### ABSTRACT

We present **Augustus**, a catalog of distance, extinction, and stellar parameter estimates to 170 million stars from  $14 \text{ mag} < r < 20 \text{ mag}$  and with  $|b| > 10^\circ$  drawing on a combination of optical to near-IR photometry from Pan-STARRS, 2MASS, UKIDSS, and unWISE along with parallax measurements from *Gaia* DR2 and 3-D dust extinction maps. After applying quality cuts, we find 125 million objects have “high-quality” posteriors with statistical distance uncertainties of  $\lesssim 10\%$  for objects with well-constrained stellar types. This is a substantial improvement over distance estimates derived from *Gaia* parallaxes alone and in line with recent results from Anders et al. (2019). We find the fits are able to accurately reproduce the de-reddened *Gaia* color-magnitude diagram, which serves as a useful consistency check of our results. We show that we are able to clearly detect large, kinematically-coherent substructures in our data relative to the input priors, including the Monoceros Ring and the Sagittarius stream, attesting to the quality of the catalog. Our results are publicly available at [doi:10.7910/DVN/WYMSXV](https://doi.org/10.7910/DVN/WYMSXV). An accompanying interactive visualization can be found at <http://allsky.s3-website.us-east-2.amazonaws.com>.

*Keywords:* stellar distance – Milky Way Galaxy – sky surveys – photometry – parallax

### 1. INTRODUCTION

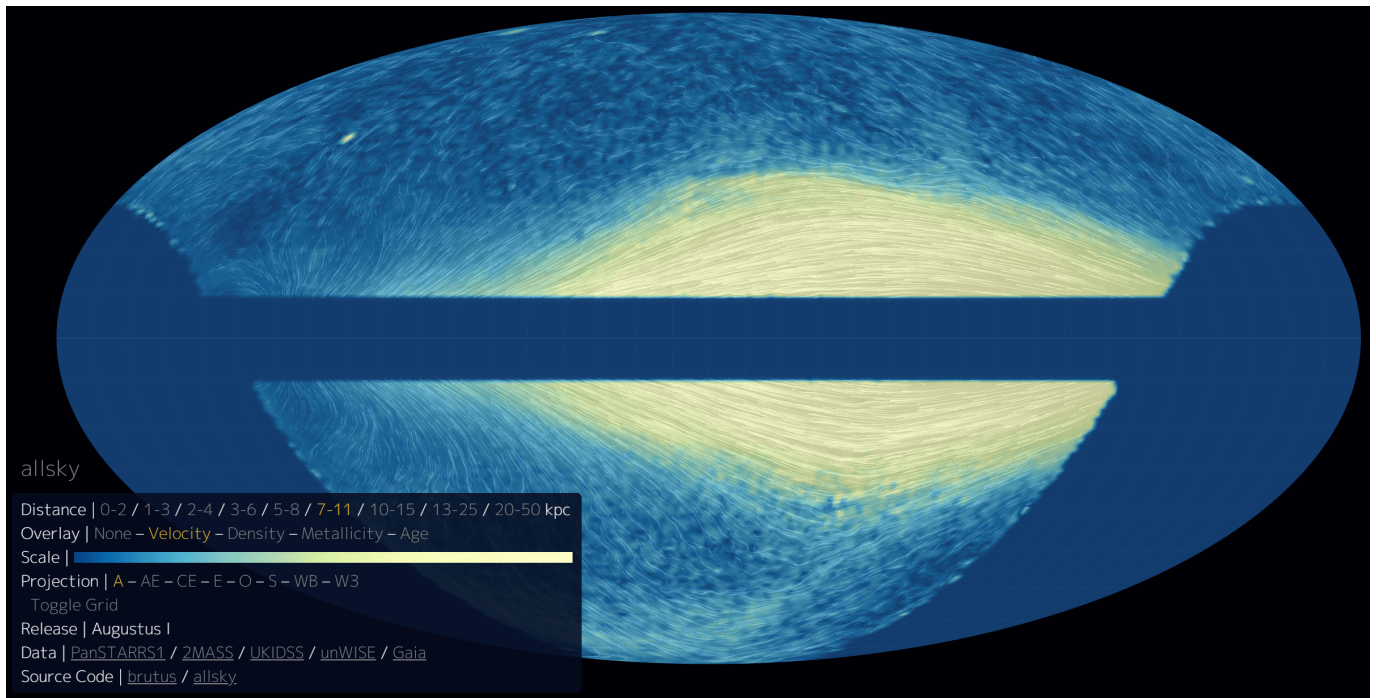

A central challenge in astronomy is converting the projected 2-D positions of sources on the sky into 3-D maps that we can use to infer properties about the Universe. This is especially true when studying the Milky Way, where recent observational advances have opened possibilities for 3-D mapping across our Galaxy. But many

new discoveries depend on the fidelity of such 3-D mapping. Recent work has exploited full phase-space data to uncover the remnants of a major merger  $\sim 10$  Gyr ago (e.g., Koppelman et al. 2018; Belokurov et al. 2018; Helmi et al. 2018; Naidu et al. 2021) and a phase-space “spiral” (e.g., Antoja et al. 2018) while in the halo accurate phase-space maps of stellar streams have begun to constrain the potential of the Galaxy (e.g. Johnston et al. 1999; Law & Majewski 2010; Bonaca & Hogg 2018).

