Abstract

The exploration of entanglement and Bell non-locality among multi-particle quantum systems offers a profound avenue for testing and understanding the limits of quantum mechanics and local real hidden variable theories. In this work, we examine non-local correlations among three massless spin-1/2 particles generated from the three-body decay of a massive particle, utilizing a framework based on general four-fermion interactions. By analyzing several inequalities, we address the detection of deviations from quantum mechanics as well as violations of two key hidden variable theories: fully local-real and bipartite local-real theories. Our approach encompasses the standard Mermin inequality and the tight $4 \times 4 \times 2$ inequality introduced by Laskowski et al., providing a comprehensive framework for probing three-partite non-local correlations. Our findings provide deeper insights into the boundaries of classical and quantum theories in three-particle systems, advancing the understanding of non-locality in particle decays and its relevance to particle physics and quantum foundations.

1 Introduction

Quantum mechanics stands apart from classical physics due to its inherent probabilistic nature and the baffling phenomenon of entanglement [1,2]. Entanglement describes a situation where two or more particles become intrinsically linked, sharing a combined quantum state that cannot be factored into independent states for each particle. This interconnectedness, regardless of spatial separation, leads to correlations that profoundly challenge our classical intuitions and are fundamentally incompatible with local realism — the idea that physical systems have definite properties independent of measurement and that influences cannot propagate faster than the speed of light.

The seminal work of John Bell [3] provided a rigorous framework for experimentally testing the predictions of quantum mechanics against the constraints imposed by local realism. Bell-type inequalities, mathematical expressions derived from the assumption of local realism, predict upper bounds on the correlations measurable in experiments. The violation of the CHSH inequality [4], one of the Bell-type inequalities for the two-qubit system, in numerous experiments [5–12], has decisively confirmed the non-locality of quantum mechanics, demonstrating the existence of correlations that cannot be explained by any local realistic theory. The correlation measurements and corresponding observables involving Bell-type inequalities also provide a powerful framework for testing quantum mechanics itself. Quantum mechanics often gives upper bounds on these observables [13]; if a violation of these upper bounds is experimentally confirmed, quantum mechanics would be falsified.

While the violation of CHSH inequality and its experimental verification have firmly established non-locality in two-particle systems, the extension to multipartite systems presents significantly greater complexity and remains an active area of research. The intricacies of multipartite entanglement, involving three or more particles, introduce a rich landscape of correlations far exceeding the complexity of two-particle scenarios.

Understanding these multipartite correlations is crucial not only for advancing fundamental physics but also for developing emerging quantum technologies, such as quantum computing and quantum communication, where multipartite entanglement plays a central role. Following early works [14,15], there has recently been a surge of interest in exploring quantum informationtheoretic properties within the context of high-energy particle physics [16–50] (see also [51] for the recent review). Particle scattering and the decay of unstable particles provide a natural laboratory where multipartite entanglement and nonlocal correlations emerge spontaneously (see, however, [52]).¹ In this context, the ATLAS and CMS collaborations have recently measured spin correlations in the $t\bar{t}$ system produced in pp collisions at the LHC, observing entanglement within a specific phase-space region at a 5- σ significance level [53–55]. Precise measurements of

¹There are issues to conduct a loophole-free test of local realism at conventional collider experiments. Highenergy collider experiments have imperfect acceptance and detection efficiency, resulting in the detection loophole. Additionally, the spin correlation between particles A and B is only inferred indirectly from the momentum distribution of decay products of A and B, assuming Standard Model predictions or those decays behave the same way as they do in an independent experiment. Even if we accept those assumptions, we do not have the freedom to choose the spin measurement axes, as the spin measurement is constituted indirectly and statistically by analysing the momentum distributions. This makes the local realism test prone to the so-called freedom-of-choice loophole. Finally, the momenta of observed particles are essentially commuting observables. Therefore, there is always some hidden variable theory that can explain the observed momentum data. The interest of this paper is not a high-energy test of local realism. Our goal is to study what type of spin correlation emerges in different phase-space regions of three-body decays in different underlying particle interactions within the quantum field theory framework. We also discuss the spin correlation beyond quantum theories.

entanglement and non-locality observables have been recognized as valuable tools for probing non-perturbative effects within the Standard Model [34,56], as well as exploring physics beyond the Standard Model [22–25].

Another motivation lies in the potential of collider measurements of quantum properties to directly test quantum mechanics at high energy scales. It is plausible that quantum mechanics undergoes modifications at some short distance scales to achieve compatibility with gravity. Such modifications could, in principle, be detected by measuring Bell-type observables or through quantum process tomography, as outlined in [48].

Finally, studying particle physics through the lens of quantum information theory offers the potential to uncover new insights into quantum field theory. For instance, recent research has explored the interplay between a theory's internal (emergent) symmetries and the entanglement generated by specific scattering processes [42–45]. Additionally, efforts have been made to establish connections between scattering cross sections and the entanglement entropy produced during these processes [46, 47, 57–59].

While the present literature has focused on quantum properties in two-particle systems, systematic investigations of three-particle entanglement and non-locality in particle physics are significantly underexplored [26–28].

This paper addresses this gap by investigating the three-body decay of a massive fermion into three massless spin-1/2 particles, a scenario that offers a tractable yet non-trivial setting for studying three-partite entanglement and non-locality. This specific choice allows for a detailed theoretical analysis while maintaining relevance to experimentally accessible scenarios in particle physics. Utilizing a theoretical framework with general four-fermion interactions, we systematically analyze the correlations emerging from this decay process using a variety of entanglement measures and Bell-type inequalities. While we have analyzed the entanglement generated in the aforementioned decay process in our earlier work [26], the present study shifts focus to the non-locality arising from the same decay process. This study aims to quantify the degree of non-local correlations and identify the conditions under which deviations from local realistic predictions are maximized in the decay kinematic phase space. The study strives to provide a deeper and more comprehensive understanding of three-body entanglement and non-locality, bridging the gap between fundamental physics and the rapidly advancing field of quantum information science.

The rest of the paper is organised as follows. In the next section, we provide a short review of entanglement and non-locality, supplementing the necessary background and introducing some observables and formulae used in the later sections. Readers familiar with multiparticle entanglement and non-locality may wish to skip this section. In section 3, we describe the three-body kinematics and the resulting spin states. The theoretical and numerical analyses of entanglement and non-locality in the particle decays are presented in section 4. We explore these properties in three different types of four fermion interactions. Section 5 is devoted to the conclusion.

2 A Review of Basic Features of Non-locality and Entanglement

This section provides a concise overview of entanglement and nonlocality in bipartite and tripartite quantum systems. The content summarized here can be found in several review articles, such as [60–62].

2.1 Entanglement

Entanglement is known as the characteristic trait of quantum mechanics, distinguishing it from classical mechanics [1]. When two subsystems, A and B, are entangled, the prediction of measurement outcomes for A cannot be fully described independently of the state of B, and vice versa, no matter how far they are spatially separated. In contrast, quantum states without entanglement, called *separable states*, can be expressed as a simple tensor product of the local states of A and B:

$$\psi_{AB}^{\text{sep}}\rangle = |\psi\rangle_A \otimes |\psi\rangle_B. \tag{1}$$

The concept of separability extends naturally to mixed states. A mixed state is considered separable if its density operator can be written as a convex combination of tensor products of local density operators [63]

$$\rho_{AB}^{\rm sep} = \sum_{k} p_k \,\rho_{A,k} \otimes \rho_{B,k},\tag{2}$$

where $p_k \ge 0$ are probabilities satisfying $\sum_k p_k = 1$, and $\rho_{A,k}$ and $\rho_{B,k}$ are density operators for the subsystems A and B, respectively.²

If the system is inseparable, the degree of entanglement can be measured by a class of functions, $E(\rho)$, called entanglement measures (or entanglement monotones) [64]. Those functions must vanish for all separable states and positive for entangled states. Additionally, entanglement measures must be invariant under local unitary transformations, reflecting changes in the local basis. Another important property involves Local Operations and Classical Communication (LOCC) [65]. In this class of operations, two experimenters, Alice and Bob, each control subsystems A and B, respectively. They are allowed to manipulate their particles by local unitary operations and making local measurements while also communicating classically. Motivated by the fact that separable states cannot be transformed into entangled states under LOCC, entanglement measures are required to be non-increasing under LOCC.³ The above consideration also introduces the notion of maximally entangled states. Maximally entangled states cannot be reached from non-invertible LOCC from any other states.

Among several entanglement measures proposed in the literature, in this work, we use a particular one called *concurrence*, which is defined for the pure state, $|\psi_{AB}\rangle \in \mathcal{H}_{AB}$, as

$$\mathcal{C}(|\psi\rangle_{AB}) \equiv \sqrt{2(1 - \operatorname{Tr} \varrho_A^2)},\tag{3}$$

where $\rho_A = \text{Tr}_B \rho_{AB}$ is the reduced density operator of subsystem A, obtained by tracing out the degrees of freedom of subsystem B. The same result can be obtained by exchanging the role of subsystems A and B: $C(|\psi\rangle_{AB}) = \sqrt{2(1 - \text{Tr} \rho_B^2)}$. With this definition, the concurrence takes the maximum value, C = 1, for maximally entangled two-qubit states.

For a mixed state ρ , the concurrence is defined as the convex roof [66] of the pure state concurrence as

$$\mathcal{C}(\rho) \equiv \inf_{p_k, |\psi_k\rangle} \sum_k p_k \mathcal{C}(|\psi_k\rangle), \tag{4}$$

²We denote the Hilbert spaces of the subsystems A and B as \mathcal{H}_A and \mathcal{H}_B , respectively. The Hilbert space of the combined system is given by $\mathcal{H}_{AB} = \mathcal{H}_A \otimes \mathcal{H}_B$. The set of all density operators (positive semi-definite Hermitian operators with unit trace) of the Hilbert space \mathcal{H} is denoted as $\mathcal{S}(\mathcal{H})$. In this notation, $|\psi_A\rangle \in \mathcal{H}_A$, $|\psi_B\rangle \in \mathcal{H}_B$, $|\psi_{AB}\rangle \in \mathcal{H}_{AB}$, $\rho_A \in \mathcal{S}(\mathcal{H}_A)$, $\rho_B \in \mathcal{S}(\mathcal{H}_B)$ and $\rho_{AB} \in \mathcal{S}(\mathcal{H}_{AB})$.

³This property contains the invariance under local unitaries as unitary operations are invertible.

where the infimum is taken over all possible decompositions of ρ into sets of $\{p_k\}$ and $\{|\psi_k\rangle\}$ with $\rho = \sum_k p_k |\psi_k\rangle \langle \psi_k|$.

The advantage of the concurrence is that the analytical formula of $C(\rho)$ is known for twoqubit systems [67]:

$$C(\rho) = \max(0, \eta_1 - \eta_2 - \eta_3 - \eta_4) \in [0, 1],$$
(5)

where η_i are the decreasingly ordered eigenvalues of $\sqrt{\sqrt{\rho}(\sigma_y \otimes \sigma_y)\rho^*(\sigma_y \otimes \sigma_y)\sqrt{\rho}}$, obtained in the computational basis.

2.2 Three-particle entanglement

The spin state of a multiparticle final state produced from the decay of a massive particle is generally pure, provided it is evaluated at a specific point in momentum phase space.⁴ Accordingly, we focus our analysis on the general pure three-qubit state, $|\Psi\rangle \in \mathcal{H}_{ABC} =$ $\mathcal{H}_A \otimes \mathcal{H}_B \otimes \mathcal{H}_C$. In the three-qubit system, there are two types of separable states. One is called *fully separable* state, which can be written as

$$|\psi\rangle_{\rm fs} = |\alpha\rangle_A \otimes |\beta\rangle_B \otimes |\gamma\rangle_C \,. \tag{6}$$

Fully separable states contain no entanglement of any kind. The second is called *bi-separable* states, which are of the types

$$|\alpha\rangle_A \otimes |\delta\rangle_{BC}, \quad |\beta\rangle_B \otimes |\delta\rangle_{AC}, \quad |\gamma\rangle_C \otimes |\delta\rangle_{AB}, \tag{7}$$

where $|\delta\rangle_{IJ}$ may not be factorised as $|\delta_1\rangle_I \otimes |\delta_2\rangle_J$. The general bi-separable state is given by a superposition of three such kets:

$$|\psi\rangle_{\rm bs} = c_1 |\alpha\rangle_A \otimes |\delta\rangle_{BC} + c_2 |\beta\rangle_B \otimes |\delta\rangle_{AC} + c_3 |\gamma\rangle_C \otimes |\delta\rangle_{AB} \,. \tag{8}$$

with $c_i \in \mathbb{C}$ and $\sum_i |c_i|^2 = 1$.

If the state is neither fully separable nor bi-separable, it is called *genuine tripartite entangled* (GTE). There are two important GTE states: GHZ [68, 69] and W [70] states. The former is defined by

$$|GHZ\rangle = \frac{1}{\sqrt{2}} \left(|000\rangle + |111\rangle\right),\tag{9}$$

while the latter is given as

$$|W\rangle = \frac{1}{\sqrt{3}} \left(|100\rangle + |010\rangle + |001\rangle\right) \,.$$
 (10)

The importance of these states is appreciated by the fact that any GTE state can be transformed by local invertible operation, $|\Psi\rangle \rightarrow (\mathcal{O}_A \otimes \mathcal{O}_B \otimes \mathcal{O}_C) |\Psi\rangle$, either into $|GHZ\rangle$ or $|W\rangle$, respectively. Since these operations are invertible, they naturally introduce an equivalence relation. Namely, all GTE states can be classified into either the GHZ or the W class.

The generalisation of the Schmidt decomposition to three-qubit systems implies that any three-qubit pure state can be transformed by local unitaries into the canonical form [71]

$$\xi_0|000\rangle + e^{i\varphi}\xi_1|100\rangle + \xi_2|101\rangle + \xi_3|110\rangle + \xi_4|111\rangle \tag{11}$$

⁴Spin and momentum degrees of freedom are generally entangled. The spin state becomes mixed if the momentum degrees of freedom are traced out (i.e., averaged over).

with $\xi_i \ge 0$, $\sum_i \xi_i^2 = 1$ and $0 \le \varphi \le \pi$. This means that six real parameters essentially characterise the entanglement and non-local properties of three-qubit pure states. Also, it has been shown that $\xi_4 = \varphi = 0$ is required for the W class states, implying that W class states are much rare compared to the GHZ class states.

