountered in the Rabi oscillation spectroscopy of impurities [22, 34]. While this statement applies to a quasiparticle peak (for which Z is the quasiparticle residue), this statement is more general and would be valid for spectral features for which Γ is not necessarily much smaller than the energy, thus do not represent standard quasiparticles.

- [37] G. Baym, C. J. Pethick, Z. Yu, and M. W. Zwierlein, Phys. Rev. Lett. 99, 190407 (2007).
- [38] A notable qualitative difference is that for the spin-balanced case $\Omega_{\rm R}/\Omega_0 \leq 1$ while in the impurity case, $\Omega_{\rm R}/\Omega_0 > 1$ at large Ω_0 [22].
- [39] The diagram away from $\omega_{\rm p}$ will be qualitatively similar as long as $|\omega - \omega_{\rm p}| \lesssim \Gamma_0$. For far-off-resonant drives, there will be more notable differences. For instance, even for low Ω_0 , damped Rabi oscillations ($\propto \frac{\Omega_0^2}{\omega^2} \sin^2(\omega t/2)$), whose frequency and lifetime depend on ω and Γ_0 respectively, will be observed at early times, before entering FGR's regime.
- [40] Note that the Rabi-oscillation and the linear response regimes overlap at early times. While full Rabi oscillations are not visible in Fig. 3 (since it is limited to the linear response regime), their initial t^2 behavior is (for $\Omega_0 > \Omega_{\text{thres}}$).

I. DENSITY HOMOGENEITY OF THE INITIAL AND OUTCOUPLED INTERNAL STATES

The realization of uniform quantum gases confined in optical boxes greatly simplifies the interpretation of density-dependent phenomena and eliminates inhomogeneous broadening in spectroscopy [17, 47]. Here we characterize the density homogeneity of the initial spin mixture and of the outcoupled state. Our system initially consists of a two-component gas of ⁶Li fermions in a spin-balanced mixture. The atoms are trapped in a cylindrical optical box trap (for more technical details, see *e.g.* [33, 48]). Examples of *in situ* absorption images of the occupied internal state $|\downarrow\rangle$ before the spectroscopic probe and the final outcoupled state $|o\rangle$ after the spectroscopic probe are shown on the left of Fig. S1. The density profiles correspond respectively to the cuts along the dashed line on the OD images (the middle and rightmost profiles are respectively the cuts along the radial and axial directions). These profiles agree very well with fits that assume a homogeneous density inside the box (see solid lines).

FIG. S1. Spatial homogeneity of the initial spin-mixture and of the outcoupled state in the optical box. The upper (resp. lower) row corresponds to the state $|\downarrow\rangle$ before the spectroscopic probe (resp. $|o\rangle$ after the spectroscopic probe). The color code is the same as Fig. 1 of the main text. The solid lines on the density profile cuts are fits assuming a uniform density distribution within a box trap. The vertical dotted lines mark the edge of the box trap and are located at the same position for each column. Here $N_{\downarrow} = 1.71(5) \times 10^5 (\approx N_{\uparrow})$ and $N_0 = 2.2(1) \times 10^4$.

II. VALIDITY RANGE OF FGR AWAY FROM THE RESONANCE

The validity range of FGR with respect to Ω_0 is ω dependent and is most stringent at $\omega = \omega_p$. In the main text, we observed the on-resonance power broadening of the spectral response. Here we briefly look into the applicability of FGR away from

 $\omega_{\rm p}$. In Fig. S2, we show the measurement of the linear transfer rate $I_{\rm linfit}$ for a detuned drive of frequency $\hbar\omega/E_{\rm F} = 0.76(2)$, which is approximately $\Gamma_0/2$ away from $\omega_{\rm p}$ (see blue points in the inset of Fig. S2); we use pulses of duration up to $2\pi/(5\Omega_0)$. We show this data alongside the original data of the lower panel of Fig. 4 (orange points). For the detuned drive, the response remains unchanged up to $\hbar\Omega_0/E_{\rm F} \approx 0.07$; in the resonant case, deviations can already be seen for $\hbar\Omega_0/E_{\rm F} \gtrsim 0.01$.

FIG. S2. Validity of FGR away from the resonance. The linear rate is extracted with a linear fit of the transfer fraction with pulse durations up to $t = 2\pi/(5\Omega_0)$. Inset: same spectrum as in the upper inset of Fig. 3, where color markers are adjusted to match the main panel, *i.e.* the blue (resp. orange) point corresponds to the detuned (resp. on-resonance) response. Note that for this spectrum, $\hbar\Gamma_0/E_F \approx 0.24$.