These discoveries have benefited from simultaneous advances across multiple fronts. On the data side, large

**Figure 1.** A screenshot of an interactive visualization of 3-D distance and 2-D velocity structure from the *Augustus* catalog that can be accessed online at <http://allsky.s3-website.us-east-2.amazonaws.com>. The background color is based on the overall tangential speed of the sources in a given distance bin, while the white streamlines follow the tangential velocities of the same sources in the given coordinate projection. The interface to change these properties (distance bin, background properties, and projection) is shown in the bottom left and can be opened/minimized by clicking on the “allsky” text.

missions such as the ground-based Sloan Digital Sky Survey (SDSS; York et al. 2000) and the space-based *Gaia* mission (Gaia Collaboration et al. 2016) have published enormous public datasets. Together, these observational efforts promise to provide new, much sharper maps of the stellar components of the Galaxy using billions of individual sources. Simultaneously, advances in statistical modeling and computational power have enabled us to more robustly infer the 3-D distribution of a large number of stars (e.g., Green et al. 2014; Bailer-Jones et al. 2018) along with additional properties such as ages and abundances (e.g., Ness et al. 2015; Anders et al. 2019; Xiang et al. 2019; Leung & Bovy 2019a). Finally, advances in numerical simulations and Galactic dynamics have enabled us to interpret these results in much more detail (see Rix & Bovy 2013; Sellwood 2014; Helmi 2020, and references therein).

As most sources ( $\sim 99\%$ ) seen in large photometric surveys do not have measured spectra, much of the work associated with deriving 3-D maps to billions of stars has relied on modeling coarse spectral energy distributions (SEDs) comprised of flux densities estimated across a range of broad-band and narrow-band photometric filters (e.g., Green et al. 2019; Anders et al. 2019). More recently, *Gaia* DR2 (Gaia Collaboration et al. 2018) has also provided astrometric parallax measurements for

many of these sources, giving independent constraints on the distance.

Efforts in this area range from 3-D dust mapping (e.g., Rezaei Kh. et al. 2018; Leike & Enßlin 2019; Lalletment et al. 2019; Green et al. 2019) to stellar parameter estimation (e.g., Ness et al. 2015; Cargile et al. 2020; Anders et al. 2019). In Speagle et al. (2021a, subm.), we described new methods implemented in the public, open-source PYTHON package BRUTUS<sup>1</sup> that further contribute to these efforts by allowing for quick and robust estimation of stellar properties, distances, and reddenings to stars with photometric and astrometric data. In this paper, we present *Augustus*, a “proof-of-concept” application of BRUTUS to estimate distances, reddenings, and various stellar properties to 170 million sources brighter than  $r < 20$  mag with Galactic latitudes  $|b| > 10^\circ$ .

The outline of the paper is as follows. In §2, we describe the datasets, quality cuts, and selections used to select the 170 million objects in this work. In §3, we summarize the approach taken to modeling and fitting the 170 million sources described with BRUTUS. In §4, we describe the catalogs produced by this modeling. In §5, we discuss results demonstrating the qual-

<sup>1</sup> <https://github.com/joshspeagle/brutus>

ity of the output data, including “blind” recovery of the *Gaia* color-magnitude diagram and the detection of known large-scale Galactic substructure. We conclude in §6. A detailed description of the data products provided as part of this work can be found in Appendix A. An interactive figure highlighting many of the features of our output catalog can be found at <http://allsky.s3-website.us-east-2.amazonaws.com>; a screenshot is shown in Figure 1 and described in more detail in §5.5.

Throughout the paper, individual parameters (scalars) are notated using standard italicized math fonts ( $\theta$ ) while vectors and matrices are notated using boldface ( $\boldsymbol{\theta}$ ). Collections of parameters are notated using sets ( $\boldsymbol{\theta} = \{\theta_i\}_{i=1}^n$ ). Vectors should be assumed to be in column form (i.e. of shape  $n \times 1$ ) unless explicitly stated otherwise. All magnitudes reported are in the native units provided by their corresponding datasets.

## 2. DATA

Our analysis is based on the combination of several surveys:

- the Panoramic Survey Telescope and Rapid Response System (Pan-STARRS; Chambers et al. 2016),
- the Two Micron All Sky Survey (2MASS; Skrutskie et al. 2006),
- the United Kingdom Infrared Telescope Infrared Deep Sky Survey (UKIDSS; Lawrence et al. 2007),
- the “unofficial” Wide-field Infrared Survey Explorer catalog (unWISE; Wright et al. 2010; Schlafly et al. 2019), and
- the *Gaia* survey (Gaia Collaboration et al. 2016).

In §2.1-§2.5, we describe each of the various datasets. In §2.6, we describe how the datasets are combined into a final catalog. The overall sky and wavelength coverage from these combination of surveys are shown in Figure 2 and 3, respectively.