For three-qubit systems, one can consider three types of entanglement. One is an entanglement between two individual particles, say between A and B. This *one-to-one* entanglement can be computed by first tracing out subsystem C and then using formula (4):

$$C_{AB} = C(\varrho_{AB}), \quad \varrho_{AB} = \text{Tr}_C(|\Psi\rangle\langle\Psi|).$$
 (12)

The one-to-one entanglement between A-C (\mathcal{C}_{AC}) and B-C (\mathcal{C}_{BC}) can also be computed in the similar way. These entanglement measures are nonvanishing even if the state is bi-separable. For example, \mathcal{C}_{AB} can be nonzero for $|\gamma\rangle_C \otimes |\delta\rangle_{AB}$, while it vanishes for $|\alpha\rangle_A \otimes |\delta\rangle_{BC}$ and $|\beta\rangle_B \otimes |\delta\rangle_{AC}$.

Another type is an entanglement between one particle and the rest of the system, known as *one-to-other* bipartite entanglement. The concurrence between A and the composite subsystem BC is computed as follows. First, we write the general pure state as

$$|\Psi\rangle = \sum_{ijk} c_{ijk} |ijk\rangle = c_{00} |0\rangle_A \otimes |0\rangle_{BC} + c_{11} |1\rangle_A \otimes |1\rangle_{BC}$$
(13)

with $|0\rangle_{BC} = \sum_{jk} c_{0jk} |jk\rangle_{BC}$ and $|1\rangle_{BC} = \sum_{jk} c_{1jk} |jk\rangle_{BC}$, and pretend that it is a two-qubit pure state. The concurrence formula for two-qubit pure states (3) may then be used:

$$C_{A(BC)} = \sqrt{2(1 - \operatorname{Tr} \varrho_{BC}^2)}, \quad \varrho_{BC} = \operatorname{Tr}_A(|\Psi\rangle\langle\Psi|) .$$
 (14)

The one-to-other entanglement for other combinations, $C_{B(AC)}$ and $C_{C(AB)}$, can be computed in the similar manner. The one-to-other entanglement measures may be nonvanishing for biseparable states. For instance, $C_{A(BC)}$ is nonvanishing for $|\beta\rangle_B \otimes |\delta\rangle_{AC}$ and $|\gamma\rangle_C \otimes |\delta\rangle_{AB}$, but vanishing for $|\alpha\rangle_A \otimes |\delta\rangle_{BC}$.

The one-to-one and one-to-other entanglement are related by the monogamy relations [72, 73]:

$$\mathcal{C}^{2}_{A(BC)} = \mathcal{C}^{2}_{AB} + \mathcal{C}^{2}_{AC} + \tau ,
 \mathcal{C}^{2}_{B(AC)} = \mathcal{C}^{2}_{AB} + \mathcal{C}^{2}_{BC} + \tau ,
 \mathcal{C}^{2}_{C(AB)} = \mathcal{C}^{2}_{AC} + \mathcal{C}^{2}_{BC} + \tau ,$$
(15)

where τ is called three-tangle and given by

$$\tau = 4\xi_0^2 \xi_4^2 \,, \tag{16}$$

where ξ_i are the coefficients in the Schmidt decomposition (11). The first monogamy relation implies that there is a trade-off between A's entanglements with B and C. For example, when A is maximally entangled with B, A cannot be entangled with C; $\mathcal{C}_{AB} = 1 \Rightarrow \mathcal{C}_{AC} = 0$. More generally, the sum of the squared one-to-one concurrence measures is bounded from above by the corresponding one-to-other concurrence square: e.g. $\mathcal{C}_{AB}^2 + \mathcal{C}_{AC}^2 \leq \mathcal{C}_{A(BC)}^2$.

For the GHZ state, Eq. (9), $\tau = 1$. We therefore have $C_{A(BC)} = C_{B(AC)} = C_{C(AB)} = 1$, while $C_{AB} = C_{BC} = C_{AC} = 0$. In other words, any one particle is maximally entangled with the

Figure 1: The concurrence triangle and a genuinely three-particle entanglement measure F_3 .

rest of the system, although all particle pairs are individually separable. On the other hand, $\tau = 0$ for the W state in Eq. (10). One-to-one and one-to-other concurrence values are found to be $C_{AB} = C_{BC} = C_{AC} = \frac{2}{3}$ and $C_{A(BC)} = C_{B(AC)} = C_{C(AB)} = \frac{2\sqrt{2}}{3}$. The third type of entanglement is entanglement among genuinely three particles. A good

The third type of entanglement is entanglement among genuinely three particles. A good genuinely three-particle entanglement (GTE) measure should satisfy the following conditions: (1) invariant under local basis changes, (2) vanishes for all fully-separable and bi-separable states, (3) positive for all GTE states, and (4) non-increasing under LOCC. A GTE measure satisfying all these criteria has recently been found [74] (see [75] for alternative construction). The measure is motivated by the observation that the sum of any two monogamy relations is larger than the remaining one, which can be seen in Eq. (15). Since all terms in Eq. (15) are positive, one can consider the square root of each term and obtain

$$\mathcal{C}_{A(BC)} + \mathcal{C}_{B(AC)} > \mathcal{C}_{C(AB)}, \qquad (17)$$

and the similar inequality for other combinations. These inequalities guarantee that one can always draw a triangle whose three sides are given by the three one-to-other concurrence measures (*concurrence triangle*). The area of the concurrence triangle gives a GTE measure satisfying all criteria [74] (see Fig. 1). With Heron's formula, we define the GTE measure

$$F_3 \equiv \frac{4}{\sqrt{3}} \cdot \sqrt{Q(Q - \mathcal{C}_{A(BC)})(Q - \mathcal{C}_{B(AC)})(Q - \mathcal{C}_{C(AB)})}, \qquad (18)$$

with $Q = \frac{1}{2}[\mathcal{C}_{A(BC)} + \mathcal{C}_{B(AC)} + \mathcal{C}_{C(AB)}]$. With the normalisation factor $\frac{4}{\sqrt{3}}$, F_3 takes values between 0 and 1. For the symmetric case, $\mathcal{C}_{A(BC)} = \mathcal{C}_{B(AC)} = \mathcal{C}_{C(AB)} = \mathcal{C}$, we have $F_3 = \mathcal{C}^2$. One can see that the GHZ state is maximally GTE, $F_3(|GHZ\rangle) = 1$. On the other hand, for the W state, $F_3(|W\rangle) = \frac{8}{9}$; the state is highly entangled but not maximally GTE.

We stress that all the analyses here concern pure states only. The analogous quantities for mixed states are usually very hard to compute (see e.g. [76,77]).

2.3 Bell nonlocality

Bell-type inequalities distinguish between correlations that can be achieved by local real hidden variable (LRHV) theories and those that cannot. Typically, the following experiment is considered. A pair of particles, A and B, which locally interacted with each other in the past, are specially separated far apart. Two observers, Alice and Bob, who are also separated far apart, have access to each particle. Alice can measure one of the two spin components (axes) A_1 or A_2 of particle A, and Bob can measure one of the two spin components (axes) B_1 or B_2 of particle B. The corresponding outcomes of those spin component measurements are denoted by a and b for Alice and Bob, respectively. We assume the outcomes are either +1 or -1; $a, b \in \{+1, -1\}$. The experiment is repeated many times. Each time, Alice and Bob can choose which spin components they measure. After collecting a large number of measurement results, we compute the correlations $\langle A_i B_i \rangle$.

If the theory is local, Alice's measurement outcome cannot be influenced by Bob's choice of measurement axes and vice versa. If the theory is real, their measurement outcomes are predetermined before the act of measurement. Under the assumptions of locality and realism, their measurement outcomes may be described by a set of common hidden variables λ with the probability distribution $P(\lambda)$. In particular, the joint conditional probability that Alice and Bob measure A_i and B_j then obtain the outcomes a and b may be expressed in terms of λ as

$$P(a, b|A_i, B_j) = \sum_{\lambda} P_{\lambda} \mathcal{A}_{\lambda}(a|A_i) \mathcal{B}_{\lambda}(b|B_j) \dots \dots \text{ (LRHV)}$$
(19)

The function $\mathcal{A}_{\lambda}(a|A_i)$ can be interpreted as Alice's conditional probability of finding her outcome *a* for given λ and A_i . The analogous interpretation follows for Bob's function $\mathcal{B}_{\lambda}(b|B_i)$. The form of Eq. (19) encompasses the deterministic, i.e., realism picture. One can always assume that Alice's probability of finding outcome *a*, for given λ and A_i , is either 0 or 1, invoking a probability function $\overline{\mathcal{A}}_{\lambda}(a|A_i) \in \{0,1\}$. The corresponding deterministic probability for Bob is denoted by $\overline{\mathcal{B}}_{\lambda}(b|B_j) \in \{0,1\}$. The same conditional probability (19) can be described as $P(a, b|A_i, B_j) = \sum_{\lambda} \overline{P}_{\lambda} \overline{\mathcal{A}}_{\lambda}(a|A_i) \overline{\mathcal{B}}_{\lambda}(b|B_j)$, with the relations $\overline{P}_{\lambda} = P_{\lambda} Q_A(\lambda) Q_B(\lambda)$, $\mathcal{A}_{\lambda} = Q_A(\lambda) \overline{\mathcal{A}}_{\lambda}$ and $\mathcal{B}_{\lambda} = Q_B(\lambda) \overline{\mathcal{B}}_{\lambda}$ with appropriate functions $Q_A(\lambda)$ and $Q_B(\lambda)$.

In general, Bell-type inequalities have a form

$$|\langle \mathcal{B} \rangle_{\rm LRHV}| \leq \mathcal{B}_{\rm LRHV}^{\rm bound}, \qquad (20)$$

where $\langle \mathcal{B} \rangle_{\text{LRHV}}$ is the expectation value of some observable \mathcal{B} in a given LRHV theory, while $\mathcal{B}_{\text{LRHV}}^{\text{bound}}$ is the upper bound on $\langle \mathcal{B} \rangle_{\text{LRHV}}$ within this theory. One of the well-known Bell-type observables is Clauser-Horne-Shimony-Holt (CHSH) [4] observable

$$\mathcal{B}_{\text{CHSH}} = A_1 B_1 + A_1 B_2 + A_2 B_1 - A_2 B_2 \,. \tag{21}$$

The bound by LRHV theories can be estimated by invoking locality, writing $\mathcal{B}_{\text{CHSH}} = A_1(B_1 + B_2) + A_2(B_1 - B_2)$. By the assumption of realism, when the outcomes of B_1 and B_2 being predetermined, either $(B_1 + B_2)$ or $(B_1 - B_2)$ has to vanish. The largest value for the other term is 2. Therefore, one can find the bound of Bell-type inequality by LRHV theory to be,

$$|\langle \mathcal{B}_{\text{CHSH}} \rangle_{\text{LRHV}}| \le 2.$$
(22)

This bound is violated by quantum mechanics. For example, by taking A_1 and A_2 to be σ_z and σ_x and B_1 and B_2 be $(\sigma_z \pm \sigma_x)/\sqrt{2}$, one finds

$$\langle \mathcal{B}_{\text{CHSH}} \rangle_{|\psi\rangle_{00}} = 2\sqrt{2},$$
 (23)

with $|\psi\rangle_{00}$ being the spin-0 singlet state, $|\psi\rangle_{00} = (|01\rangle - |10\rangle)/\sqrt{2}$. The quantum states which violate Bell-type inequality are called Bell-nonlocal.

In fact, $2\sqrt{2}$ is the upper bound in the quantum theory [13]. This can be seen by noting

$$(\mathcal{B}_{\text{CHSH}})^2 = 4 - [A_1, A_2][B_1, B_2].$$
(24)

With $[\sigma_i, \sigma_j] = 2\epsilon_{ijk}\sigma_k$, we see that the maximum of the right-hand-side is 8, which leads to the quantum bound $2\sqrt{2}$. The presence of the quantum bound implies that the Bell-type observables are also important in testing quantum mechanics experimentally. For example, *if a violation of quantum bound is experimentally confirmed, then quantum mechanics is falsified.* In fact, it has been known that a local probability distribution $P(a, b|A_i, B_j)$ leads to a violation of the quantum bound [78]. This class of local distributions is called No-signalling distributions. Within such distributions, the algebraic maximum 4 of (21) can be reached.⁵ We recall the No-signalling statistics that saturate this bound in Appendix A.

Violation of Bell-type inequality is related to the entanglement. By definition, separable states have a factorised form (1). For this state, the joint conditional probability is factorised as

$$P(a, b|A_i, B_j) = \operatorname{Tr} \left[\rho^{\operatorname{sep}} \left(M(a|A_i) \otimes M(b|B_j)\right)\right] \\ = \sum_k p_k \operatorname{Tr} \left[\rho^A_k M(a|A_i)\right] \operatorname{Tr} \left[\rho^B_k M(b|B_j)\right],$$
(25)

where $M(a|A_i)$ and $M(b|B_i)$ are the measurement projection operators for Alice and Bob, respectively. The latter expression coincides with the defining probability distribution of the LRHV theories. This implies that separable quantum states cannot violate the LRHV bound, meaning that the set of all Bell-nonlocal states is a subset of all entangled states, i.e., Bellnonlocal \subset Entangled. On the other hand, however, for bipartite pure states, all entangled states violate the CHSH inequality [79–81].

2.4 Three-particle non-locality

In a three-particle system, the Bell-type experiment is naturally extended by introducing a third particle, C, and its corresponding observer, Charlie. Charlie performs spin measurements along two axes, C_1 and C_2 , with the measurement outcome denoted by $c \in \{+1, -1\}$. The correlations $\langle A_i B_j C_k \rangle$ are computed by repeating the experiment multiple times.

Two types of local-real theories exist in the three-particle system [82]. One is *fully* local-real (FLR) theories, where no nonlocal correlation exists among any pair of particles and between any particle and the rest of the system. In such theories, the joint probability distribution fully factorises as

$$P(a, b, c|A_i, B_j, C_k) = \sum_{\lambda} P_{\lambda} \mathcal{A}_{\lambda}(a|A_i) \mathcal{B}_{\lambda}(b|B_j) \mathcal{C}_{\lambda}(c|C_k) \quad \cdots \quad (\text{FLR})$$
(26)

One can test this theory with the Mermin observable [83]

$$\mathcal{B}_{\rm M} = A_1 B_1 C_2 + A_1 B_2 C_1 + A_2 B_1 C_1 - A_2 B_2 C_2 \,. \tag{27}$$

Notice that the product of all four terms results in $(A_1B_1C_1)^2(A_2B_2C_2)^2$. In the fully localreal theory, where all outcomes are predetermined before the measurements, this product is 1.

