Abstract

Reliable reservoir volume estimates are crucial for water resource management, especially in arid and semi-arid regions. The present study investigates applying three machine learning regression techniques—Gradient Boosting, Random Forest, and ElasticNet—to predict key dam performance characteristics of the Loskop Dam in South Africa. The models were trained and validated on a dataset comprising geospatial elevation measurements paired with corresponding reservoir supply capacity values. The best-performing approach was a threshold-based blended model that combined random forest for higher volumes with Ridge regression for lower volumes. This model achieved an RMSE of 4.88 MCM and an R² of 0.99. These findings highlight the ability of ensemble learning techniques to capture complex relationships in dam datasets and underscore their practical utility for reliable dam performance modelling in real-world water resource management scenarios.

Keywords: Reservoir volume, ensemble learning, Gradient Boosting, Random Forest, ElasticNet, Water management, machine learning

1. Introduction

Dams play a pivotal role in water resource management, hydropower generation, and flood control. However, accurate predictive models are essential for their operation, especially when dealing with fluctuating environmental conditions and increased demand. Traditional hydrological models often struggle to capture the complexity of such systems. The advent of machine learning (ML) offers new opportunities to enhance predictive capabilities by utilizing large datasets and advanced algorithms (Maity et al., 2024).

This work aims to develop a machine-learning model that predicts dam volume using features such as water area, physical dam attributes, and other characteristics, including full supply capacity. Multiple models were iteratively built to improve predictive accuracy and performance comparison, each incorporating additional features to refine the outputs. Accurately monitoring reservoir storage is challenging since in-situ data are often unavailable; therefore, remote sensing observations of water extent and height combined with data-driven models are increasingly used for reservoir volume estimation (Ghosh et al., 2014; Hou et al., 2021). This study seeks to enhance the precision of dam volume estimates, providing a valuable tool for decision-makers in water management.

2. Data Preparation

The dataset used in the study comprises information on dam volume, water area, and observed water levels obtained from <u>Department of Water Affairs and Sanitation, South</u> <u>Africa</u> and <u>Digital Earth Africa</u>. The dataset was processed to ensure consistency and reliability before being used in the machine-learning models. Several pre-processing steps were performed to ensure data quality and model performance:

2.1. Invalid Values Removal: Entries with erroneous values (e.g., -9.9) may create biased outputs or alter results if encountered while model building; hence, they were removed.

2.2. Outlier Handling: The dataset was checked for outliers. Outliers can heavily influence models, especially regression models, and hence, they were addressed using the Interquartile Range (IQR) method, which excluded extreme values.

2.3. Feature Engineering: Additional features were generated, such as Inflow to outflow elevation as well as slope and distance along the river

In the dataset, some extreme values for the water area were identified as outliers. These values could distort the model's accuracy, so it was necessary to remove them to improve performance. The Interquartile Range (IQR) method detected and removed outliers. The IQR method identifies values that fall outside of 1.5 times the range between the first quartile (Q1) and the third quartile (Q3). This method ensures that only realistic water area values are used for model training, enhancing the model's ability to generalize. In Fig 1, the boxplot shows the water area distribution, with the outliers visible. The plot shows that most dams have a water area greater than 1500 ha. The median close to the upper quartile indicates the data is negatively skewed.

Fig 1: Boxplot showing water area distribution and outliers

3. Model Development

3.1 Base Model

The base model utilized water area as the sole predictor of dam volume, with a Random Forest Regressor serving as the model. This model produced (Fig 2) the following metrics (RMSE: 45.77 MCM with R² Score: 0.58)

Fig 2: Actual vs predicted values of dam volume obtained from the base model

3.2 Model with Full Supply Capacity Feature

An additional feature representing full supply capacity was added, defined by a threshold on water area (Fig 3). This enhancement significantly improved the model's performance (RMSE: 13.86 MCM with R² Score: 0.93).

Fig 3: Actual vs predicted values of dam volume obtained from the full capacity model

3.3 Model with Geographical Features

Geographical attributes such as inflow and outflow elevations, vertical drop, distance along the river, and slope were added. While these features added valuable context (Fig 4), they did not improve performance metrics (RMSE: 13.86 MCM with R² Score: 0.93).

3.4 Model with Full Supply Elevation

The full supply elevation (999.38m) was introduced as an additional reference point for maximum dam capacity. However, it did not further enhance the model's (Fig 5) predictive ability (RMSE: 13.86 MCM with R² Score: 0.93).

3.5. Model Parameter Comparison

Table 1 below compares the parameters and features used in each model rendition. As we progressed through the models, additional features such as full supply capacity, geographical features, and full supply elevation were incorporated to improve accuracy.