### 2.1. Pan-STARRS

The Pan-STARRS survey<sup>2</sup> is a multi-epoch, deep, broadband optical survey of the northern sky visible from Haleakala in Hawaii (i.e.  $\delta > -30^\circ$ ). It observed in five photometric bands (*grizy*) spanning  $0.4 \mu\text{m} - 1 \mu\text{m}$  with a typical single-epoch  $5\sigma$  point-source exposure depth of  $g = 22.0$  mag,  $r = 21.8$  mag,  $i = 21.5$  mag,  $z = 20.9$  mag, and  $y = 19.7$  mag in the AB system (Oke & Gunn 1983).

The photometry used in this work is based on combined single-epoch photometry obtained as part of the

<sup>2</sup> <https://panstarrs.stsci.edu/>

Pan-STARRS1  $3\pi$  Steradian Survey DR1 (Chambers et al. 2016). Photometry and astrometry were derived from combined images as described in Magnier et al. (2016). We remove galaxies by requiring that the difference between the point-spread function (PSF) model photometry and aperture photometry is  $< 0.1$  mag across at least four bands. We remove objects below the Pan-STARRS saturation limit in each band, and also objects with magnitude errors  $> 0.2$  mag.

### 2.2. 2MASS

2MASS<sup>3</sup> is a near-infrared (NIR) survey of the entire sky in three photometric bands ( $JHK_s$ ) spanning  $1 \mu\text{m} - 2.3 \mu\text{m}$  with a typical  $10\sigma$  point-source exposure depth of  $J = 15.8$  mag,  $H = 15.1$  mag, and  $K_s = 14.3$  mag in the Vega system.<sup>4</sup> We utilize data from the 2MASS “high-reliability” catalog<sup>5</sup>, which minimizes contamination and confusion by neighboring point and/or extended sources. We also require errors to be  $< 0.2$  mag and that no photometry quality (`ph_qual`), read quality (`rd_qual`), or galaxy contamination (`gal_contam`) flags are set.

### 2.3. UKIDSS

The UKIDSS project<sup>6</sup> is defined in Lawrence et al. (2007). UKIDSS uses the UKIRT Wide Field Camera (WFCAM; Casali et al. 2007). The photometric system is described in Hewett et al. (2006), and the calibration is described in Hodgkin et al. (2009). The science archive is described in Hambly et al. (2008).

We use data from the UKIDSS Large Area Survey (LAS) second data release (Dye et al. 2006; Warren et al. 2007a,b, DR2;). UKIDSS LAS imaged 4000 square degrees in three fields (an equatorial block, a northern block, and a southern stripe) that were a subset of the SDSS footprint (York et al. 2000) in four photometric bands ( $YJHK$ ) spanning  $1 \mu\text{m} - 2 \mu\text{m}$  with a typical  $5\sigma$  point-source exposure depth of  $Y = 20.5$  mag,  $J = 20.0$  mag,  $H = 18.8$  mag, and  $K = 18.4$  mag in the Vega system. We require the errors to be  $< 0.2$  mag, the probability of being a star `pstar`  $> 0.9$ , and that no processing/warning errorbit flags (`[J_1/h/k]ppErrBits`) are set.