⁵Since $a, b \in \{+1, -1\}$, the expectation value of each term of Eq. (21) is bunded by 1. Therefore, $|\langle \mathcal{B}_{CHSH} \rangle|$ has the algebraic upper bound 4. We have $\langle \mathcal{B}_{CHSH} \rangle_{NS} \leq 4$ for general No-signalling distributions.

Therefore, if the first three terms have the same sign, the last term (without the minus sign) must also have the same sign. This means at least one pair of terms must be cancelled, leading to the Mermin inequality [83]

$$|\langle \mathcal{B}_{\mathrm{M}} \rangle_{\mathrm{FLR}}| \leq 2. \tag{28}$$

Since fully-separable quantum states always lead to the probability distribution of the form (26), the quantum state must be entangled, i.e. $C_{i(jk)} > 0$ for some $i, j, k \in \{A, B, C\}$, to violate this bound.

It has been shown that quantum mechanics can violate the FLR limit. In fact, quantum mechanics can saturate the algebraic maximum

$$|\langle \mathcal{B}_{\mathrm{M}} \rangle_{\mathrm{QM}}| \le 4.$$
⁽²⁹⁾

In particular, the GHZ state can saturate the quantum bound [83]. The saturation of the algebraic maximum within quantum mechanics implies that the Mermin observable cannot be used to test quantum mechanics like the CHSH observable.

The other local-real theory is a hybrid type, where two of the particles are nonlocally correlated, but that subsystem is separated from the third particle [68, 84, 85]. The most general joint probability distributions in such *bipartite* local-real (BLR) theories are written as

$$P(a, b, c|A_i, B_j, C_k) = p_1 \sum_{\lambda} P_{\lambda} \mathcal{A}_{\lambda}(a|A_i) \overline{\mathcal{A}}_{\lambda}(b, c|B_j, C_k)$$

$$+ p_2 \sum_{\lambda} P_{\lambda} \mathcal{B}_{\lambda}(b|B_j) \overline{\mathcal{B}}_{\lambda}(a, c|A_i, C_k) + p_3 \sum_{\lambda} P_{\lambda} \mathcal{C}_{\lambda}(c|C_k) \overline{\mathcal{C}}_{\lambda}(a, b|A_i, B_j), \quad \cdots \quad (BLR)$$
(30)

with $p_i \ge 0$ and $\sum_i p_i = 1$. This probability distribution is more general than that in Eq. (26). If the probability distribution of this type cannot explain the results of correlation measurements, we say that there is genuine three-partite non-locality in the system.

The bipartite local-real theory can be tested using the Svetlichny observable [68,85]

$$\mathcal{B}_{S} = A_{1}B_{1}C_{1} + A_{1}B_{1}C_{2} + A_{1}B_{2}C_{1} + A_{2}B_{1}C_{1} - A_{2}B_{2}C_{2} - A_{2}B_{2}C_{1} - A_{2}B_{1}C_{2} - A_{1}B_{2}C_{2} \quad (31)$$

with the bound

$$|\langle \mathcal{B}_{\rm S} \rangle_{\rm BLR}| \le 4. \tag{32}$$

This bound can be understood as follows. In the calculation of the expectation value, the probability distribution appears linearly; $\langle A_i B_j C_k \rangle_{\text{BLR}} = \sum_{a,b,c} P(a,b,c|A_i,B_j,C_k)A_iB_jC_k$. The three terms in Eq. (30) can, therefore, be considered separately and then added together. In the first term, we can interpret that particle A is described independently from the rest. For this contribution, we rewrite the Svetlichny observable as

$$\mathcal{B}_{\rm S} = (A_1 + A_2)B_1C_1 + (A_1 - A_2)B_1C_2 + (A_1 - A_2)B_2C_1 - (A_1 + A_2)B_2C_2 \tag{33}$$

Within this contribution, we can assume the measurement outcomes of A_1 and A_2 are predetermined before the act of Alice's measurement and take values of either +1 or -1. Two of the above terms must, therefore, vanish. Since the largest value of each term is 2, we understand the maximum contribution to \mathcal{B}_S from this part of the probability distribution is $4p_1$. The analogous argument follows for the other two contributions in Eq. (30). Adding all three contributions gives the upper bound $4(p_1 + p_2 + p_3) = 4$. Since bi-separable quantum states necessarily give the bipartite local-real distribution (30), the quantum state must be genuinely three-particle entangled to violate the Svetlichny's BLR bound (32).

It has been shown that quantum mechanics can violate the BLR bound. Interestingly, quantum mechanics has a non-trivial bound

$$|\langle \mathcal{B}_{\rm S} \rangle_{\rm QM}| \le 4\sqrt{2} \,. \tag{34}$$

For example, the quantum limit $4\sqrt{2}$ is reached by the GHZ state by taking e.g. $(A_1, A_2) = (\sigma_x, \sigma_y)$, $(B_1, B_2) = (\sigma_x \pm \sigma_y)/\sqrt{2}$ and $(C_1, C_2) = (\sigma_x, \sigma_y)$. The quantum limit is smaller than the algebraic maximum of (31), which is 8, achieved when all eight terms of in Eq. (31) take the same value +1 (or -1). This means the Svetlichny observable is effective in testing quantum mechanics.

An intriguing question is whether or not all non-FLR distributions violate the Mermin inequality (28). It has been shown that the answer to this question is negative [86]. In fact, there exists a tighter inequality than Eq. (28). Such an inequality can be obtained by adding two more spin measurement axes to Alica and Bob, denoted by A_3 , A_4 and B_3 , B_4 , respectively. The so-called tight $4 \times 4 \times 2$ observable is defined by [86]

$$\mathcal{B}_{442} = [A_1(B_1 + B_2) + A_2(B_1 - B_2)](C_1 + C_2) + [A_3(B_3 + B_4) + A_4(B_3 - B_4)](C_1 - C_2).$$
(35)

For the fully local-real theory, one of the two terms vanishes since the outcomes of C_1 and C_2 are predetermined and either +1 or -1. Within the non-vanishing term, one of the two terms in the squared bracket vanishes because of the same argument for B_1 and B_2 . In the end, only one term of the form $A_i(B_1 \pm B_2)(C_1 \pm C_2)$ survives, which leads to the upper bound [86]

$$|\langle \mathcal{B}_{442} \rangle_{\rm FLR}| \le 4. \tag{36}$$

In fact, this bound is tight [86], meaning that all non-FLR correlations violate the above inequality.

On the other hand, quantum mechanics has a non-trivial bound (see the appendix)

$$|\langle \mathcal{B}_{442} \rangle_{\rm QM}| \le 8. \tag{37}$$

Note that if all terms in Eq. (35) were conveniently adjusted to take values of +1 or -1, the quantity $|\langle \mathcal{B}_{442} \rangle|$ would saturate its algebraic bound of 16. It can be shown (see Appendix A) that this bound is achievable within the No-signalling framework. Understanding this type of bound is important, as a violation in space-like configurations would require a careful examination/reconsideration of relativistic causality and quantum mechanics.

We summarise different types of nonlocal correlations and their detection with the Bell-type inequalities in Fig. 2.

2.5 Optimisation of the measurement axes

The Bell-type operators generally depend on the measurement axes, and Bell-type inequalities hold for all choices of measurement axes. To detect non-locality efficiently, all measurement axes should be optimised so that the expectation value of the Bell-type observable is maximised for a given state.

Let \vec{A}_I , \vec{B}_I and \vec{C}_J be the unit vectors pointing to the spin measurement axes of Alice, Bob and Charlie, respectively, where $I \in \{1, 2, (3, 4)\}$ ⁶ and $J \in \{1, 2\}$ label different choices

⁶This notation means that we shall consider either set $\{1, 2\}$ or $\{1, 2, 3, 4\}$.

Figure 2: Different types of non-localities and their detections in the three-qubit system.

of measurement axes. For given measurement axes $(\vec{A}_I, \vec{B}_I \text{ and } \vec{C}_J)$, the Bell-type operators mentioned above are written as

$$\mathcal{B}_{\mathrm{M}} = \sum_{ijk} (\overline{\mathcal{B}}_{\mathrm{M}})_{ijk} [\sigma_i \otimes \sigma_j \otimes \sigma_k], \quad \mathcal{B}_{\mathrm{S}} = \sum_{ijk} (\overline{\mathcal{B}}_{\mathrm{S}})_{ijk} [\sigma_i \otimes \sigma_j \otimes \sigma_k], \quad \mathcal{B}_{442} = \sum_{ijk} (\overline{\mathcal{B}}_{442})_{ijk} [\sigma_i \otimes \sigma_j \otimes \sigma_k], \quad (38)$$

where σ_i (i = 1, 2, 3) are the Pauli matrices and the rank-3 tensors are defined as

$$[\overline{\mathcal{B}}_{\mathrm{M}}]_{ijk} = [\vec{A}_1]_i [\vec{B}_1]_j [\vec{C}_2]_k + [\vec{A}_1]_i [\vec{B}_2]_j [\vec{C}_1]_k + [\vec{A}_2]_i [\vec{B}_1]_j [\vec{C}_1]_k - [\vec{A}_2]_i [\vec{B}_2]_j [\vec{C}_2]_k$$
(39)

$$\begin{bmatrix} \overline{\mathcal{B}}_{\mathrm{S}} \end{bmatrix}_{ijk} = \begin{bmatrix} \vec{A}_1 \end{bmatrix}_i \begin{bmatrix} \vec{B}_1 \end{bmatrix}_j \begin{bmatrix} \vec{C}_1 \end{bmatrix}_k + \begin{bmatrix} \vec{A}_1 \end{bmatrix}_i \begin{bmatrix} \vec{B}_1 \end{bmatrix}_j \begin{bmatrix} \vec{C}_2 \end{bmatrix}_k + \begin{bmatrix} \vec{A}_1 \end{bmatrix}_i \begin{bmatrix} \vec{B}_2 \end{bmatrix}_j \begin{bmatrix} \vec{C}_1 \end{bmatrix}_k + \begin{bmatrix} \vec{A}_2 \end{bmatrix}_i \begin{bmatrix} \vec{B}_1 \end{bmatrix}_j \begin{bmatrix} \vec{C}_1 \end{bmatrix}_k \\ - \begin{bmatrix} \vec{A}_2 \end{bmatrix}_i \begin{bmatrix} \vec{B}_2 \end{bmatrix}_j \begin{bmatrix} \vec{C}_2 \end{bmatrix}_k - \begin{bmatrix} \vec{A}_2 \end{bmatrix}_i \begin{bmatrix} \vec{B}_2 \end{bmatrix}_j \begin{bmatrix} \vec{C}_1 \end{bmatrix}_k - \begin{bmatrix} \vec{A}_2 \end{bmatrix}_i \begin{bmatrix} \vec{B}_1 \end{bmatrix}_j \begin{bmatrix} \vec{C}_2 \end{bmatrix}_k - \begin{bmatrix} \vec{A}_1 \end{bmatrix}_i \begin{bmatrix} \vec{B}_2 \end{bmatrix}_j \begin{bmatrix} \vec{C}_2 \end{bmatrix}_k$$
(40)

$$\begin{bmatrix} \overline{\mathcal{B}}_{442} \end{bmatrix}_{ijk} = \left([\vec{A}_1]_i [\vec{B}_1 + \vec{B}_2]_j + [\vec{A}_2]_i [\vec{B}_1 - \vec{B}_2]_j \right) [\vec{C}_1 + \vec{C}_2]_k + \left([\vec{A}_3]_i [\vec{B}_3 + \vec{B}_4]_j + [\vec{A}_4]_i [\vec{B}_3 - \vec{B}_4]_j \right) [\vec{C}_1 - \vec{C}_2]_k,$$
(41)

where $[\vec{A}_I]_i$, $[\vec{B}_I]_j$ and $[\vec{C}_J]_k$ $(i, j, k \in \{1, 2, 3\})$ are the components of the measurement axis vectors.

A general three-qubit state, $\rho,$ can be expanded as

$$\rho = \frac{1}{8} \sum_{\mu,\nu,\rho} T_{\mu\nu\rho} \left[\sigma_{\mu} \otimes \sigma_{\nu} \otimes \sigma_{\rho} \right], \tag{42}$$

with $\mu, \nu, \rho \in \{0, 1, 2, 3\}$, $T_{\mu\nu\rho} \in \mathbb{R}$ and $\sigma^0 = \mathbf{1}$. The Bloch vectors of qubits A, B and C correspond to T_{i00}, T_{0i0} and T_{00i} , respectively, with $i, j, k \in \{1, 2, 3\}$. The two-qubit correlation (AB), (AC) and (BC) are given by T_{ij0}, T_{i0j} and T_{0ij} , respectively. Finally,

$$T_{ijk} = \operatorname{Tr} \left(\rho \cdot \left[\sigma_i \otimes \sigma_j \otimes \sigma_k \right] \right) \tag{43}$$

is the three-qubit correlation.

The expectation values of Bell-type operators are given by

$$\langle \mathcal{B}_{\mathrm{M}} \rangle_{\rho} = \mathrm{Tr} \left[\mathcal{B}_{\mathrm{M}} \rho \right] = \sum_{i,j,k} [\overline{\mathcal{B}}_{\mathrm{M}}]_{ijk} T_{ijk},$$

$$\langle \mathcal{B}_{\mathrm{S}} \rangle_{\rho} = \mathrm{Tr} \left[\mathcal{B}_{\mathrm{S}} \rho \right] = \sum_{i,j,k} [\overline{\mathcal{B}}_{\mathrm{S}}]_{ijk} T_{ijk},$$

$$\langle \mathcal{B}_{442} \rangle_{\rho} = \mathrm{Tr} \left[\mathcal{B}_{442} \rho \right] = \sum_{i,j,k} [\overline{\mathcal{B}}_{442}]_{ijk} T_{ijk},$$

$$(44)$$

Only the three-qubit correlation T_{ijk} appears in these quantities.