Model Rendition	Water Area	Full Supply	Geographical	Full	Supply
		Capacity	Features	Elevation	
Base model	Yes	No	No	No	
Full capacity	Yes	Yes	No	No	
Geographical	Yes	Yes	Yes	No	
Full elevation	Yes	Yes	Yes	Yes	

Table 1 Comparison of parameters and features used in each model rendition

3.6 Ensemble Models

Ensembles are combination of multiple models that are used to improve accuracy and handle complex relationships. Several ensemble techniques were explored, including ElasticNet, Lasso, and Ridge which are linear regression models with regularization. Table 2 provides a summary of the obtained RMSE and R² Sore for each of the three regression models.

Model	RMSE (MCM)	R ²	
ElasticNet	8.36	0.983	
Lasso	8.361	0.983	
Ridge	8.228	0.983	

Table 2 Performance comparison of all ensemble techniques

3.7 ElasticNet: Time Series Chart

The following chart shows (Fig 6) the actual vs predicted dam volume over the entire time period for the ElasticNet model.

Fig 6: Actual vs predicted values of dam volume obtained from the ElasticNet ensemble model

3.8 Lasso: Time Series Chart

The following chart shows (Fig 7) the actual vs predicted dam volume over the entire time period for the Lasso model.

Fig 7: Actual vs predicted values of dam volume obtained from the Lasso Ensemble model

3.9 Ridge: Time Series Chart

The following chart shows (Fig 8) the actual vs predicted dam volume over the entire time period for the Ridge model.

Fig 8: Actual vs predicted values of dam volume obtained from the Ridge ensemble model

4. Observed vs Predicted Performance across Models

The following plot (Fig 9) shows the comparison of observed vs predicted dam volume values for each model rendition. A perfect prediction would fall along the diagonal line, allowing us to visualize the accuracy of each model in comparison to the actual values. The closer the points are to the diagonal line, the better the model's performance.

Fig 9: Observed vs predicted values of dam volume obtained from all models

4.1 Blended Model

Based on the residual analysis, a blended model was developed by combining the strengths of different models. For dam volumes below a threshold (median), the Ridge model (Fig 10) was used, and for higher volumes, the Random Forest model was applied. This blended model achieved the RMSE 8.02 MCM with R² 0.98. This approach marginally improved the model's performance over using any single model alone. The following chart shows the actual vs predicted dam volume over the entire time for the blended model.

Fig 10: Actual vs predicted values of dam volume obtained from the blended model

4.2 Residuals by Volume Ranges

The following plot (Fig 11) shows the residuals (observed - predicted) for each model, compared against the observed dam volumes. This helps in visualizing how well each model performs for different volume ranges, and whether certain models perform better at lower or higher volumes.

Fig 11: Residuals vs observed values of dam volume for all models

4.3 Threshold-Based Blending

Various thresholds were tested for the blended model, with the 200 MCM threshold providing the best performance (RMSE 4.88 MCM with R² 0.99). Using the rating curve, a threshold of 244 MCM was identified. This gauge-based blending model yielded RMSE 5.02 MCM with R² 0.99.

4.4 Blended Model Performance by Thresholds

To determine the optimal threshold for blending the models, we tested different thresholds based on the percentiles of the observed dam volume (25th, 50th, and 75th) and specific volume levels (200 MCM and 300 MCM). The goal was to identify the threshold that results in the best predictive performance for the blended model. The table below (Table 3) shows the performance of the blended model at each threshold, with the 200 MCM threshold achieving the best results.

Threshold	RMSE	R ²
25 th Percentile	5.968	0.987
50 th Percentile (Median)	8.019	0.977
75 th Percentile	8.906	0.971
200 MCM	4.881	0.991
300 MCM	6.516	0.985

Table 3 Performances of the blended model at different thresholds

4.5 Blended Model at 25th Percentile: Time Series Chart

The following chart (Fig 12) shows the actual vs predicted dam volume over the entire time period for the blended model at the 25th percentile threshold.

Fig 12: Actual vs predicted values of dam volume obtained from the blended model at 25th percentile

4.6 Blended Model at 50th Percentile (Median): Time Series Chart

The following chart (Fig 13) shows the actual vs predicted dam volume over the entire period for the blended model at the 50th percentile (median) threshold.

Fig13: Actual vs predicted values of dam volume obtained from the blended model at 50th percentile

4.7 Blended Model at 75th Percentile: Time Series Chart

The following chart (Fig 14) shows the actual vs predicted dam volume over the entire time period for the blended model at the 75th percentile threshold.

4.8 Blended Model at 200 MCM: Time Series Chart

The following chart (Fig 15) shows the actual vs predicted dam volume over the entire time period for the blended model at the 200 MCM threshold.

Fig 15: Actual vs predicted values of dam volume obtained from the blended model at 200 MCM

4.9 Blended Model at 300 MCM: Time Series Chart

The following chart (Fig 16) shows the actual vs predicted dam volume over the entire time period for the blended model at the 300 MCM threshold.