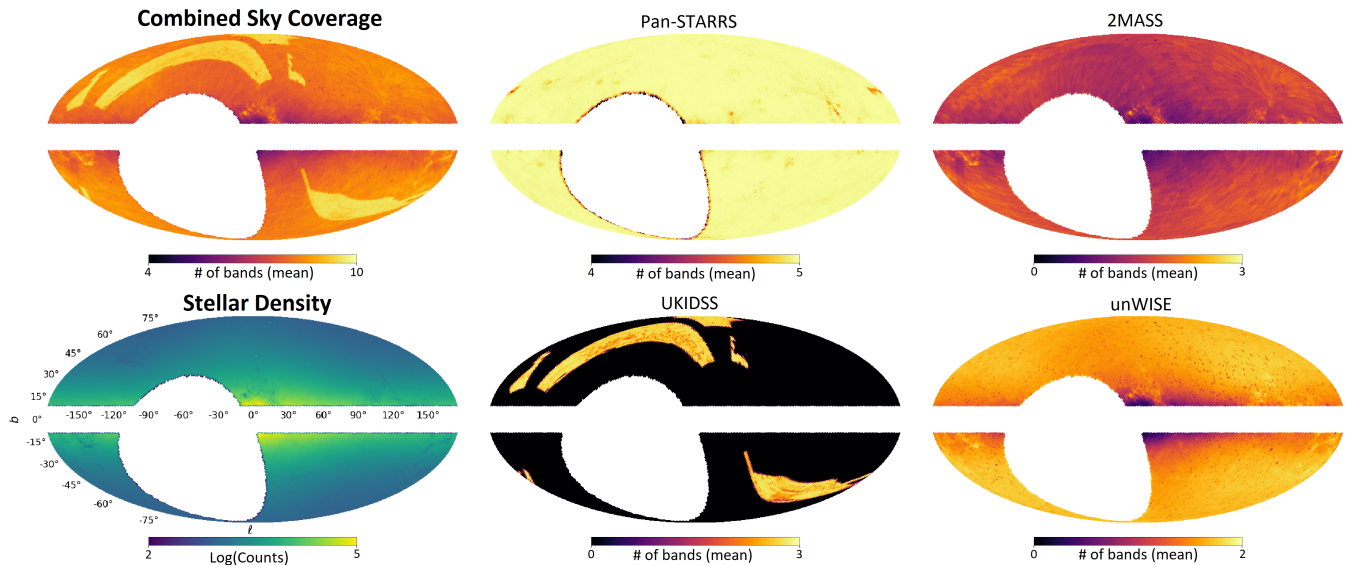

### 2.4. unWISE

<sup>3</sup> <https://old.ipac.caltech.edu/2mass/>

<sup>4</sup> While references to the “Vega system” suggest a single alternate system, it instead represents a variety of independent photometric calibrations to differing models of Vega. This introduces additional systematics when attempting to combine photometry across different surveys, which will be discussed later.

<sup>5</sup> The cuts used in this selection are described at <https://old.ipac.caltech.edu/2mass/releases/allsky/doc/sec22.html>.

<sup>6</sup> <http://www.ukidss.org/surveys/surveys.html>

**Figure 2.** Projected maps showing the coverage of the data used in the work at a `healpix` resolution of `nside = 64` plotted as a function of Galactic longitude  $\ell$  and latitude  $b$ , centered on  $(\ell, b) = (0^\circ, 0^\circ)$ . The top left panel shows the mean number of bands from all surveys combined, while the bottom left panel shows the overall (log-)number of stars in each pixel. The mean number of bands from the individual surveys are shown in the remaining panels, with Pan-STARRS (§2.1) in the top middle panel, 2MASS (§2.2) in the top right panel, UKIDSS (§2.3) in the bottom middle panel, and unWISE (§2.4) in the bottom right panel. While towards the Galactic center we lose a substantial amount of coverage (transition from orange/yellow to purple in the upper left panel) due to crowding and dust extinction (transition from blue to yellow in the lower left panel), at high Galactic latitudes and in the Galactic outskirts we have 8 – 10 bands of optical to near-IR (NIR) coverage. The uniform coverage of the Pan-STARRS data is due to the sample selection, which requires  $\geq 4$  bands of Pan-STARRS photometry. Due to the depth of the UKIDSS LAS data, in regions that overlap with the survey area we have almost 10 bands of wavelength coverage from the optical through the infrared. *An interactive version of this figure is available online at [this link](#).*

The unWISE catalog<sup>7</sup> (Schlafly et al. 2019) is a collection of two billion sources observed over the entire sky in the infrared (IR) over two bands ( $W_1, W_2$ ) from  $3\ \mu\text{m} - 5\ \mu\text{m}$  with the WISE satellite as part of the WISE and Near Earth Object WISE (NEOWISE) missions. Compared to the existing AllWISE catalog (Cutri & et al. 2013), the unWISE catalog is 0.7 mag deeper due to its use of additional images from the extended mission along with improved source modeling in crowded regions using the CROWDSOURCE code (Schlafly et al. 2018). This allows it to reach a 50% completeness point-source depth of  $W_1 = 17.9$  mag and  $W_2 = 16.7$  mag in the Vega system.

We select all objects which are flagged as `primary` (no duplicate sources), contain no bitwise quality flags (`flags_unwise`) and that have errors of  $< 0.2$  mag. We also further constrain the fractional flux (`fracflux`) at an object’s given position, which measures the fraction of contamination of light from the source due to neighboring objects, to be  $> 0.5$  (i.e. a majority of the light

at a given position is contributed by the source being modeled).