III. EXTRACTION OF SPECTRAL PROPERTIES

FIG. S3. Robustness of spectral property extraction. (a) Example of an rf spectrum, together with two models for extracting the spectral properties. The solid blue (resp. dashed beige) line is a smoothened interpolation using an SG filter (resp. fitting with Lorentzian lineshape). (b) Comparison between the spectral properties extracted using the two models; the color style is the same as in (a).

In Fig. 4 of the main text, we extracted properties from the measured spectra using smoothened interpolations of the data

via a Savitzky–Golay (SG) filter [49]. To validate the robustness of these extracted properties, we also use a Lorentzian fitting function. An example of a direct comparison on a typical spectrum is shown in Fig. S3a. In Fig. S3b, we also show the comparison of the extracted spectral properties. The parameters largely match (even though the Lorentzian fit performs badly in the tails of the spectrum).

IV. CALIBRATION OF Ω_0 AND MAGNETIC FIELD STABILITY

Here we present the calibration of the bare-transition Rabi frequency Ω_0 between internal states $|\downarrow\rangle$ and $|o\rangle$. We prepare a fully polarized Fermi gas in $|\downarrow\rangle$ and apply a resonant rf pulse for a duration t. Typical Rabi flops are shown in Fig. S4a, with the solid lines representing sine-squared fits to the data.

To provide an upper bound to our magnetic field stability, we show an rf spectrum in Fig. S4b taken for a pulse duration of 12 ms. The solid line is a fit to a sinc-squared function, whose FWHM is $2\pi \times 70(4)$ Hz; this agrees well with the expected Fourier limit $\approx 2\pi \times 73.8$ Hz. This implies that our magnetic field stability is better than ≈ 35 mG.

In Fig. 3, we restricted the data to pulse durations below 12 ms. In Figs. S4a and c, we show the data for pulse durations longer than 12 ms as open markers. Although the transfer fraction is low, $\alpha < 0.1$, we observe a deviation from the predicted solid black line. We attribute this to the magnetic field drifts over longer times.

FIG. S4. Calibration of Ω_0 and magnetic field stability. (a) Rabi oscillations of fully polarized gases using on-resonant rf. The solid lines are fits to the data. The dotted lines are the extension of the fits and the open markers are beyond the pulse duration where the Fourier-limited spectrum can be achieved. (b) Rf spectrum of a fully polarized gas that is Fourier limited for a pulse duration of t = 12 ms. The solid line is a fit using sinc-squared function. (c) Deviation from linear-response expectation due to magnetic field noise. The solid-marker data, the solid black line, and the dotted blue line are the same as in Fig. 3. Open markers are the measurements beyond our limit of 12 ms.

V. LINEAR RESPONSE THEORY: FGR AND BEYOND

In this section, we formally prove the different regimes that appeared in the linear response framework as depicted in Fig. 6. We use the lowest three hyperfine states of 6 Li, with the general Hamiltonian

$$\hat{H} = \hat{H}_{\rm S} + \hat{V}_{\rm pr} \tag{S1}$$

where $\hat{H}_{\rm S}$ is the system Hamiltonian that includes the kinetic energy and the interaction energy, and

$$\hat{V}_{\rm pr} = \frac{\hbar\Omega_0}{2} s(t) e^{-i\omega_{\rm pr}t} \sum_{\mathbf{k}} \hat{c}^{\dagger}_{\mathbf{o},\mathbf{k}} \hat{c}_{\downarrow,\mathbf{k}} + \text{h.c.}$$
(S2)

is the spectroscopic probe that couples state $|\downarrow\rangle$ and $|o\rangle$ with a driving frequency $\omega_{\rm pr}$, where Ω_0 is the bare-transition Rabi frequency, s(t) is the temporal profile of the rf field and is assumed to be a square pulse in the main text for simplicity, $\hat{c}_{\sigma,\mathbf{k}}$ ($\hat{c}^{\dagger}_{\sigma,\mathbf{k}}$)

is the annihilation (creation) operator for particles with state σ and momentum $\hbar \mathbf{k}$, and h.c. is the hermitian conjugate. We then use the transition rate as the observable, which is defined as