For a given quantum state ρ (or equivalently a T_{ijk}), we would like to optimise the measurement axis vectors, \vec{A}_I , \vec{B}_I and \vec{C}_J , such that the Bell-type observable is maximised. For the Mermin and Svetlichny observables, the expectation can be expressed as

$$\langle \mathcal{B}_{M/S} \rangle_{\rho} = (\vec{A}_1 \cdot \vec{D}_{M/S}^{(1)}) + (\vec{A}_2 \cdot \vec{D}_{M/S}^{(2)}),$$
 (45)

with

$$[\vec{D}_{\rm M}^{(1)}]_i \equiv \sum_{j,k} T_{ijk} \left([\vec{B}_1]_j [\vec{C}_2]_k + [\vec{B}_2]_j [\vec{C}_1]_k \right) \,, \tag{46}$$

$$[\vec{D}_{\rm M}^{(2)}]_i \equiv \sum_{j,k} T_{ijk} \left([\vec{B}_1]_j [\vec{C}_1]_k - [\vec{B}_2]_j [\vec{C}_2]_k \right) \,, \tag{47}$$

$$[\vec{D}_{\rm S}^{(1)}]_i \equiv \sum_{j,k} T_{ijk} \left([\vec{B}_1]_i [\vec{C}_1]_k + [\vec{B}_1]_i [\vec{C}_2]_k + [\vec{B}_2]_i [\vec{C}_1]_k - [\vec{B}_2]_i [\vec{C}_2]_k \right), \tag{48}$$

$$[\vec{D}_{\rm S}^{(2)}]_i \equiv \sum_{j,k} T_{ijk} \left([\vec{B}_1]_i [\vec{C}_1]_k - [\vec{B}_2]_i [\vec{C}_2]_k - [\vec{B}_2]_i [\vec{C}_1]_k - [\vec{B}_1]_i [\vec{C}_2]_k \right) \,. \tag{49}$$

The expectation values $\langle \mathcal{B}_{M} \rangle_{\rho}$ and $\langle \mathcal{B}_{S} \rangle_{\rho}$ are optimised by taking \vec{A}_{1} and \vec{A}_{2} aligned with $\vec{D}_{M/S}^{(1)}$ and $\vec{D}_{M/S}^{(2)}$, respectively; $\vec{A}_{1} = \vec{D}_{M/S}^{(1)} / |\vec{D}_{M/S}^{(1)}|$ and $\vec{A}_{2} = \vec{D}_{M/S}^{(2)} / |\vec{D}_{M/S}^{(2)}|$. The resulting values are given by

$$\langle \mathcal{B}_{\mathrm{M/S}} \rangle_{\rho} = \left| \vec{D}_{\mathrm{M/S}}^{(1)} \right| + \left| \vec{D}_{\mathrm{M/S}}^{(2)} \right| \,. \tag{50}$$

In the following analysis, we numerically optimise four unit vectors, $\vec{B}_{1/2}$ and $\vec{C}_{1/2}$, to maximize the Mermin and Svetlichny observables expressed in Eq. (50).

For the tight $4 \times 4 \times 2$ observable, the optimisation is more involved as it has ten independent measurement axes, \vec{A}_I , \vec{B}_I ($I \in \{1, \dots, 4\}$) and \vec{C}_J ($J \in \{1, 2\}$). We developed a semianalytical approach to optimise the tight $4 \times 4 \times 2$ observable, which is detailed in Appendix B. In this approach, the $\langle \mathcal{B}_{442} \rangle$ is optimised analytically for all degrees of freedom except for one polar angle and two azimuthal angles. The numerical optimisation can be performed for the remaining three degrees of freedom, which is relatively straightforward.

3 Three-Body Kinematics and Spin States

We consider a three-body decay, $X \to ABC$, at the rest frame of particle X. We assume all particles are spin-1/2 fermions⁷ and particle X has the mass m, while the other particles are massless⁸. We specify the momenta of the final state particles (p_A, p_B, p_C) as follows. First, we take the z-axis in the direction of \mathbf{p}_A : $p_A^{\mu} = p_A(1, 0, 0, 1)$. The x and y axes are chosen such that the y axis is perpendicular to the decay plane and the p_B has a positive x component. The opening angles between A-B and A-C are denoted by θ_B and θ_C ($0 \le \theta_B, \theta_C \le \pi$), respectively. With these angles, we can write $p_B^{\mu} = p_B(1, \sin \theta_B, 0, \cos \theta_B)$ and $p_C^{\mu} = p_C(1, -\sin \theta_C, 0, \cos \theta_C)$ with $0 \le \theta_B, \theta_C \le \pi$.

The energy-momentum conservation gives the constraints

$$p_A + p_B + p_C = m,$$

$$p_A + p_B \cos \theta_B + p_C \cos \theta_C = 0,$$

$$p_B \sin \theta_B - p_C \sin \theta_C = 0.$$
(51)

The solution is

$$p_A = -mD\sin(\theta_B + \theta_C), \quad p_B = mD\sin\theta_C, \quad p_C = mD\sin\theta_B,$$
 (52)

with $D = [\sin \theta_B + \sin \theta_C - \sin(\theta_B + \theta_C)]^{-1}$. In this way, the kinematics is completely determined by specifying two decay angles θ_B and θ_C . The positivity of p_A in Eq. (52) restricts the sum of these angles in the range, $\pi \leq \theta_B + \theta_C \leq 2\pi$.

We denote the helicities of outgoing particles by λ_A, λ_B and λ_C and the spin polarisation of the initial particle by $\mathbf{n} = (\sin \theta \cos \phi, \sin \theta \sin \phi, \cos \theta)$ (see Fig. 3). We write $|\mathbf{n}\rangle$ for the asymptotic state of the initial state with the polarization \mathbf{n} at time $t = -\infty$. This state is evolved with the S-matrix into an "out" state at $t = +\infty$. The state is then expanded in terms of the complete set of the Fock space at $t = +\infty$

$$\hat{\mathbf{1}} = \sum_{f} \left[\left(\prod_{i \in f} \int d\Pi_i \right) |f\rangle \langle f| \right], \quad d\Pi_i = \frac{d^3 \mathbf{p}_i}{(2\pi)^3 2E_i}, \tag{53}$$

where f denotes single and multiparticle final states with fixed polarisations and i is a particle in f. We select a particular decay mode, $X \to ABC$

$$S|\mathbf{n}\rangle = \sum_{f} \left[\left(\prod_{i \in f} \int d\Pi_i \right) |f\rangle \langle f| \right] S|\mathbf{n}\rangle \ni \sum_{\lambda} \int d\Pi_{ABC} \mathcal{M}^{\mathbf{n}}_{\lambda,p} |\lambda,p\rangle,$$
(54)

where λ and p represent the helicities and momenta of three outgoing particles collectively, i.e. $\lambda = \{\lambda_A, \lambda_B, \lambda_C\}$ and $p = \{p_A^{\mu}, p_B^{\mu}, p_C^{\mu}\}$. The Lorentz invariant three-particle phase space is represented as

$$d\Pi_{ABC} = \frac{d^3 \mathbf{p}_A d^3 \mathbf{p}_B d^3 \mathbf{p}_C}{(2\pi)^9 8 E_A E_B E_C} (2\pi)^4 \delta^4 (p_X - p_A - p_B - p_C) , \qquad (55)$$

⁷Strictly speaking, particle B in the final state is antifermion.

⁸Ref. [52] shows that using Bell-type inequalities at colliders to test non-locality is highly challenging due to the difficulty in measuring the final state's non-commuting observables. We leave the assessment of how well the quantities in Fig. 2 can be experimentally reconstructed for future work.

Figure 3: The momentum and spin configuration. The momentum of A is fixed to the zdirection. At the rest frame of X, the decay plane is aligned with the x-z plane and the two opening angles, A-B and A-C, are given by θ_B and θ_C , respectively, with $0 \le \theta_B, \theta_C \le \pi$ and $\pi \le \theta_B + \theta_C \le 2\pi$. The spin direction of X is given by $\mathbf{n} = (\sin \theta \cos \phi, \sin \theta \sin \phi, \cos \theta)$.

and $\mathcal{M}^{\mathbf{n}}_{\lambda,p}$ is the matrix element, which is related to the transition amplitude $\langle \lambda, p | i \mathcal{T} | \mathbf{n} \rangle = i \mathcal{M}^{\mathbf{n}}_{\lambda,p} (2\pi)^4 \delta^4 (p_X - p_A - p_B - p_C)$ with \mathcal{T} being the *T*-matrix defined as $S = 1 + i \mathcal{T}$.

In the following analysis, we are interested in the spin state at a given phase space point

$$|\Psi\rangle \propto \sum_{\lambda_A,\lambda_B,\lambda_C} \mathcal{M}^{\mathbf{n}}_{\lambda_A,\lambda_B,\lambda_C} |\lambda_A,\lambda_B,\lambda_C\rangle.$$
(56)

In this expression, we suppressed the momentum label in the final state kets and dropped the common proportionally factor $d\Pi_{ABC}$. This is a pure state of three qubits, in which, after properly normalising, all mathematical formulae introduced in the previous sections can be used.

4 Non-locality and Entanglement in Three-Body Decays

4.1 Four-fermion Interactions

There are 16 non-redundant Lorentz structures formed from bilinear combinations of Dirac spinors $\bar{\psi}\Gamma\psi$ with

$$\Gamma = \left\{ \mathbf{1}, \gamma^5, \gamma^\mu, \gamma^\mu \gamma^5, \sigma^{\mu\nu} \right\} , \qquad (57)$$

where γ^{μ} is the Dirac γ matrices, $\gamma^5 \equiv i\gamma^0\gamma^1\gamma^2\gamma^3$ and $\sigma^{\mu\nu} \equiv \frac{i}{2}[\gamma^{\mu}, \gamma^{\nu}]$. We combine two of these fermion bilinears to form Lorentz invariant four-fermion operators. Such operators are classified into the following three types:

Scalar:

$$[\bar{\psi}_A(c_S + ic_A\gamma_5)\psi_X][\bar{\psi}_C(d_S + id_A\gamma_5)\psi_B], \qquad (58)$$

Vector:

$$[\bar{\psi}_A \gamma_\mu (c_L P_L + c_R P_R) \psi_X] [\bar{\psi}_C \gamma^\mu (d_L P_L + d_R P_R) \psi_B], \qquad (59)$$

Tensor:

$$[\bar{\psi}_A(c_M + ic_E\gamma_5)\sigma^{\mu\nu}\psi_X][\bar{\psi}_C(d_M + id_E\gamma_5)\sigma_{\mu\nu}\psi_B], \qquad (60)$$

where $c_S, c_A, d_S, d_A, c_L, c_R, d_L, d_R, c_M, c_E, d_M, d_E \in \mathbb{R}$ are coupling constants. For vector interactions, instead of using γ^{μ} and $\gamma^{\mu}\gamma_5$, we organise the bilinaers with the chiral projection operators $P_{R/L} \equiv \frac{1}{2}(1 \pm \gamma^5)$. We included a fermion bilinear for tensor interactions with $\gamma_5 \sigma^{\mu\nu}$. Although this bilinear is not independent, it can represent a Lorentz construction of the type $\epsilon^{\mu\nu\rho\sigma}[\bar{\psi}_A\sigma_{\mu\nu}\psi_X][\bar{\psi}_C\sigma_{\rho\sigma}\psi_B]$ through the identity $i\gamma_5\sigma^{\mu\nu} = -\frac{1}{2}\epsilon^{\mu\nu\rho\sigma}\sigma^{\rho\sigma}$. In fact, one can show

$$[\bar{\psi}_{1}(c_{M}+ic_{E}\gamma_{5})\sigma^{\mu\nu}\psi_{0}][\bar{\psi}_{3}(d_{M}+id_{E}\gamma_{5})\sigma_{\mu\nu}\psi_{2}] = \alpha[\bar{\psi}_{1}\sigma^{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{2}] - \frac{\beta}{2}\epsilon^{\mu\nu\rho\sigma}[\bar{\psi}_{1}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\rho\sigma}\psi_{2}] + \frac{\beta}{2}\epsilon^{\mu\nu\rho\sigma}[\bar{\psi}_{1}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\rho\sigma}\psi_{2}] + \frac{\beta}{2}\epsilon^{\mu\nu\rho\sigma}[\bar{\psi}_{1}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}]][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}]][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}]][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}]][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}]][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}]][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}]][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}]][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}]][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}]][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}]][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}]][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}]][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}]][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}]][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}]][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}]][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}][\bar{\psi}_{3}\sigma_{\mu\nu}\psi_{0}$$

with $\alpha = c_M d_M - c_E d_E$ and $\beta = c_M d_E + c_E d_M$. The number of parameters is reduced to half in the latter expression. However, we prefer to work with the former expression since the coupling convention is more aligned with the other (scalar and vector) cases and the final expression becomes neat as we will see in the following section.

4.2 Scalar interaction

For a given phase space point (θ_B, θ_C) and the initial spin $\mathbf{n}(\theta, \phi)$, the matrix element of $X \to ABC$ can be calculated from the scalar interaction (58) as [26]

$$\mathcal{M}^{\mathbf{n}}_{\lambda_{A},\lambda_{B},\lambda_{C}} \propto 2\sqrt{2mp_{A}p_{B}p_{C}} \cdot s\frac{\theta_{B}+\theta_{C}}{2} \cdot \left[-cd \cdot \delta^{-}_{\lambda_{A}}\delta^{-}_{\lambda_{B}}\delta^{-}_{\lambda_{C}} \cdot e^{i\phi}s\frac{\theta}{2} + cd^{*} \cdot \delta^{-}_{\lambda_{A}}\delta^{+}_{\lambda_{B}}\delta^{+}_{\lambda_{C}} \cdot e^{i\phi}s\frac{\theta}{2} - c^{*}d \cdot \delta^{+}_{\lambda_{A}}\delta^{-}_{\lambda_{B}}\delta^{-}_{\lambda_{C}} \cdot c\frac{\theta}{2} + c^{*}d^{*} \cdot \delta^{+}_{\lambda_{A}}\delta^{+}_{\lambda_{B}}\delta^{+}_{\lambda_{C}} \cdot c\frac{\theta}{2} \right],$$

$$(62)$$

In this expression, we defined $c = c_S + ic_A$ and $d = d_S + id_A$ and took |c| = |d| = 1 as we are not interested in the overall scale of the amplitude. We also introduced shorthand notations $c\alpha \equiv \cos \alpha$ and $s\alpha \equiv \sin \alpha$ are used. As can be seen, the state depends only on the spin polarisation of the initial particle, $\mathbf{n}(\theta, \phi)$, and independent of the decay angles, θ_B and θ_C . The above expression implies there are only four helicity assignments producing non-zero amplitudes. The corresponding normalised spin state can be written as

$$|\Psi\rangle = M_{LL}|--\rangle + M_{LR}|-++\rangle + M_{RL}|+--\rangle + M_{RR}|+++\rangle, \tag{63}$$

with $M_{LL} = -\frac{cd}{|cd|\sqrt{2}} \cdot e^{i\phi}s\frac{\theta}{2}$, $M_{LR} = \frac{cd^*}{|cd|\sqrt{2}} \cdot e^{i\phi}s\frac{\theta}{2}$, $M_{RL} = -\frac{c^*d}{|cd|\sqrt{2}} \cdot c\frac{\theta}{2}$ and $M_{RR} = \frac{c^*d^*}{|cd|\sqrt{2}} \cdot c\frac{\theta}{2}$. This state can be factorised in the following form

$$|\Psi\rangle = \frac{1}{|cd|} \left[ce^{i\phi} s\frac{\theta}{2} |-\rangle_A + c^* c\frac{\theta}{2} |+\rangle_A \right] \otimes \frac{1}{\sqrt{2}} \left[d|++\rangle_{BC} - d^*|--\rangle_{BC} \right], \tag{64}$$

which implies that the state is bi-separable for particle A and subsystem BC. This structure stems from the form of the four-fermion operator (58), in which the spinors for A are factorised from those for B and C.