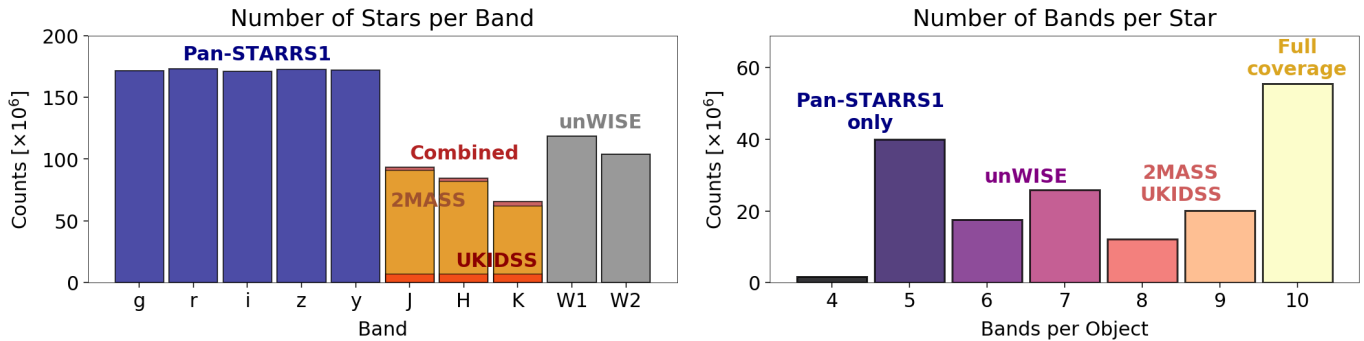

## 2.5. Gaia

We use data taken from the *Gaia* second data release (DR2; Gaia Collaboration et al. 2018), which provides photometry ( $G, BP, RP$ ) and astrometry (proper motion and parallax) measurements for over one billion stars, along with radial velocity measurements for a small fraction of nearby sources. The astrometric catalog has a 99.875% completeness point-source depth of  $G \approx 21$  mag in the Vega system (Lindgren et al. 2018; Gaia Collaboration et al. 2018). The typical astrometric uncertainty is around 0.7 mas for the faintest stars and 0.04 mas in the bright limit.

In this work, we only incorporate Gaia parallax measurements and their uncertainties when modeling individual sources. We only use the photometry and proper motions as additional checks to validate our results, as will be discussed in §5. We impose the same quality cuts as recommended in Equation (11) of Lindgren et al. (2018), which requires sources to have:

- $G \leq 21$ ,
- `visibility_periods_used`  $\geq 6$ , and

<sup>7</sup> <https://catalog.unwise.me/>

**Figure 3.** Histograms illustrating the wavelength coverage of the data used in this work that serves to complement Figure 2. The left panel shows the number of stars available in each band, color coded by survey, illustrating the uniform Pan-STARRS1 selection and amount of NIR and IR coverage available through 2MASS and unWISE, respectively. Compared with Figure 2, we can see that although UKIDSS data is quite deep, the total amount of objects with UKIDSS photometry is quite small due to its high-latitude targeting. We also see a substantial amount of objects are detected in the unWISE catalog. The right panel shows the number of bands per star, highlighting that the majority of the sample has full coverage across all 10 possible bands. Regions where we roughly lose coverage across various surveys are labeled, with the next largest peak of objects having only  $\sim 5$  bands of coverage (mostly in the optical) closer to the Galactic plane. An interactive version of this figure is available online at [this link](#).

- `astrometric_sigma5d_max`  $\leq 1.2 \text{ mas} \times \gamma(G)$ ,

where  $\gamma(G) = \max[1, 10^{0.2(G-18)}]$ . We do not impose or record astrometric quality information from any other quantities (e.g., RUWE).

As discussed in Lindegren et al. (2018), there are numerous systematics present in the parallax measurements provided as part of *Gaia* DR2. The ones we consider here are overall zero-point offsets in the parallax measurements as well as possible underestimates of the provided errors. Following work by Schönrich et al. (2019), Leung & Bovy (2019b), and Khan et al. (2019), among others, we add  $0.054 \text{ mas}$  to all parallaxes and increase the measurement errors by adding  $0.043 \text{ mas}$  in quadrature with the reported uncertainties.

### 2.6. Assembling the *Augustus* Catalog

We cross-matched all sources in Pan-STARRS, 2MASS, UKIDSS, unWISE, and *Gaia* DR2 after applying the cuts described above within a radius of 1 arcsecond, with the closest source being selected in the presence of multiple matches. This operation was performed using the Large Survey Database (LSD; Juric 2011) hosted on the *Cannon* computing cluster at Harvard University and required Pan-STARRS to be the “primary” catalog that all others were matched to. We impose a minimum error threshold of  $0.005 \text{ mag}$  in all bands after removing any additional survey-imposed error floors; we also add in our own (larger) error floors as described in §3. In addition, we purposely mask out 2MASS photometry whenever UKIDSS photometry in the same band is available. This helps to avoid adding additional noise from the 2MASS observations, which are substantially shallower than the UKIDSS ob-

servations in the same footprint, and also prevents us “double-counting” systematics.<sup>8</sup>

In addition to the cuts described above, we imposed four additional cuts:

1.  $\geq 4$  bands of photometry in Pan-STARRS,
2. a parallax measurement in *Gaia* DR2,
3.  $r < 20 \text{ mag}$  in Pan-STARRS, and
4. a Galactic latitude of  $|b| > 10^\circ$ .

The first cut guarantees that we have approximately uniform coverage in Pan-STARRS and guarantees we have enough photometry ( $\geq 4$  bands) to be able to run BRUTUS, and ensures our spatial coverage matches that of the 3-D dust prior from Green et al. (2019). The second requirement guarantees that all sources will have parallax measurements (and *Gaia* photometry), making it straightforward to compare to previous work such as Anders et al. (2019). The third requirement limits the size of the sample and helps us remain within the *Gaia*  $G \lesssim 21 \text{ mag}$  completeness limit, making our sample roughly  $r$ -band magnitude-limited. Finally, the fourth cut helps to further limit the size of the sample while avoiding the intense crowding/dust extinction near the Galactic plane.

The final combined catalog, which we refer to as *Augustus*, has roughly *170 million sources*. The distribution of sources on the sky is shown in Figure 2, while the wavelength coverage for stars in our sample

<sup>8</sup> If we estimate uncertainties to be dominated by a systematic error  $\Delta$ , observations from  $n \sim$  identical bands with errors floors of  $\Delta$  in each effectively makes the error floor  $\Delta/\sqrt{n}$ .