Fig 16: Actual vs predicted values of dam volume obtained from the blended model at 300 MCM

4.10 Blended Model Using Rating Curve for Threshold Definition

In this approach, we utilized the rating curve, which provides the relationship between gauge reading (stage height) and dam volume, to define a more meaningful threshold for blending the models. By analyzing points of significant volume change along the rating curve, we identified a key threshold at approximately 22.2m, where the volume is around 244 MCM (Fig 17).

Fig 17: Rating curve between gauge reading vs volume

Using this threshold, the Ridge model was applied for volumes below 244 MCM, and the Random Forest model was used for higher volumes. This gauge-based blending achieved an RMSE 5.02 MCM with R² 0.99. The rating curve shows how volume increases with the gauge reading (stage height). There are some notable inflection points where the volume starts increasing more rapidly. The curve shows a gradual increase in volume with stage height. The specific gauge readings can be used to define thresholds where the volume increase becomes more pronounced.

4.10.1 Blended Model at 244 MCM (Gauge Threshold): Time Series Chart

1. *Define Thresholds*: Based on the curve, we can select specific gauge readings to set as thresholds for the blended model. For example:

- A lower threshold around a gauge reading of 2-3m, where the volume increases more slowly.
- A higher threshold where the volume begins to increase rapidly at higher stage heights.
- 2. *Implement Blending*: We can adjust the blending of the models based on these gauge reading thresholds rather than volume alone.

The following chart (Fig 18) shows the actual vs predicted dam volume over the entire time period for the blended model at the 244 MCM (gauge-based) threshold. Except at some points where lags are visible between the actual and predicted dam volumes, the model accurately predicts the time series variations.

Fig 18: Actual vs predicted values of dam volume obtained from the blended model at 244 MCM

5. Model Performance Comparison

The Random Forest model, a tree-based ensemble method, aggregates predictions from multiple decision trees to reduce overfitting. In contrast, ElasticNet, Lasso, and

Ridge are linear regression models that incorporate regularization to manage overfitting. These techniques were compared as follows:

- The initial model used in this project was a Random Forest, which is an ensemble of decision trees that works by averaging the predictions of multiple decision trees to reduce overfitting and improve generalization. This method is a type of ensemble method.
- In contrast, the ElasticNet, Lasso and Ridge models are linear regression-based techniques with regularization. These models help address overfitting by adding a penalty term to the regression equation, which controls the complexity of the model.
- ElasticNet combines both L1 (Lasso) and L2 (Ridge) penalties, making it effective for datasets with correlated features.
- Lasso applies L1 regularization, forcing some coefficients to become zero, effectively selecting a subset of features.
- Ridge applies L2 regularization, penalizing large coefficients, but does not eliminate any feature entirely.

These ensemble methods were evaluated alongside Random Forest to see how linear regression-based approaches perform compared to tree-based methods. Table 4 presents each model performance. It can be observed that the Blended (200 MCM Threshold) model shows best performance. The blended model approach combined the strengths of the Ridge and Random Forest models by applying them at different volume thresholds.

Model	RMSE	R ²
Base Model	45.77	0.58
Full Capacity Feature	13.86	0.93
Geographical Features	13.86	0.93
Full Supply Elevation	13.86	0.93
ElasticNet	8.36	0.983
Lasso	8.361	0.983
Ridge	8.228	0.983
Blended (244 MCM Threshold)	5.02	0.99
Blended (200 MCM Threshold)	4.88	0.99

Table 4 Performances of all models

6. Conclusion

In summary, we developed a machine learning approach for dam volume prediction that progressively incorporated key features and ensemble techniques to boost accuracy. The inclusion of the full supply capacity feature had the most significant positive impact on model performance, reducing the RMSE from 45.77 to 13.86 and improving the R² score to 0.93. While additional features such as geographical attributes did not improve accuracy, they provided valuable context. The exploration of ensemble models, including ElasticNet, Lasso, and Ridge, led to further improvements. A blended model approach using thresholds like 200 MCM and 244 MCM provided the best overall performance, with RMSE values as low as 4.88 and an R² score of 0.99.

This level of accuracy is on par with the remote-sensing-based methods is acceptable (Pimenta et al., 2025) and was achieved by combining data-driven models with domain knowledge. The final blended model can serve as a highly reliable tool for estimating reservoir storage volumes. Such a model is valuable for water resource managers, as it enables better monitoring of reservoir conditions and can inform decision-making for allocation, flood control, and drought management. Our approach demonstrates that integrating physical reservoir characteristics (like capacity and rating curves) with modern machine learning techniques can yield robust and interpretable predictive models for dam volume, contributing to more effective and informed water management practices.