Since the state is factorised as in Eq. (64), A is unentangled with B and C individually and also collectively:

$$\mathcal{C}_{AB} = \mathcal{C}_{AC} = \mathcal{C}_{A(BC)} = 0, \tag{65}$$

Particles B and C are, on the other hand, maximally entangled:

$$\mathcal{C}_{BC} = 1. \tag{66}$$

The monogamy relations (15) implies B and C must also be maximally entangled with the rest of the system:

$$\mathcal{C}_{B(AC)} = \mathcal{C}_{C(AB)} = 1, \tag{67}$$

and the three-tangle is vanishing, $\tau = 0$. Because the state is bi-separable, the GTE measure vanishes

$$F_3 = 0.$$
 (68)

For the bi-separable state (64), the three-particle correlation tensor (43) is factorised as

$$T_{ijk} = V_i \otimes U_{jk} \,, \tag{69}$$

with

$$V_{i} = (\sin \theta \cos \phi, \sin \theta \sin \phi, \cos \theta),$$

$$U_{jk} = \begin{pmatrix} -\cos 2\delta & -\sin 2\delta & 0 \\ -\sin 2\delta & \cos 2\delta & 0 \\ 0 & 0 & 1 \end{pmatrix},$$
(70)

where δ is a CP phase, $d \equiv e^{i\delta}$. Notice that \vec{V} coincides with the initial spin polarisation $\mathbf{n}(\theta, \phi)$. The matrix U has two eigenvalues, ± 1 . The eigenvector corresponding to the -1 eigenvalue is $\vec{u}_{-} = (\cos \frac{\delta}{2}, \sin \frac{\delta}{2}, 0)$. The two orthonormal eigenvectors corresponding to the +1 eigenvalue can be expressed as $\vec{u}_{+}^{(1)} = (-\sin \frac{\delta}{2}, \cos \frac{\delta}{2}, 0)$ and $\vec{u}_{+}^{(2)} = (0, 0, 1)$. The one-parameter family of normalised eigenvectors with the +1 eigenvalue can be written as $\vec{u}_{+}(\alpha) = \cos \alpha \cdot \vec{u}_{+}^{(1)} + \sin \alpha \cdot \vec{u}^{(2)}$.

For the state with the correlation matrix, Eqs. (69), (70), the Mermin, Svetlichny and tight $4 \times 4 \times 2$ observables can be optimised analytically. Plugging Eqs. (69) and (70) into Eqs. (39), (40), (41) and (44), we see that all terms are proportional to $\vec{A}_I \cdot \vec{V}$. This means the observables are maximised by taking $\vec{A}_I = \vec{V} = \mathbf{n}(\theta, \phi)$ for all $I \in \{1, 2, (3, 4)\}$. After fixing \vec{A}_I in this way, the observables are reduced to

$$\langle \mathcal{B}_{\mathrm{M}} \rangle_{\rho} = \vec{B}_{1} \cdot U \cdot \left(\vec{C}_{1} + \vec{C}_{2}\right) + \vec{B}_{2} \cdot U \cdot \left(\vec{C}_{1} - \vec{C}_{2}\right)$$

$$\langle \mathcal{B}_{\mathrm{S}} \rangle_{\rho} = 2 \left[\vec{B}_{1} \cdot U \cdot \vec{C}_{1} - \vec{B}_{2} \cdot U \cdot \vec{C}_{2}\right]$$

$$\langle \mathcal{B}_{442} \rangle_{\rho} = 2 \left[\vec{B}_{1} \cdot U \cdot \left(\vec{C}_{1} + \vec{C}_{2}\right) + \vec{B}_{3} \cdot U \cdot \left(\vec{C}_{1} - \vec{C}_{2}\right)\right]$$

$$(71)$$

For the Mermin and tight 442 observables, we introduce a pair of orthonormal vectors (\vec{C}_+, \vec{C}_-) as

$$\vec{C}_1 + \vec{C}_2 = 2\bar{c}\vec{C}_+, \quad \vec{C}_1 - \vec{C}_2 = 2\bar{s}\vec{C}_-,$$
(72)

with $|\vec{C}_{\pm}| = 1$, $\vec{C}_{+} \cdot \vec{C}_{-} = 0$ and $\vec{c}^{2} + \vec{s}^{2} = 1$. For these new vectors, the observables are written as

$$\langle \mathcal{B}_{\mathrm{M}} \rangle_{\rho} = 2 \left[\bar{c} \left(\vec{B}_{1} \cdot U \cdot \vec{C}_{+} \right) + \bar{s} \left(\vec{B}_{2} \cdot U \cdot \vec{C}_{-} \right) \right]$$

$$\langle \mathcal{B}_{442} \rangle_{\rho} = 4 \left[\bar{c} \left(\vec{B}_{1} \cdot U \cdot \vec{C}_{+} \right) + \bar{s} \left(\vec{B}_{3} \cdot U \cdot \vec{C}_{-} \right) \right]$$

$$(73)$$

There are several ways to arrange the two curly brackets in an observable simultaneously to its maximum magnitude ± 1 . For example, \vec{C}_{\pm} , \vec{B}_1 , \vec{B}_2 and \vec{B}_3 can be taken as eigenvectors of the U matrix, making sure that \vec{C}_+ and \vec{C}_- are orthogonal. Once the two curly brackets

are optimised to the values either +1 or -1, then \bar{c} and \bar{s} are set either to $\frac{1}{\sqrt{2}}$ or $-\frac{1}{\sqrt{2}}$. This completes the optimisation, and the resulting values are

$$\langle \mathcal{B}_{\mathrm{M}} \rangle_{\rho} = 2\sqrt{2}, \quad \langle \mathcal{B}_{442} \rangle_{\rho} = 4\sqrt{2}.$$
 (74)

We see that the expectation of these observables exceeds the fully local-real bounds, $\langle \mathcal{B}_M \rangle_{FLR} \leq 2$ and $\langle \mathcal{B}_{442} \rangle_{FLR} \leq 4$, while they do not saturate the quantum mechanical bounds, $\langle \mathcal{B}_M \rangle_{QM}^{max} = 4$ and $\langle \mathcal{B}_{442} \rangle_{QM}^{max} = 8$.

The optimisation of the Svetlichny observable is more straightforward. In the expression (71) one can take $\vec{B}_1 = \vec{C}_1 = \vec{u}_+(\alpha)$, and $\vec{B}_2 = -\vec{C}_2 = \vec{u}_+(\alpha)$ or $\vec{B}_2 = \vec{C}_2 = \vec{u}_-$. Then, we find the value of the optimised Svetlichny observable as

$$\langle \mathcal{B}_{\rm S} \rangle_{\rho} = 4. \tag{75}$$

This saturates but does not violate the bi-partite local-real bound, as the state is bi-separable.

4.3 Vector interaction

The matrix element of $X \to ABC$ for the vector interaction (59) is found as [26]

$$\mathcal{M}^{\mathbf{n}}_{\lambda_{A},\lambda_{B},\lambda_{C}} \propto 4\sqrt{2mp_{A}p_{B}p_{C}} \cdot \left[\qquad (76) \right] \\ \delta^{-}_{\lambda_{A}}\delta^{+}_{\lambda_{B}}\delta^{-}_{\lambda_{C}} \cdot c_{L}d_{L}s\frac{\theta_{C}}{2} \left[c\frac{\theta}{2}c\frac{\theta_{B}}{2} + e^{i\phi}s\frac{\theta}{2}s\frac{\theta_{B}}{2} \right] - \delta^{-}_{\lambda_{A}}\delta^{-}_{\lambda_{B}}\delta^{+}_{\lambda_{C}} \cdot c_{L}d_{R}s\frac{\theta_{B}}{2} \left[c\frac{\theta}{2}c\frac{\theta_{C}}{2} - e^{i\phi}s\frac{\theta}{2}s\frac{\theta_{C}}{2} \right] \\ + \delta^{+}_{\lambda_{A}}\delta^{+}_{\lambda_{B}}\delta^{-}_{\lambda_{C}} \cdot c_{R}d_{L}s\frac{\theta_{B}}{2} \left[c\frac{\theta}{2}s\frac{\theta_{C}}{2} + e^{i\phi}s\frac{\theta}{2}c\frac{\theta_{C}}{2} \right] + \delta^{+}_{\lambda_{A}}\delta^{-}_{\lambda_{B}}\delta^{+}_{\lambda_{C}} \cdot c_{R}d_{R}s\frac{\theta_{C}}{2} \left[c\frac{\theta}{2}s\frac{\theta_{B}}{2} - e^{i\phi}s\frac{\theta}{2}c\frac{\theta_{B}}{2} \right] \right].$$

These matrix elements imply the final spin state

$$|\Psi\rangle = M_{LL}|-+-\rangle + M_{LR}|--+\rangle + M_{RL}|++-\rangle + M_{RR}|+-+\rangle, \qquad (77)$$

with $(M_{LL}, M_{LR}, M_{RL}, M_{RR}) = (\mathcal{M}_{-+-}^{\mathbf{n}}, \mathcal{M}_{--+}^{\mathbf{n}}, \mathcal{M}_{++-}^{\mathbf{n}}, \mathcal{M}_{+-+}^{\mathbf{n}})/\mathcal{N}$ and $|\mathcal{N}|^2 = \sum_{\lambda_A, \lambda_D, \lambda_C} |\mathcal{M}_{\lambda_A, \lambda_B, \lambda_C}^{\mathbf{n}}|^2$. In the limit of chiral interactions, the above state reduces to a bi-separable or a fully separable state. For example, if $c_R = 0$ in the interaction term (59), the final state is bi-separable:

$$|\Psi\rangle \propto |-\rangle \otimes \left\{ d_L s \frac{\theta_C}{2} \left[c_2^{\theta} c_2^{\theta_B} + e^{i\phi} s_2^{\theta} s_2^{\theta_B} \right] |+-\rangle - d_R s \frac{\theta_B}{2} \left[c_2^{\theta} c_2^{\theta_C} - e^{i\phi} s_2^{\theta} s_2^{\theta_C} \right] |-+\rangle \right\}.$$
(78)

On the other hand, for $d_R = 0$, it becomes a fully separable state

$$|\Psi\rangle \propto \left\{ c_L s \frac{\theta_C}{2} \left[c_2 \frac{\theta_B}{2} c_2 \frac{\theta_B}{2} + e^{i\phi} s_2 \frac{\theta_B}{2} \right] |-\rangle + c_R s \frac{\theta_B}{2} \left[c_2 \frac{\theta_C}{2} s \frac{\theta_C}{2} + e^{i\phi} s_2 \frac{\theta_C}{2} \right] |+\rangle \right\} \otimes |+-\rangle.$$
(79)

From explicit calculations, we find

$$C_{AB} = C_{AC} = 0, \quad C_{BC} = 2|M_{LL}M_{LR}^* + M_{RL}M_{RR}^*|.$$
(80)

In the assumed form of interaction (59), particle A is never entangled individually with B and C. For one-to-other entanglement, we obtain

$$C_{A(BC)} = 2 |M_{RR}M_{LL} - M_{LR}M_{RL}|,$$

$$C_{B(AC)} = C_{C(AB)}$$

$$= 2\sqrt{(|M_{LL}|^2 + |M_{RL}|^2)(|M_{LR}|^2 + |M_{RR}|^2)}.$$
(81)

Since all three one-to-other concurrence measures are non-vanishing in general, the GTE measure F_3 is also non-vanishing in that case.

The three-tangle can be calculated by

$$\tau \equiv \mathcal{C}_{i(jk)}^2 - [\mathcal{C}_{ij}^2 + \mathcal{C}_{ik}^2],\tag{82}$$

for any choice of $\{i, j, k\} \in \{A, B, C\}$ with $i \neq j \neq k \neq i$. Since $\mathcal{C}_{AB} = \mathcal{C}_{AC} = 0$, it follows

$$\tau = \mathcal{C}^2_{A(BC)} \,. \tag{83}$$

Non-zero components of the three-particle correlation tensor are found as

$$T_{333} = |M_{LL}|^2 + |M_{LR}|^2 - |M_{RL}|^2 - |M_{RR}|^2,$$

$$T_{133} = -2\text{Re}[M_{RL}^*M_{LL} + M_{RR}^*M_{LR}],$$

$$T_{233} = -2\text{Im}[M_{RL}^*M_{LL} + M_{RR}^*M_{LR}],$$

$$T_{311} = T_{322} = 2\text{Re}[M_{RR}^*M_{RL} - M_{LR}^*M_{LL}],$$

$$T_{312} = -T_{321} = 2\text{Im}[M_{RR}^*M_{RL} - M_{LR}^*M_{LL}],$$

$$T_{111} = T_{122} = 2\text{Re}[M_{RR}^*M_{LL} + M_{RL}^*M_{LR}],$$

$$T_{222} = T_{211} = 2\text{Im}[M_{RR}^*M_{LL} + M_{RL}^*M_{LR}],$$

$$T_{221} = -T_{212} = 2\text{Re}[M_{RR}^*M_{LL} - M_{RL}^*M_{LR}],$$

$$T_{112} = -T_{121} = 2\text{Im}[M_{RR}^*M_{LL} - M_{RL}^*M_{LR}],$$

(84)

which allows us to calculate the Bell-type observables.