**Table 1.** A summary of the photometric offsets that are *multiplied* to the *observed* flux densities and the error floors (as a fraction of the flux density) that are added in quadrature to the observational uncertainties.

Filter	Offset	Error Floor
Pan-STARRS		
<i>g</i>	1.01	0.02
<i>r</i>	0.97	0.02
<i>i</i>	0.97	0.02
<i>z</i>	0.96	0.02
<i>y</i>	0.97	0.02
2MASS		
<i>J</i>	0.99	0.03
<i>H</i>	1.04	0.03
<i>K<sub>s</sub></i>	1.04	0.03
UKIDSS		
<i>J</i>	0.99	0.03
<i>H</i>	1.04	0.03
<i>K</i>	1.04	0.03
unWISE		
W1	1.02	0.04
W2	1.03	0.04

is shown in Figure 3. The lack of data in the south is due to the required coverage in Pan-STARRS, which only allows for  $3\pi$  steradians of coverage. In general, we find a plurality of sources ( $\sim 60$  million) have 10 bands of optical-through-IR photometry across Pan-STARRS, 2MASS/UKIDSS, and unWISE, and that only 40 million ( $\sim 25\%$ ) have  $\leq 5$  bands of coverage.

### 3. MODELING

The modeling approach for constructing this catalog, BRUTUS, is described in Speagle et al. (2021a, *subm.*). We provide a brief summary below.

#### 3.1. Statistical Framework

**Table 2.** Grid of parameters for the MIST models used in this work. See §3.2 for additional details.

Minimum	Maximum	Spacing
<b>Initial Mass (<math>M_{\text{init}}</math>)</b>		
$0.5 M_{\odot}$	$2.8 M_{\odot}$	$0.02 M_{\odot}$
$2.8 M_{\odot}$	$3.0 M_{\odot}$	$0.1 M_{\odot}$
$3.0 M_{\odot}$	$8.0 M_{\odot}$	$0.25 M_{\odot}$
$8.0 M_{\odot}$	$10.0 M_{\odot}$	$0.5 M_{\odot}$
<b>Initial Metallicity (<math>[\text{Fe}/\text{H}]_{\text{init}}</math>)</b>		
-4.0	+0.5	0.06
<b>Equivalent Evolutionary Point (EEP)</b>		
202	454	12
454	808	6

BRUTUS uses Bayesian inference to model the posterior probability  $\mathcal{P}(\boldsymbol{\theta}, \boldsymbol{\phi})$  of a set of *intrinsic* stellar parameters  $\boldsymbol{\theta}$  (e.g., initial mass  $M_{\text{init}}$ ) and *extrinsic* stellar parameters (e.g., distance  $d$ ) as the product of three different components:

$$\mathcal{P}(\boldsymbol{\theta}, \boldsymbol{\phi}) \propto \mathcal{L}_{\text{phot}}(\boldsymbol{\theta}, \boldsymbol{\phi}) \mathcal{L}_{\text{astr}}(\boldsymbol{\phi}) \pi(\boldsymbol{\theta}, \boldsymbol{\phi}) \quad (1)$$