$$\hat{R} \equiv \frac{1}{N_{\downarrow}} \frac{\mathrm{d}N_{\mathrm{o}}}{\mathrm{d}t} = \frac{i}{\hbar N_{\downarrow}} [\hat{V}_{\mathrm{pr}}, \hat{N}_{\mathrm{o}}] = -i \frac{\Omega_{0}}{2N_{\downarrow}} s(t) e^{-i\omega_{\mathrm{pr}}t} \sum_{\mathbf{k}} \hat{c}^{\dagger}_{\mathrm{o},\mathbf{k}} \hat{c}_{\downarrow,\mathbf{k}} + \mathrm{h.c.},$$
(S3)

where $\hat{N}_{o} = \sum_{\mathbf{k}} \hat{c}^{\dagger}_{o,\mathbf{k}} \hat{c}_{o,\mathbf{k}}$ is the number operator of the outcoupled particles, and N_{\downarrow} is the initial number of particles in state $|\downarrow\rangle$.

A. Linear response theory of the transfer rate

Using linear response theory and assuming $|o\rangle$ is non-interacting with both $|\downarrow\rangle$ and $|\uparrow\rangle$, the time evolution of the transition rate in the interaction picture under rotating wave approximation, which is denoted by the superscript $\hat{R}^{I}(\omega,t) = e^{i\hat{H}_{\rm S}t/\hbar}\hat{R}(\omega,t)e^{-i\hat{H}_{\rm S}t/\hbar}$, is [50]

$$\begin{split} R(\omega,t) &\equiv \langle \hat{R}^{I}(\omega,t) \rangle = -\frac{i}{\hbar} \int_{-\infty}^{\infty} \mathrm{d}t' \Theta(t-t') \Big\langle \left[\hat{R}^{I}(t), \hat{V}_{\mathrm{pr}}^{I}(t') \right] \Big\rangle_{0} \\ &= \frac{\Omega_{0}^{2}}{4N_{\downarrow}} \sum_{k} \int_{0}^{t} \mathrm{d}t' \; e^{i(\xi_{k\downarrow}/\hbar - \omega)(t-t')} (-i) G_{\downarrow}^{<}(\mathbf{k}, t-t') + \mathrm{c.c.} \\ &= \frac{\Omega_{0}^{2}}{4N_{\downarrow}} \sum_{k} \int_{0}^{t} \mathrm{d}t' \int_{-\infty}^{\infty} \frac{\mathrm{d}\omega'}{2\pi} \; e^{i(\xi_{k\downarrow}/\hbar - \omega - \omega')(t-t')} A(\mathbf{k}, \omega') n_{\mathrm{F}}(\hbar \omega') + \mathrm{c.c.}, \end{split}$$
(S4)

where $\langle \cdot \rangle_0$ is the average over the equilibrium ensemble without the probe, $\omega = \omega_{\rm pr} - \omega_0$ is the detuning, $G_{\downarrow}^{<}(\mathbf{k}, t - t') \equiv i \langle \hat{c}_{\downarrow,\mathbf{k}}^{\dagger}(t') \hat{c}_{\downarrow,\mathbf{k}}(t) \rangle_0$ is the lesser Green's function, $A(\mathbf{k},\omega)$ is the spectral function related to the Fourier transform of the lesser Green's function through $A(\mathbf{k},\omega)n_{\rm F}(\hbar\omega) = G_{\downarrow}^{<}(\mathbf{k},\omega) \equiv \int_{-\infty}^{\infty} e^{-i\omega t} G_{\downarrow}^{<}(\mathbf{k},t) \mathrm{d}t$, and $n_{\rm F}(\epsilon) = 1/(e^{(\epsilon-\mu)/k_{\rm B}T} + 1)$ is the Fermi-Dirac distribution. A square pulse is assumed for the equation as well.