Fig. 4 illustrates how various entanglement measures and Bell-type observables respond to changes in the initial spin direction, **n**. The horizontal axes of the plots represent the angle between the z-axis and **n**. In the upper (lower) panels, **n** rotates about the y(x)-axes clackwise with the rotation angle $\omega_y(\omega_x)$. In each plot, the decay angles, θ_B and θ_C , are fixed to some reference values. In the left and right panels, we take $(\theta_B, \theta_C) = (\frac{4}{6}\pi, \frac{5}{6}\pi)$ and $(\frac{2}{6}\pi, \frac{5}{6}\pi)$, respectively. In all plots, the coupling constants are taken so that the four-fermion interaction (59) is vector-like, that is, $c_L = c_R = d_L = d_R = \frac{1}{\sqrt{2}}$.

The entanglement measures shown in the plots are the GTE measure F_3 (black dotted), a non-vanishing one-to-one concurrence C_{BC} (orange dashed), two one-to-other concurrences, $C_{A(BC)}$ (magenta dotted) and $C_{B(AC)} = C_{C(AB)}$ (purple dashed-dotted). The presented values of Bell-type observables are divided by the corresponding local-real theory bounds, 2, 4 and 4, for $\langle \mathcal{B}_{M} \rangle$ (blue solid), $\langle \mathcal{B}_{S} \rangle$ (green solid) and $\langle \mathcal{B}_{442} \rangle$ (red solid), respectively. If those curves are above 1, it indicates the quantum state is nonlocal, violating the corresponding local-real bounds.

In all plots in Fig. 4, we observe that the one-to-one concurrence C_{BC} is independent of the initial spin axis **n**, whereas all the other observables depend on **n** in nontrivial ways.

In the upper panels, the one-to-other concurrence measures, $C_{A(BC)}$ and $C_{B(AC)} = C_{C(AB)}$, exhibit two peaks and two troughs over the course of the entire evolution of **n** around the y-axis. Their peak and trough positions in ω_y also agree between $C_{A(BC)}$ and $C_{B(AC)} = C_{C(AB)}$. The GTE measure F_3 also behaves the same way, and it vanishes at the trough positions together with $C_{B(AC)} = C_{C(AB)}$. The behaviours of Bell-type observables in the same plots are more complicated. The $\langle \mathcal{B}_M \rangle$ and $\langle \mathcal{B}_S \rangle$ exhibit two global maxima, two local maxima and four global minima. Additionally, their values display non-smooth transitions at certain values of ω_y . We

Figure 4: The dependence of various entanglement measures, F_3 (black dotted), $C_{A(BC)}$ (magenta dotted) and $C_{B(AC)} = C_{C(AB)}$ (purple dashed-dotted), and the Bell-type observables, $\langle \mathcal{B}_{M} \rangle/2$ (blue solid), $\langle \mathcal{B}_{S} \rangle/4$ (green solid) and $\langle \mathcal{B}_{442} \rangle/4$ (red solid), on the initial spin direction **n**, assuming the vector interaction in Eq. (59). The maximum values of the corresponding local-real theories normalise the values of Bell-type observables. In the left and right columns, the decay angles are fixed at $(\theta_B, \theta_C) = (\frac{4\pi}{6}, \frac{5\pi}{6})$ and $(\frac{2\pi}{6}, \frac{5\pi}{6})$, respectively. In the upper (lower) panels, the initial spin is rotated about the y (x) axis clockwise, and the horizontal axis indicates the rotation angle ω_y (ω_x).

see that $\langle \mathcal{B}_{M} \rangle$ and $\langle \mathcal{B}_{442} \rangle$ violate fully local-real bounds for all ω_{y} . On the other hand, we observe that Svetlichny's BLR bound is not violated in two regions of ω_{y} . In the upper left plot, \mathcal{B}_{442} coincides with $2\mathcal{B}_{M}$ over large regions of ω_{y} .

In the lower panel, where the initial spin is rotated about the x-axis, the change of various entanglement measures and Bell-type observables are milder. All observables, except for a constant C_{BC} , exhibit two peaks and two troughs at the same locations of ω_x among all observables. In all regions of ω_x , the FLR bounds are violated; $\langle \mathcal{B}_M \rangle_{\rho} > 2$ and $\langle \mathcal{B}_{442} \rangle > 4$. The Svetlichny's BLR bound is also violated in the left plot's ω_x regions. In the right plot, on the other hand, the bound is saturated at two points, $\omega_x = 0$ and π .

In Fig. 5, we show the dependence on the GTE measure, F_3 (the top panels), and various Bell-type observables, $\langle \mathcal{B}_{\rm M} \rangle / 2$ (the second panels), $\langle \mathcal{B}_{\rm S} \rangle / 4$ (the third panels) and $\langle \mathcal{B}_{442} \rangle / 4$ (the fourth panels), on the decay angles, θ_B and θ_C . In the left and middle columns, the initial spin is fixed in the directions of the z ($\theta = \phi = 0$) and y ($\theta = \phi = \frac{\pi}{2}$) -axes, respectively. In the right column, **n** is taken in the direction of $\mathbf{e}_x + \mathbf{e}_y + \mathbf{e}_z$, corresponding to $\theta = \phi = \frac{\pi}{4}$. The coupling

Figure 5: The dependence of the GTE measure, F_3 , (the first line), $\langle \mathcal{B}_M \rangle$ (the second line), $\langle \mathcal{B}_S \rangle$ (the third line) and $\langle \mathcal{B}_{442} \rangle$ (the fourth line) on the decay angles θ_B and θ_C , evaluated assuming the vector interaction Eq. (59). In the left, middle and right columns, the initial spin is fixed as $\mathbf{n} \propto \mathbf{e}_z$, \mathbf{e}_y and $(\mathbf{e}_x + \mathbf{e}_y + \mathbf{e}_z)$, respectively. For the Bell-type observables, the colour indicates the expectation values of the observables normalised by their local-real theory maxima. Namely, the colour indicates $\langle \mathcal{B}_M \rangle/2$, $\langle \mathcal{B}_S \rangle/4$ and $\langle \mathcal{B}_{442} \rangle/4$ for the plots in the second, third and fourth lines, respectively. The maximum of the colour bar is set at the corresponding quantum mechanical maximum values, $F_3^{\max} = 1$, $\langle \mathcal{B}_M \rangle_{\text{QM}}^{\max} = 4$, $\langle \mathcal{B}_S \rangle_{\text{QM}}^{\max} = 4\sqrt{2}$ and $\langle \mathcal{B}_{442} \rangle_{\text{QM}}^{\max} = 8$. The black solid curves appearing in some of the $\langle \mathcal{B}_M \rangle$ and $\langle \mathcal{B}_S \rangle$ plots indicate the saturation of the corresponding local-real bounds, $\langle \mathcal{B}_M \rangle = 2$ and $\langle \mathcal{B}_S \rangle = 4$.

constants are fixed as $c_L = c_R = d_L = d_R = \frac{1}{\sqrt{2}}$. The black contours, which appear in some plots, represent the boundary of the corresponding local-real bounds, $\langle \mathcal{B}_M \rangle = 2$ and $\langle \mathcal{B}_S \rangle = 4$. The lower-left half of the plot is empty, as the kinematics in this region are unphysical.

In the left panels with $\mathbf{n} = \mathbf{e}_z$, all observables are invariant under the exchange, $\theta_B \leftrightarrow \theta_C$, as this operation is related to the π rotation about the z axis. F_3 vanishes at three points $(\theta_B, \theta_C) = (\pi, 0), (0, \pi)$ and (π, π) and reaches the maximum value one at $(\theta_B, \theta_C) = (\frac{\pi}{2}, \frac{\pi}{2})$. A similar behaviour is observed for all Bell-type observables. Their expectation values are maximised around $(\theta_B, \theta_C) = (\frac{\pi}{2}, \frac{\pi}{2})$ and minimised around $(\theta_B, \theta_C) = (0, \frac{\pi}{2})$ and $(0, \frac{\pi}{2})$.

In the bottom left plot, we observe that the tight $4 \times 4 \times 2$ bound is always violated in the entire regions of the decay angles. This indicates that the three-particle correlations are non-FLR type in all decay angles. On the other hand, the non-violation of the Mermin inequality is observed at the top-left and bottom-right corners. This means the Mermin inequality fails to detect non-FLR correlations in these regions, as \mathcal{B}_{442} gives a tighter bound than \mathcal{B}_{M} . We also see that Svetlichny's bound is violated in some regions at the top-left and bottom-right corners. In these regions, the three-particle correlations may be describable by a bipartite local-real theory.

In the middle column with $\mathbf{n} = \mathbf{e}_y$, all observables are again symmetric under $\theta_B \leftrightarrow \theta_C$, as these configurations are related by the parity symmetry. We also see that all observables depend only on the combination $\theta_B + \theta_C$. In the top plot, we see that F_3 reaches the maximum value one at $\theta_B + \theta_C = \pi$ and vanishese at $\theta_B = \theta_C = \pi$. The same dependency is observed for the Bell-type observables. We observe that the fully local-real bounds, $\mathcal{B}_M \leq 2$ and $\mathcal{B}_{442} \leq 4$, are violated in all decay angles. The bipartite local bound, $\mathcal{B}_S \leq 4$, is also violated in all angles except at $\theta_B = \theta_C = \pi$. At this top right corner, the Svetlichny bound is saturated, $\mathcal{B}_S = 4$. In fact, the bound cannot be violated as F_3 vanishes at this point.

In the right column with $\mathbf{n} \propto (\mathbf{e}_x + \mathbf{e}_y + \mathbf{e}_z)$, the observables are not symmetric under $\theta_B \leftrightarrow \theta_C$ as expected, because the initial spin is not on the (z-y) plane (the set of fixed points under $x \to -x$). All observables have the maximum around $(\theta_B, \theta_C) \sim (\frac{3\pi}{4}, \frac{\pi}{4})$. The GTE measure, F_3 , exhibts the global minimum, $F_3 = 0$, at $(\theta_B, \theta_C) = (\pi, \pi)$. F_3 also has a local minimum around $\theta_B \sim \frac{\pi}{4}$. The Bell-type observables take the minimum values in the region corresponding to the local minimum of F_3 . While the fully local-real bounds are violated in all decay angles, non-violation of the bipartite local-real bound is observed at the vicinity of F_3 's local minimum (the top-left corner). The bound is saturated, $\langle \mathcal{B}_S \rangle = 4$, at the top-right corner, $\theta_B = \theta_C = \pi$, as the state is not genuinely three-particle entangled, $F_3 = 0$, at this point.

4.4 Tensor interaction

The matrix elements of $X \to ABC$ for the tensor-type interaction (60) are given by [26]

$$\mathcal{M}^{\mathbf{n}}_{\lambda_{A},\lambda_{B},\lambda_{C}} \propto -8\sqrt{2mp_{1}p_{2}p_{3}} \cdot \left[c^{*}d^{*} \cdot \delta^{+}_{\lambda_{A}} \delta^{+}_{\lambda_{B}} \delta^{+}_{\lambda_{C}} \cdot \left[2e^{i\phi}s\frac{\theta}{2}s\frac{\theta}{2}s\frac{\theta}{2} - c\frac{\theta}{2}s\frac{\theta}{2}-c\frac{\theta}{2}s\frac{\theta}{2} - c\frac{\theta}{2}s\frac{\theta}{2} \right] + cd \cdot \delta^{-}_{\lambda_{A}} \delta^{-}_{\lambda_{B}} \delta^{-}_{\lambda_{C}} \cdot \left[e^{i\phi}s\frac{\theta}{2}s\frac{\theta}{2}-c\frac{\theta}{2}s\frac{\theta}{2}s\frac{\theta}{2}-c\frac{\theta}{2}s\frac{\theta}{2}s\frac{\theta}{2} \right], \quad (85)$$

where we defined $c = c_M + ic_E$, $d = d_M + id_E$ and took |c| = |d| = 1. The corresponding state is found as

$$|\Psi\rangle = M_R |+++\rangle + M_L |---\rangle, \qquad (86)$$

with $(M_R, M_L) = (\mathcal{M}_{+++}^{\mathbf{n}}, \mathcal{M}_{---}^{\mathbf{n}})/\mathcal{N}$ and $|\mathcal{N}|^2 = |\mathcal{M}_{+++}^{\mathbf{n}}|^2 + |\mathcal{M}_{---}^{\mathbf{n}}|^2$. This state interpolates between fully separable states, $|+++\rangle$ and $|---\rangle$, and the maximally entangled GHZ state, $|\text{GHZ}\rangle = (|+++\rangle + |---\rangle)/\sqrt{2}$.

As in the GHZ state, all one-to-one entanglement measures vanish for this state

$$\mathcal{C}_{AB} = \mathcal{C}_{AC} = \mathcal{C}_{BC} = 0.$$
(87)

On the other hand, one-to-other entanglements are non-vanishing and universal

$$\mathcal{C}_{A(BC)} = \mathcal{C}_{B(AC)} = \mathcal{C}_{C(AB)} = 2|M_R M_L|.$$
(88)

In this symmetric case, the GTE measure F_3 is given by the square of the one-to-other concurrence (as mentioned below Eq. (18))

$$F_3 = \mathcal{C}_{i(jk)}^2 = 4|M_R M_L|^2 \,. \tag{89}$$

Many components of the three-particle correlation tensor, T_{ijk} , vanish apart from the following ones:

$$T_{111} = -T_{122} = -T_{212} = -T_{221} = 2\operatorname{Re}[M_R^*M_L],$$

$$T_{222} = -T_{112} = -T_{121} = -T_{211} = 2\operatorname{Im}[M_R^*M_L],$$

$$T_{333} = |M_R^2| - |M_L^2|.$$
(90)

Fig. 6 illustrates the response of the GTE measure, F_3 (black dotted), and Bell-type observables, $\langle \mathcal{B}_M \rangle / 2$ (blue solid), $\langle \mathcal{B}_S \rangle / 4$ (green solid) and $\langle \mathcal{B}_{442} \rangle / 4$ (red solid), to changes in the initial spin direction, **n**, assuming the tensor-type interaction in Eq. (60). The couplings are fixed as $c_M = c_E = d_M = d_E = \frac{1}{\sqrt{2}}$. The convention of the figure is the same as of Fig. 4.

In the upper panels, where the **n** rotates about the *y*-axis clockwise with the rotation angle ω_y , F_3 reaches the maximum value one at two positions and exhibits zero GTE at two places. Around the two points with $F_3 = 1$, three Bell-type observables also peak. In particular, the Mermin observable saturates its quantum mechanical maximum $\langle \mathcal{B}_M \rangle = 4$ at these points. At the vicinity of the points with $F_3 = 0$, $\langle \mathcal{B}_M \rangle$ and $\langle \mathcal{B}_S \rangle$ go below their local-real bounds. However, we see that in the region where the Mermin inequality is not violated, the tight $4 \times 4 \times 2$ bound is violated except for the two points with $F_3 = 0$. At these two points, the bound is saturated, $\langle \mathcal{B}_{442} \rangle = 4$. This means in all ω_y , there exists a spin correlation experiment whose result cannot be described by the fully local-real theory, except for the two points in ω_y . On the other hand, the experimental outcome may be explained by some bipartite local-real theory in the region ω_x .