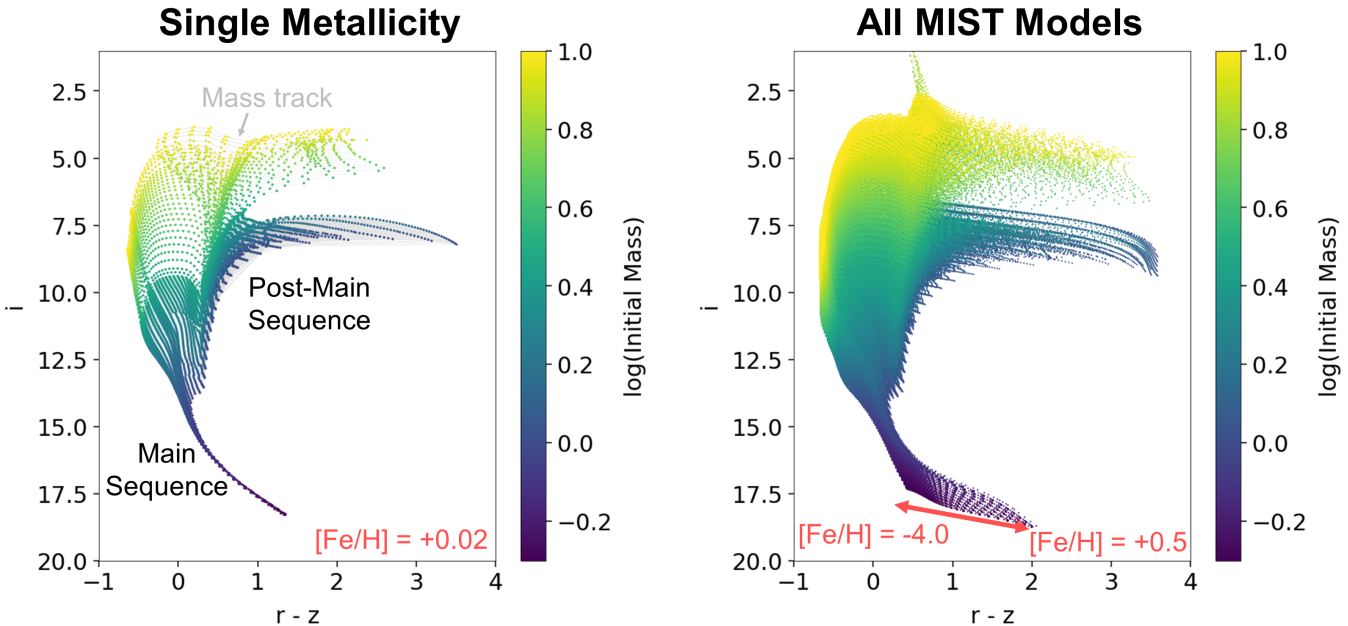

The first term is the *photometric likelihood* between our model of the flux densities  $\mathbf{F}(\boldsymbol{\theta}, \boldsymbol{\phi}) \equiv \{F_i(\boldsymbol{\theta}, \boldsymbol{\phi})\}_{i=1}^b$  and the observed flux densities  $\hat{\mathbf{F}} \equiv \{\hat{F}_i\}_{i=1}^b$  and their associated errors  $\hat{\boldsymbol{\sigma}} \equiv \{\hat{\sigma}_i\}_{i=1}^b$  across  $b$  bands. We assume the data follows a Normal distribution in each band such that

$$\mathcal{L}_{\text{phot}}(\boldsymbol{\theta}, \boldsymbol{\phi}) \equiv \prod_{i=1}^b \frac{1}{\sqrt{2\pi\hat{\sigma}_i^2}} \exp \left[ -\frac{1}{2} \frac{(F_i(\boldsymbol{\theta}, \boldsymbol{\phi}) - \hat{F}_i)^2}{\hat{\sigma}_i^2} \right] \quad (2)$$

The second term is the *astrometric likelihood*, which compares the predicted parallax  $\varpi(\boldsymbol{\phi})$  to the observed value  $\hat{\varpi}$  and the associated error  $\hat{\sigma}_{\varpi}$ .<sup>9</sup> We also assume the data follow a Normal distribution such that

$$\mathcal{L}_{\text{astr}}(\boldsymbol{\phi}) \equiv \frac{1}{\sqrt{2\pi\hat{\sigma}_{\varpi}^2}} \exp \left[ -\frac{1}{2} \frac{(\varpi(\boldsymbol{\phi}) - \hat{\varpi})^2}{\hat{\sigma}_{\varpi}^2} \right] \quad (3)$$

<sup>9</sup> Note that while other astrometric measurements such as proper motions are measured by *Gaia*, we do not model them here.

**Figure 4.** Color-magnitude diagrams (CMDs) for the MIST models used in this work as a function of Pan-STARRS  $i$ -band magnitude at  $d = 1$  kpc and Pan-STARRS  $r - z$  color. The left panel shows the models used with  $[\text{Fe}/\text{H}]_{\text{init}} = +0.02$ , with the rough locations of Main Sequence and post-Main Sequence evolutionary phases indicated. The underlying mass tracks are shown as light grey lines, with the actual models used shown as points and colored by  $\log M_{\text{init}}$ . The right panel shows the entire collection of  $\sim 750,000$  models defined over  $[\text{Fe}/\text{H}]_{\text{init}} = -4.0$  to  $+0.5$  that are used in this work.

The final term is the *Galactic prior*, which describes our prior belief over the 3-D distribution of stars, dust, and their associated properties. We use the same default prior outlined in Speagle et al. (2021a, subm.). This includes a thin disk, thick disk, and halo component whose size/shape are based on Bland-Hawthorn & Gerhard (2016) and Xue et al. (2015) with simple, spatially-independent distributions of initial metallicities  $[\text{Fe}/\text{H}]_{\text{init}}$  and ages  $t_{\text{age}}$  as described in Speagle et al. (2021a, subm.).<sup>10</sup> The 3-D distribution of dust attenuation  $A_V$  is taken to follow the 3-D dust map from Green et al. (2019), with variations in the dust curve (as parameterized by  $R_V$ ) taken to be spatially-independent following that from Schlafly et al. (2016).