B. Long-time limit: FGR

In the appropriate time range, FGR provides the simple expression for the rf spectrum $R_{\rm FGR}(\omega)$

$$R_{\rm FGR}(\omega) \equiv \frac{\Omega_0^2}{4N_{\downarrow}} \sum_{\mathbf{k}} A(\mathbf{k}, \xi_{k\downarrow}/\hbar - \omega) n_{\rm F}(\xi_{k\downarrow} - \hbar\omega), \tag{S5}$$

where $\xi_{k\downarrow} = \hbar^2 k^2 / (2m) - \mu_{\downarrow}$ is the single-particle kinetic energy with $k = |\mathbf{k}|$ and chemical potential μ_{\downarrow} . The normalization of $R_{\text{FGR}}(\omega)$ is

$$\int_{-\infty}^{\infty} \frac{\mathrm{d}\omega}{2\pi} R_{\mathrm{FGR}}(\omega) = \frac{\Omega_0^2}{4}.$$
(S6)

In the main text, we defined a normalized spectrum I_{FGR} as $I_{\text{FGR}}(\hbar\omega/E_{\text{F}}) = R_{\text{FGR}}(\omega) \cdot (E_{\text{F}}/\hbar\Omega_0^2)$. This spectrum is normalized such that

$$\int_{-\infty}^{\infty} \mathrm{d}(\hbar\omega/E_{\mathrm{F}}) I_{\mathrm{FGR}}(\hbar\omega/E_{\mathrm{F}}) = \frac{\pi}{2}.$$
(S7)

C. Relation between linear response and FGR

The time evolution Eq. (S4) can be related to the long-time response Eq. (S5) by a change of variable $\omega' \rightarrow \xi_{k\downarrow}/\hbar - \omega'$

$$R(\omega, t) = 2 \cdot \operatorname{Re}\left[\int_{0}^{t} dt' \int_{-\infty}^{\infty} \frac{d\omega'}{2\pi} e^{i(\omega'-\omega)t'} R_{\mathrm{FGR}}(\omega')\right]$$

= $2t \int_{-\infty}^{\infty} \frac{d\omega'}{2\pi} \operatorname{sinc}\left[(\omega'-\omega)t\right] R_{\mathrm{FGR}}(\omega').$ (S8)

We can obtain Eq. (2) for α via an integration:

$$\alpha(\omega, t) = \int_0^t \mathrm{d}t' \ R(\omega, t') = t^2 \int_{-\infty}^\infty \frac{\mathrm{d}\omega'}{2\pi} \operatorname{sinc}^2\left(\frac{\omega' - \omega}{2}t\right) R_{\mathrm{FGR}}(\omega'). \tag{S9}$$

D. Short time limit: quadratic dependence in time

At fixed ω , the leading-order transition rate Eq. (S8) for small t is

$$R(\omega,t) \approx 2t \int_{-\infty}^{\infty} \frac{d\omega'}{2\pi} R_{\rm FGR}(\omega') = \frac{\Omega_0^2 t}{2},$$
(S10)

where we have used the normalization condition Eq. (S7). The transfer fraction is then

$$\alpha \approx \frac{\Omega_0^2 t^2}{4}.$$
 (S11)

Note that the sub-leading order can be calculated using the contact C, which characterizes the high-frequency limit of the rf spectrum [45, 51, 52]

$$R_{\rm FGR}(\hbar\omega/E_{\rm F}\gg 1) \approx \frac{\sqrt{\hbar}\Omega_0^2}{8\pi N_{\downarrow}} \frac{C}{\sqrt{m}\omega^{3/2}}.$$
 (S12)

The sub-leading correction to the transfer fraction is thus $\propto t^{5/2}$:

$$\alpha(\omega,t) \approx \frac{\Omega_0^2}{4} t^2 \left[1 - \frac{4}{15} \frac{\tilde{C}}{\pi^{3/2}} \left(\frac{t}{t_{\rm F}} \right)^{1/2} \left(1 - \frac{3}{7} \omega t \right) + \cdots \right],\tag{S13}$$

where $t_{\rm F} \equiv h/E_{\rm F}$, and $\tilde{C} \equiv C/(N_{\downarrow}k_{\rm F})$.

E. Generalization for arbitrary pulse form

In both the main text and previous sections, a square pulse is assumed for simplicity. Here we consider more general pulse functions s(t) as stated in Eq. (S3), in this case, Eq. (S9) becomes

$$\alpha(\omega,t) = \int_{-\infty}^{\infty} \frac{\mathrm{d}\omega'}{2\pi} \left| \int_{0}^{t} \mathrm{d}t' \, s(t') e^{i(\omega'-\omega)t'} \right|^{2} R_{\mathrm{FGR}}(\omega'), \tag{S14}$$

indicating that the transfer fraction in the linear response regime is a convolution of the truncated Fourier transform with R_{FGR} .