In the lower panels, the initial spin is rotated around the x-axis by an angle ω_x . In the lower-right plot, where $(\theta_B, \theta_C) = (\frac{4\pi}{6}, \frac{5\pi}{6})$, the behaviour of the observables resembles that in the upper plots. However, a key difference is that F_3 never reaches zero, indicating that the states remain genuinely three-particle entangled (GTE) throughout. Additionally, $\langle \mathcal{B}_{442} \rangle$ never touches the line with $\langle \mathcal{B}_{442} \rangle/4 = 1$. In this family of configurations, there is not a fully local-real theory that can account for all outcomes of three-particle correlation measurements.

In the lower-right plot, with $(\theta_B, \theta_C) = \left(\frac{2\pi}{6}, \frac{5\pi}{6}\right)$, the behavior of the observables is notably different. The relation $\langle \mathcal{B}_{\rm S} \rangle = 2 \langle \mathcal{B}_{\rm M} \rangle$ holds across all values of ω_x . Furthermore, both the FLR and BLR bounds are violated throughout the entire range of ω_x .

Fig. 7 presentes the dependence of F_3 (the first line), $\langle \mathcal{B}_M \rangle$ (the second line), $\langle \mathcal{B}_S \rangle$ (the third line) and $\langle \mathcal{B}_{442} \rangle$ (the fourth line) on the decay angles θ_B and θ_C , evaluated assuming the tensor-type interaction in Eq. (60). The convention of the figure is the same as of Fig. 5

Figure 6: The dependence of the GTE measure, F_3 (black dotted), and and Bell-type observables, $\langle \mathcal{B}_{M} \rangle / 2$ (blue solid), $\langle \mathcal{B}_{S} \rangle / 4$ (green solid) and $\langle \mathcal{B}_{442} \rangle / 4$ (red solid), on the initial spin direction **n**, assuming the tensor-type interaction in Eq. (60). The convention of the figure is the same as of Fig. 4.

In the left column, where the initial spin is aligned along the z-axis ($\theta = \phi = 0$), the plots exhibit symmetry under $\theta_B \leftrightarrow \theta_C$, as this operation corresponds to a rotation about the z-axis. The GME measure F_3 vanishes at the top-left $[(\theta_B, \theta_C) = (0, \pi)]$ and bottom-right $[(\theta_B, \theta_C) = (\pi, 0))]$ corners, as well as along the line defined by $\theta_B = \theta_C$. At these points and along this line, the tight $4 \times 4 \times 2$ bound is saturated, $\langle \mathcal{B}_{442} \rangle = 4$. Outside these regions, no non-violation of the FLR bound is observed for $\langle \mathcal{B}_{442} \rangle$. In contrast, the Mermin inequality is violated within finite regions where F_3 takes small values. In these regions with $\langle \mathcal{B}_{442} \rangle > 4$, the Mermin observable fails to detect the nonlocality associated with the fully local-real theory. In regions where F_3 takes small values, the Svetlichny bound, $\langle \mathcal{B}_S \rangle \leq 4$, is not violated. Conversely, in the two regions around $\theta_B \sim \frac{\pi}{4}$ and $\theta_C \sim \frac{\pi}{4}$, the GTE measure reaches its maximum value, $F_3 = 1$. Within these regions, the Bell-type observables also attain their maximum values, saturating their quantum mechanical bounds: $\langle \mathcal{B}_M \rangle_{QM}^{max} = 4$, $\langle \mathcal{B}_S \rangle_{QM}^{max} = 4\sqrt{2}$ and $\langle \mathcal{B}_{442} \rangle_{QM}^{max} = 8$.

In the middle column, the initial spin is fixed as $\mathbf{n} = \mathbf{e}_y$ ($\theta = \phi = \frac{\pi}{2}$). In this configuration, the quantum state (85) reduces to the maximally entangled GHZ state, $|\Psi\rangle = [|+++\rangle - i| - --\rangle]\sqrt{2}$ independently of the decay angles. As a result, F_3 and all Bell-type observables take the quantum mechanical maximum values across the (θ_B, θ_C) plane.

We take the initial spin to be aligned along $(\mathbf{e}_x + \mathbf{e}_y + \mathbf{e}_z)$, corresponding to $\theta = \phi = \frac{\pi}{2}$, in the right column. The behaviour of the observables is similar to the case with $\mathbf{n} = \mathbf{e}_z$

Figure 7: The dependence of the GTE measure, F_3 , (the first line), $\langle \mathcal{B}_M \rangle$ (the second line), $\langle \mathcal{B}_S \rangle$ (the third line) and $\langle \mathcal{B}_{442} \rangle$ (the fourth line) on the decay angles θ_B and θ_C , evaluated assuming the tensor-type interaction in Eq. (60). The convention of the figure is the same as of Fig. 5.

(shown in the left column), as two strips appear where the observables reach their quantum mechanical maximum values. However, there are notable differences. First, the response of the observables is asymmetric under the exchange $\theta_B \leftrightarrow \theta_C$. Second, F_3 does not vanish anywhere in the (θ_B, θ_C) plane. Additionally, the Mermin inequality is consistently violated across the entire plane, indicating that we cannot have a fully local-realistic theory that can account for all experimental results about the three-particle correlations for any decay configuration. On the

other hand, there are two regions in the decay plane where Svetlichny's bound is not violated. In these regions, a bipartite local-real theory may exist that explains all experimental results involving three-particle correlations.

5 Conclusion

In this work, we investigated a three-body entanglement and non-locality arising from the decay of a massive fermion into three massless spin-1/2 particles. Employing a framework based on general four-fermion interactions, we have analysed the resulting correlations through the lens of several Bell-type inequalities, including the Mermin inequality and the tight $4 \times 4 \times 2$ inequality. Our analysis reveals the complex interplay between entanglement and non-locality in this three-particle system.

We demonstrated that the scalar interaction leads to bi-separable states exhibiting maximal two-body entanglement but lacking genuine three-body entanglement or non-locality. In contrast, the vector interaction generates genuinely entangled states, which violate both fully local-real and bipartite local-real bounds under specific conditions. The tensor interaction produces states that can saturate the quantum bounds of both Mermin and Svetlichny inequalities, highlighting the rich structure of three-partite entanglement.

Our numerical optimization of measurement axes, particularly for the tight $4 \times 4 \times 2$ inequality, has yielded insights into the detection capabilities of different Bell-type inequalities for various initial spin and decay configurations. We observe regions where the Mermin inequality fails to detect non-locality while the $4 \times 4 \times 2$ inequality successfully does. This highlights the need for properly choosing observables for experimental tests of quantum mechanics in multipartite systems.

The results presented in this paper advance our understanding of non-locality in threeparticle systems. The presented analysis, combining theoretical and numerical optimization of the measurement axes, provides a useful framework for future experimental investigations of three-body non-locality in particle physics, ultimately contributing to a deeper understanding of the fundamental principles of quantum mechanics. Further research should focus on extending these techniques to more complex decay channels with higher spins and exploring the implications for specific particle decay processes.

A Saturating an algebraic bound by No-Signalling correlations

A.1 General remarks on No-Signalling correlations

A natural question that has been considered is what physical statistics are allowed in a possible post-quantum theory. In particular — what physical constraints should they obey? The most natural constraints are so-called *No-Signalling conditions* [87], where a change of a setting in one laboratory can not change and output statistics in other laboratories. The only additional assumption is that the laboratories are space-like separated, and there is no further dependence on space-time [87]. Remarkably, there is also an extended formalism called *relativistically causal* [88,89], which explicitly depends on the space-time variables and, in principle, allows for so-called jamming of correlations. However, any conceivable extension of the Standard Model seems to fit the no-signalling post-quantum formalism, so this is one that we consider here. In the case of bipartite statistics, the no-signalling conditions are formulated as follows ([87]):

$$\sum_{a} P(a, b|A_i, B_j) = \sum_{a} P(a, b|A_{i'}, B_j) := P(b|B_j) \text{ for all } i, i',$$

$$\sum_{b} P(a, b|A_i, B_j) = \sum_{b} P(a, b|A_i, B_{j'}) := P(a|A_i) \text{ for all } j, j'.$$
(91)

Similarly, for the three observers, we have analogous conditions (cf. [90]):

$$\sum_{a} P(a, b, c | A_i, B_j, C_k) = \sum_{a} P(a, b, c | A_{i'}, B_j, C_k) := P(b, c | B_j, C_k) \text{ for all } i, i',$$

$$\sum_{b} P(a, b, c | A_i, B_j, C_k) = \sum_{b} P(a, b, c | A_i, B_{j'}, C_k) := P(a, c | A_i, C_k) \text{ for all } j, j',$$

$$\sum_{c} P(a, b, c | A_i, B_j, C_k) = \sum_{c} P(a, b, c | A_i, B_j, C_{k'}) := P(a, b | A_i, B_j) \text{ for all } k, k'.$$
(92)

The above scheme can be extended to many parties as well [90]. The interpretation is clear: local changes in settings can not alter remote statistics.

A.2 PR-boxes: no-signalling correlations saturating the CHSH inequality

Below, we shall recall the behaviour of the CHSH inequality from the perspective of the nosignalling framework (see [87,90]). In comparison to the main text, we shall change the indices of the values of the CHSH operator (21). Instead of A_i , B_j with i, j = 1, 2 we shall use the binary values A_x , B_y with x, y = 0, 1 (x(i) = i - 1, y(i) = i - 1) which gives:

$$\mathcal{B}_{\text{CHSH}} = A_0(B_0 + B_1) + A_0(B_0 - B_1).$$
(93)

Additionally, with a slight abuse of notation, we shall label the outcomes $A_x, B_y \in \{+1, -1\}$ using the indices $a, b \in \{0, 1\}$, such that the outcomes are expressed as $A_x = (-1)^a$ and $B_y = (-1)^b$. Given the family of statistics $\mathbf{P} = \{P(a, b|A_x, B_y)\}$ with binary inputs and the above binary enumeration of the results, one can write the mean value of (93) as

$$\langle \mathcal{B}_{\text{CHSH}} \rangle_{\boldsymbol{P}} = \langle A_0 B_0 \rangle_{\boldsymbol{P}} + \langle A_0 B_1 \rangle_{\boldsymbol{P}} + \langle A_1 B_0 \rangle_{\boldsymbol{P}} - \langle A_1 B_1 \rangle_{\boldsymbol{P}} ,$$

$$= \sum_{x,y=0,1} (-1)^{xy} \langle A_x B_y \rangle_{\boldsymbol{P}} .$$

$$(94)$$

However, we know that because of the binary character of the observables A_x and B_y , one has $\langle A_x B_y \rangle_{\mathbf{P}} = \sum_{ab} (-1)^{a \oplus b} P(a, b | A_x, B_y)$. Therefore, we have

$$\langle \mathcal{B}_{\text{CHSH}} \rangle_{\boldsymbol{P}} = \sum_{a,b,x,y=0,1} (-1)^{a \oplus b} (-1)^{xy} P(a,b|A_x,B_y) \,.$$
(95)

Here, \oplus means addition modulo 2 (for example, $0 \oplus 1 = 1$ but $1 \oplus 1 = 0$).

The following no-signalling statistics $\mathbf{P}^s = \{P^s(a, b|A_x, B_y)\}$ (s = 0, 1), called *Popescu-Rohrlich (PR) boxes* [87]

$$P^{s}(a,b|A_{x},B_{y}) = \begin{cases} \frac{1}{2} & a \oplus b \oplus s = xy\\ 0 & \text{otherwise} \end{cases},$$
(96)

are known to reach the algebraic maximum value of CHSH, namely,

$$\langle \mathcal{B}_{\text{CHSH}} \rangle_{\boldsymbol{P}^s} = (-1)^s 4.$$
⁽⁹⁷⁾

 P^0 and P^1 are often called PR-box and anti-PR-box, respectively. It is easy to see that those statistics are no-signalling since their marginals are fully random:

$$\sum_{a=0,1} P^{s}(a, b|A_{x}, B_{y}) = P(b) = \frac{1}{2},$$

$$\sum_{b=0,1} P^{s}(a, b|A_{x}, B_{y}) = P(a) = \frac{1}{2}.$$
 (98)

so they do not depend not only on the distant settings (which is required by no-signalling conditions) but also on the local ones. If one defines the completely random (therefore manifestly no-signalling) bipartite box

$$P^*(a, b|A_x, B_y) = \frac{1}{4}, \text{ for all } a, b, x, y \in \{0, 1\},$$
(99)

then the quantum extremal values can be achieved by a special convex combination $P_Q^s = (1 - \frac{1}{\sqrt{2}})P^* + \frac{1}{\sqrt{2}}P^s$ which reproduces the statistics of measurements in a maximally entangled quantum state $|\Psi\rangle = \frac{1}{\sqrt{2}}(|01\rangle + |10\rangle)$ with the measurement settings $(\theta_0^A, \theta_1^A) = (\frac{\pi}{4}, -\frac{\pi}{4})$ and $(\theta_0^B, \theta_1^B) = (0, \frac{\pi}{2})$ with $\theta_{x/y}^{A/B}$ being the angle from the z-axis on the x-z plane. In short:

$$\langle \mathcal{B}_{\text{CHSH}} \rangle_{\boldsymbol{P}_{O}^{s}} = (-1)^{s} 2\sqrt{2}. \tag{100}$$

The remarkable property, which we shall need later, is that unbiased mixture of the PR and anti-PR boxes produces a maximally random one

$$\boldsymbol{P}^* = \frac{1}{2}\boldsymbol{P}^{0\oplus r} + \frac{1}{2}\boldsymbol{P}^{1\oplus r}.$$
(101)

Here, we added a trivially arbitrary bit r = 0, 1 (which either permutes or not the boxes in the mixture) for the sake of future analysis.

A.3 No-signalling correlations saturating algebraic bound of \mathcal{B}_{442}

For the tight $4 \times 4 \times 2$ observable, there are four settings on Alice and Bob's sites A_i (i = 1, 2, 3, 4)and B_j (j = 1, 2, 3, 4) and two at Charlie's site C_k (k = 1, 2). We shall use again a binary mapping for the latter; z = k - 1 getting the mapping $C_k = (C_1, C_2) \rightarrow (C_0, C_1) = C_z$, and binary expansions for the former two; $A_i = (A_1, A_2, A_3, A_4) \rightarrow (A_{00}, A_{01}, A_{10}, A_{11}) = A_{uu'}$ and $B_j = (B_1, B_2, B_3, B_4) \rightarrow (B_{00}, B_{01}, B_{10}, B_{11}) = B_{vv'}$. Generally, the inequality will now involve the triples $A_{uu'}B_{vv'}C_z$. This gives us eventually the observable \mathcal{B}_{442} in the form

$$\mathcal{B}_{442} = [A_{00}(B_{00} + B_{01}) + A_{01}(B_{00} - B_{01})](C_0 + C_1) + [A_{10}(B_{10} + B_{11}) + A_{11}(B_{10} - B_{11})](C_0 - C_1).$$
(102)

Note that given any tripartite box $\mathbf{P} = \{P(a, b, c | A_{uu'}, B_{vv'}, C_z)\}$ the mean value of the above inequality would be

$$\langle \mathcal{B}_{442} \rangle_{\boldsymbol{P}} = \sum_{a,b,c,u,u',v,v',z=0,1} \delta_{uv} (-1)^{a \oplus b \oplus c} (-1)^{u'v'} (-1)^{uvz} P(a,b,c|A_{uu'},B_{vv'},C_z).$$
(103)

Let us consider the following tripartite boxes \tilde{P}

$$\tilde{P}(a,b,c|A_{uu'},B_{vv'},C_z) = \begin{cases} \frac{1}{4} & a \oplus b \oplus c \oplus uvz = u'v' \\ 0 & \text{otherwise} \end{cases}$$
(104)

One can check that \tilde{P} makes the expectation value of \mathcal{B}_{442} reach its algebraic maximum, i.e.⁹

$$\langle \mathcal{B}_{442} \rangle_{\tilde{\boldsymbol{P}}} = 16. \tag{105}$$

This can be easily proven by using the fact that \tilde{P} can be expressed in terms of bipartite Popescu-Rohrlich boxes P^s in Eq. (96), namely,

$$\tilde{P}(a,b,c|A_{uu'},B_{vv'},C_z) = \frac{1}{2}P^{c\oplus uvz}(a,b,|A_{u'},B_{v'}).$$
(106)

The last thing is to prove that $\tilde{\boldsymbol{P}}$ is no-signalling. This, however, is immediate. First, exploiting (101), r = uvz, and with (106) we get $\sum_{c=0,1} \tilde{P}(a, b, c|A_{uu'}, B_{vv'}, C_z) = P^*(a, b, |A_{u'}, B_{v'}) = \frac{1}{4}$, i.e. it is independent on all the input values u, u', v, v', z. Second, exploiting (98) with $s = c \oplus uvz$ together with (106), we again get $\sum_{a=0,1} \tilde{P}(a, b, c|A_{uu'}, B_{vv'}, C_z) = \sum_{b=0,1} \tilde{P}(a, b, c|A_{uu'}, B_{vv'}, C_z) = \frac{1}{4}$, which are completely independent on all the inputs.

B A semi-analytical optimisation for \mathcal{B}_{442}

The tight $4 \times 4 \times 2$ observable, \mathcal{B}_{442} , in (35) assumes in total ten measurement axes for three observers. In order to maximise its sensitivity in detecting the corresponding non-locality, one must optimise these measurement axes. A numerical optimisation over ten axes is computationally expansive, and we, therefore, adopt a semi-analytical optimisation described below. In this procedure, we analytically optimise the measurement axes up to a pair of orthonormal vectors. The $\langle \mathcal{B}_{442} \rangle_{\rho}$ can be maximised numerically over the remaining degrees of freedom.

⁹There are other distributions that lead to the algebraic maximum of $\langle \mathcal{B}_{442} \rangle$. For example, one can consider similar distributions as (104) but changing the condition for $\frac{1}{4}$ to $a \oplus b \oplus c \oplus uz = u'v'$ or $a \oplus b \oplus c \oplus vz = u'v'$. This can be understood because $\delta_{uv}(-1)^{uvz} = \delta_{uv}(-1)^{uz} = \delta_{uv}(-1)^{vz}$ in Eq. (103).

Our task is to maximise the expectation value of the tight $4 \times 4 \times 2$ observable

$$\langle \mathcal{B}_{442} \rangle_{\rho} = \sum_{i,j,k} T_{ijk} \Big\{ \left[[\vec{A}_1]_i [\vec{B}_1 + \vec{B}_2]_j + [\vec{A}_2]_i [\vec{B}_1 - \vec{B}_2]_j \right] [\vec{C}_1 + \vec{C}_2]_k \\ + \left[[\vec{A}_3]_i [\vec{B}_3 + \vec{B}_4]_j + [\vec{A}_4]_i [\vec{B}_3 - \vec{B}_4]_j \right] [\vec{C}_1 - \vec{C}_2]_k \Big\},$$

$$(107)$$

over all measurement axes represented by ten unit vectors, \vec{A}_I , \vec{B}_I $(I \in \{1, 2, 3, 4\})$ and \vec{C}_J (J = 1, 2).

We define pairs of orthonormal vectors, \vec{C}_{\pm} , $(\vec{C}_{+} \cdot \vec{C}_{-} = 0)$ as

$$\vec{C}_1 + \vec{C}_2 \equiv 2c_{\gamma}\vec{C}_+, \quad \vec{C}_1 - \vec{C}_2 \equiv 2s_{\gamma}\vec{C}_-,$$
 (108)

where $|\vec{C}_{\pm}|^2 = 1$ implies $c_{\gamma}^2 + s_{\gamma}^2 = 1$. Similarly, we define

$$\vec{B}_{1} + \vec{B}_{2} \equiv 2c_{\delta}\vec{D}_{+}, \qquad \vec{B}_{1} - \vec{C}_{2} \equiv 2s_{\delta}\vec{D}_{-}, \vec{B}_{3} + \vec{B}_{4} \equiv 2c_{\epsilon}\vec{E}_{+}, \qquad \vec{B}_{3} - \vec{B}_{4} \equiv 2s_{\epsilon}\vec{E}_{-},$$
(109)

with $|\vec{D}_{\pm}|^2 = |\vec{E}_{\pm}|^2 = 1$, $|\vec{D}_+ \cdot \vec{D}_- = \vec{E}_+ \cdot \vec{E}_- = 0$ and $c_{\delta}^2 + s_{\delta}^2 = c_{\epsilon}^2 + s_{\epsilon}^2 = 1$. We further define rank-2 tensors (3 × 3 matrices) T_{\pm} as

$$[T_{\pm}]_{ij} = \sum_{k} T_{ijk} [\vec{C}_{\pm}]_k, \tag{110}$$

In terms of these new vectors and tensors, Eq. (107) can be written as

$$\langle \mathcal{B}_{442} \rangle_{\rho} = 4 \left[c_{\gamma} X + s_{\gamma} Y \right] \tag{111}$$

with

$$X = c_{\delta} \left(\vec{A}_{1} \cdot T_{+} \cdot \vec{D}_{+} \right) + s_{\delta} \left(\vec{A}_{2} \cdot T_{+} \cdot \vec{D}_{-} \right) ,$$

$$Y = c_{\epsilon} \left(\vec{A}_{3} \cdot T_{-} \cdot \vec{E}_{+} \right) + s_{\epsilon} \left(\vec{A}_{4} \cdot T_{-} \cdot \vec{E}_{-} \right) .$$
(112)

For given T_{ijk} , \vec{A}_I , \vec{B}_I , and \vec{C}_{\pm} , X and Y are fixed, and one can optimise c_{γ} and s_{γ} as

$$c_{\gamma} = \frac{X}{\sqrt{X^2 + Y^2}}, \quad s_{\gamma} = \frac{Y}{\sqrt{X^2 + Y^2}},$$
 (113)

which leads to $\langle \mathcal{B}_{442} \rangle_{\rho} = 4\sqrt{X^2 + Y^2}$. This quantity is further optimised over $c_{\delta}, s_{\delta}, c_{\epsilon}$ and s_{ϵ} with

$$c_{\delta} = \frac{\vec{A}_{1} \cdot T_{+} \cdot \vec{D}_{+}}{\sqrt{\left[\vec{A}_{1} \cdot T_{+} \cdot \vec{D}_{+}\right]^{2} + \left[\vec{A}_{2} \cdot T_{+} \cdot \vec{D}_{-}\right]^{2}}}, \quad s_{\delta} = \frac{\vec{A}_{2} \cdot T_{+} \cdot \vec{D}_{-}}{\sqrt{\left[\vec{A}_{1} \cdot T_{+} \cdot \vec{D}_{+}\right]^{2} + \left[\vec{A}_{2} \cdot T_{+} \cdot \vec{D}_{-}\right]^{2}}}, \\ c_{\epsilon} = \frac{\vec{A}_{3} \cdot T_{-} \cdot \vec{E}_{+}}{\sqrt{\left[\vec{A}_{3} \cdot T_{-} \cdot \vec{E}_{+}\right]^{2} + \left[\vec{A}_{4} \cdot T_{-} \cdot \vec{E}_{-}\right]^{2}}}, \quad s_{\epsilon} = \frac{\vec{A}_{4} \cdot T_{-} \cdot \vec{E}_{-}}{\sqrt{\left[\vec{A}_{3} \cdot T_{-} \cdot \vec{E}_{+}\right]^{2} + \left[\vec{A}_{4} \cdot T_{-} \cdot \vec{E}_{-}\right]^{2}}}, \quad (114)$$

which results in

$$\langle \mathcal{B}_{442} \rangle_{\rho} = 4\sqrt{\left[\vec{A}_{1} \cdot T_{+} \cdot \vec{D}_{+}\right]^{2} + \left[\vec{A}_{2} \cdot T_{+} \cdot \vec{D}_{-}\right]^{2} + \left[\vec{A}_{3} \cdot T_{-} \cdot \vec{E}_{+}\right]^{2} + \left[\vec{A}_{4} \cdot T_{-} \cdot \vec{E}_{-}\right]^{2}}.$$
 (115)

For given T_{ijk} , \vec{D}_{\pm} , \vec{E}_{\pm} and \vec{C}_{\pm} , we maximise the first term by taking \vec{A}_1 in the direction of $T_+ \cdot \vec{D}_+$. The other terms can be maximised in the same way, that is, we take

$$\vec{A}_{1} = \frac{T_{+} \cdot \vec{D}_{+}}{\left|T_{+} \cdot \vec{D}_{+}\right|}, \quad \vec{A}_{2} = \frac{T_{+} \cdot \vec{D}_{-}}{\left|T_{+} \cdot \vec{D}_{-}\right|}, \quad \vec{A}_{3} = \frac{T_{-} \cdot \vec{E}_{+}}{\left|T_{-} \cdot \vec{E}_{+}\right|}, \quad \vec{A}_{4} = \frac{T_{-} \cdot \vec{E}_{-}}{\left|T_{-} \cdot \vec{E}_{-}\right|}.$$
 (116)

After these optimisation processes, $\langle \mathcal{B}_{442} \rangle_{\rho}$ can be written as

$$\langle \mathcal{B}_{442} \rangle_{\rho} = 4\sqrt{\left[\vec{D}_{+} \cdot U_{+} \cdot \vec{D}_{+}\right] + \left[\vec{D}_{-} \cdot U_{+} \cdot \vec{D}_{-}\right] + \left[\vec{E}_{+} \cdot U_{-} \cdot \vec{E}_{+}\right] + \left[\vec{E}_{-} \cdot U_{-} \cdot \vec{E}_{-}\right]}, \quad (117)$$

with $U_{\pm} \equiv (T_{\pm})^T \cdot T_{\pm}$.

Finally for given T_{ijk} and \vec{C}_{\pm} , we optimise the above expression over two pairs of orthonormal vectors (\vec{D}_+, \vec{D}_-) and (\vec{E}_+, \vec{E}_-) . We first note that U_{\pm} are real symmetric matrices. Therefore, their eigenvalues are non-negative, and the eigenvectors corresponding to different eigenvalues are orthogonal. This means Eq. (117) can be maximised by taking (\vec{D}_+, \vec{D}_-) to be the eigenvectors corresponding to the two largest eigenvalues of U_+ , λ_1^+ and λ_2^+ . Similarly, (\vec{E}_+, \vec{E}_-) should be taken as the eigenvectors corresponding to the two largest eigenvalues of U_- , λ_1^- and λ_2^- . As a result, we have

$$\langle \mathcal{B}_{442} \rangle_{\rho} = 4\sqrt{\lambda_1^+ + \lambda_2^+ + \lambda_1^- + \lambda_2^-} \,. \tag{118}$$

Note that this expression has some similarity to the analytical formula for the optimised $\mathcal{B}_{\text{CHSH}}$ derived in [91]. For a given state, ρ (or equivalently T_{ijk}), the matrices U_{\pm} are functions of a pair of orthonormal vectors (\vec{C}_+, \vec{C}_-) . One, therefore, still has to optimise the above expression over \vec{C}_{\pm} . Since a pair of orthonormal vectors can be parametrised by one polar angle, $0 \leq \bar{\theta} \leq \pi$ and two azimuthal angles, $0 \leq \phi_1, \phi_2 \leq 2\pi$ by

$$\vec{C}_{+} = \begin{pmatrix} \sin \bar{\theta} \cos \phi_1 \\ \sin \bar{\theta} \sin \phi_1 \\ \cos \bar{\theta} \end{pmatrix}, \quad \vec{C}_{-} = \begin{pmatrix} \cos \bar{\theta} \cos \phi_1 \cos \phi_2 - \sin \phi_1 \sin \phi_2 \\ \cos \bar{\theta} \sin \phi_1 \cos \phi_2 + \cos \phi_1 \sin \phi_2 \\ -\sin \bar{\theta} \cos \phi_2 \end{pmatrix}, \quad (119)$$

the expression (118) can be maximised over these three angles. Compared to an optimisation of the initial expression (107) over ten measurement axes, the numerical optimisation over three angles is computationally much less expensive.

Since the elements of the spin correlation matrix cannot exceed one and $|\vec{C}_{\pm}| = 1$, the maximum eigenvalue of the U_{\pm} matrix is bounded by 1. This and the expression (118) leads to the quantum upper bound

$$\langle \mathcal{B}_{442} \rangle_{\rm QM} \le 8. \tag{120}$$