The long-time FGR limit is

$$\alpha(\omega, E_{\rm F}t \gg 1) = \mathcal{A}_{\rm rf}R_{\rm FGR}(\omega),\tag{S15}$$

where $\mathcal{A}_{\mathrm{rf}} \equiv \int_{-\infty}^{\infty} \mathrm{d}t |s(t)|^2$ is the pulse area.

VI. SHORT-TIME EXTRAPOLATIONS FOR FIG. 3

The short-time behavior of Eq. (2) is governed by the high-frequency part of the rf spectrum. In this section, we extrapolate the theoretical prediction shown in the inset of Fig. 3 to short times. The black dashed line corresponds to $\tilde{C} = 2.85$ (at $T/T_{\rm F} \approx 0.15$) [4, 46]; the orange shaded area represents an error band corresponding to different high-frequency extrapolations (see caption).

FIG. S5. Short-time extrapolations for the theoretical prediction for $\alpha(t)$. The markers and curves share the same format as in the inset of Fig. 3. The black dashed line corresponds to $\tilde{C} = 2.85$. The orange error band is set on the low-end by truncating the integral in Eq. (2) to the measurement frequency range, and on the high-end, by completing the data with a tail of contact $\tilde{C} = 3.5$ (a reasonable upper value set by recent measurements [4, 46]).

VII. RABI OSCILLATION PROPERTIES IN THE UNPOLARIZED AND HIGHLY-POLARIZED LIMITS

In the main text, we noticed that both the low- Ω_0 limit for $(\Omega_R/\Omega_0)^2$ and the threshold $(\Omega_{\text{thres}}/\Gamma_0)$ for the spin-balanced (unpolarized) measurements are close to those measurements in the highly-polarized (Fermi polaron) limit [22]. This is especially intriguing as $(\Omega_R/\Omega_0)^2$ coincides with the Fermi polaron quasiparticle residue in the low- Ω_0 limit, while such an interpretation is not straightforward for the unpolarized case. In this section, we present a systematic comparison of the Rabi oscillation properties between the unpolarized and highly-polarized cases.

In Fig. S6a, we show four examples of the oscillation data. The first (squares) and second series (upper triangles) are respectively below and above the threshold Rabi frequency (recall that the Fermi energy is $E_{\rm F}/h \approx 4$ kHz). The solid lines are fits to a simple model $\alpha(t) = A \left(1 - e^{-\Gamma_{\rm R} t/2}\right) - B \left[\cos(\Omega_{\rm R} t) - 1\right] e^{-\Gamma_{\rm R} t/2}$; the parameters A and B are shown in Fig. S6b. The value of A gives the long-time asymptotic level of α , and it remains a constant of 0.5 across a wide range of Ω_0 . The value of B gives the oscillation amplitude; it increases monotonically with Ω_0 , indicating higher-quality oscillations at large Ω_0 . In Fig. S6c, we show the renormalized oscillation frequency $\Omega_{\rm R}$, the decay rate $\Gamma_{\rm R}$ and their ratio (the quality factor Q). It is striking that for both $\Omega_{\rm R}$ and Q the data sets are quantitatively very close.

In the absence of well-defined quasiparticles in the normal unpolarized unitary gas, it is unsurprising that $\Gamma_{\rm R}$ is significantly larger than in the highly-polarized Fermi gas (which is a clean Fermi liquid of polarons [53]), as shown by the middle panel of Fig. S6c. However, the qualitative behaviors of $\Gamma_{\rm R}(\Omega_0)$ - marked by a local maximum around $\Omega_0 \approx 3E_{\rm F}/\hbar$ - are similar.

These similarities are particularly remarkable since the low- Ω_0 plateau of Ω_R and the local maximum of Γ_R have specific interpretations in terms of Fermi-polaron physics (respectively, the quasiparticle residue and the hybridization of a dressed polaron state with the broad-continuum remnant of the repulsive unitary polaron [22]) without obvious counterparts for the unpolarized gas. This suggests that the impurity limit of the Fermi polaron could provide a useful framework to understand the seemingly very different unpolarized unitary gas.

13

FIG. S6. Rabi oscillation spectroscopy for the spin-balanced (unpolarized) and highly polarized Fermi gases. (a) A gallery of time-series for the unpolarized gas for various Ω_0 . The solid lines are fits using the phenomenological model, see text. (b) The corresponding fitting parameters A and B (see text). (c) Comparison of the extracted parameters for the unpolarized (blue points) and the highly-polarized (orange points) [22]. The same marker style is used in (a), (b) and (c).