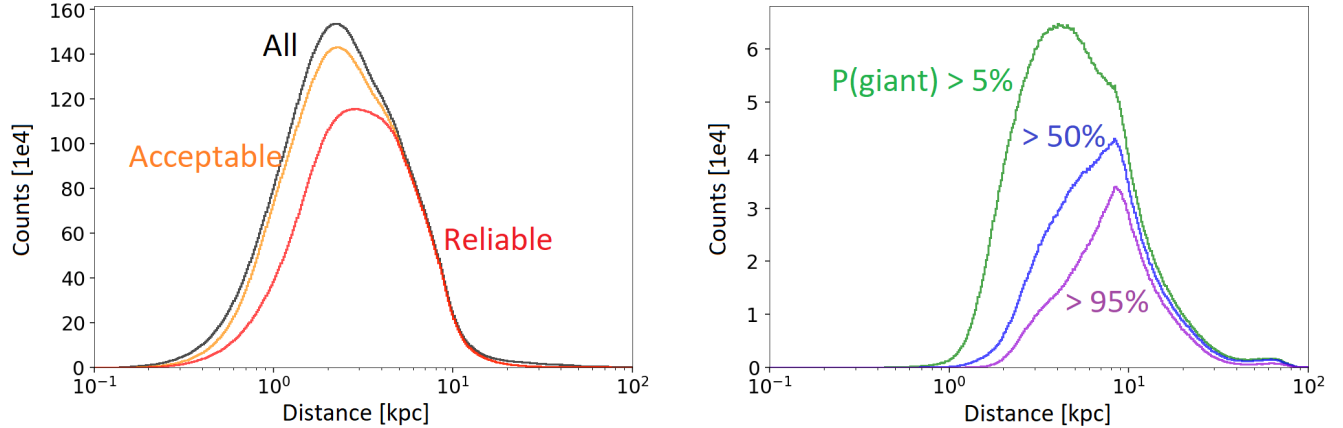

### 3.2. Stellar Modeling

The stellar models used in this work are the Modules for Experiments in Stellar Astrophysics (MESA; Paxton et al. 2011, 2013, 2015, 2018, 2019) Isochrone & Stellar Tracks (MIST; Choi et al. 2016). In particular, we utilize the *non-rotating* models from MIST version 1.2. These are defined in terms of initial mass  $M_{\text{init}}$ , initial metallicity  $[\text{Fe}/\text{H}]_{\text{init}}$ , and equivalent evolutionary point (EEP; Dotter 2016), which correspond to a

unique age  $t_{\text{age}}(\text{EEP}|M_{\text{init}}, [\text{Fe}/\text{H}]_{\text{init}})$  for a given  $M_{\text{init}}$  and  $[\text{Fe}/\text{H}]_{\text{init}}$ .

We use three separate pieces to predict the underlying stellar spectrum  $F_\nu(\lambda|\theta, \phi)$ . The first is the C3K stellar atmosphere models described in Cargile et al. (2020) and Speagle et al. (2021a, subm.), which are computed as a function of effective temperature  $T_{\text{eff}}$ , log-surface gravity  $\log g$ , surface metallicity  $[\text{Fe}/\text{H}]_{\text{surf}}$ , and surface alpha-abundance variation  $[\alpha/\text{Fe}]_{\text{surf}}$ . While version 1.2 of the MIST models provide predictions for  $T_{\text{eff}}$ ,  $\log g$ , and  $[\text{Fe}/\text{H}]_{\text{surf}}$ , they do not model any variations in  $[\alpha/\text{Fe}]$ ; as a result, we set  $[\alpha/\text{Fe}]_{\text{surf}} = 0$  by default. The second is a set of “empirical corrections” to the MIST models based on isochrone modeling of nearby open clusters described in Speagle et al. (2021a, subm.). These are implemented as adjustments to effective temperature  $T_{\text{eff}}$  and stellar radius  $\log R_\star$  (and by extension the surface gravity  $\log g$  and bolometric luminosity  $\log L_{\text{bol}}$ ) as a function of EEP and  $[\text{Fe}/\text{H}]_{\text{init}}$ . The third is a set of dust extinction curves (i.e. reddening laws) from Fitzpatrick (2004) to account for the effect of dust extinction. These are defined as a function of extinction in the V band  $A_V$  and the “differential extinction”  $R_V \equiv A_V/(A_B - A_V)$  based on the ratio of  $A_V$  to the difference in extinction  $A_B - A_V$  between the B and V bands. Altogether, these give a framework for generating spectra as a function of  $\theta = \{M_{\text{init}}, [\text{Fe}/\text{H}]_{\text{init}}, \text{EEP}\}$  and  $\phi = \{d, A_V, R_V\}$  with

<sup>10</sup> No bulge or bar component is currently included but will be added in future work.

**Figure 5.** A distribution of the distances (taken from a random posterior sample) for the 170 million objects in our catalog. The left panel shows the number of objects for the entire sample (black), all the sources with “acceptable” fits (the *Augustus-Silver* subset; orange), and all sources with “reliable” posteriors (the *Augustus-Gold* subset; red). There are around 125M sources with reliable posteriors that have distances up to 10s of kpc. The right panel shows the subset of sources for which the probability of being a giant (defined as  $\log g < 3.5$ ) is  $> 5\%$  (green),  $> 50\%$  (blue), and  $> 95\%$  (purple). These panels illustrate there are potentially millions of photometrically-classified giants in the sample, although only a few million at very high-confidence. See §4 for more information on the cuts applied here.

$\theta_* = \{t_{\text{age}}, T_{\text{eff}}, \log g, \log R_*, \log L_{\text{bol}}\}$  generated as intermediate values, where  $d$  is again the distance to the source.

Finally, to generate the model flux density in a given filter  $i$ , we integrate the underlying stellar spectrum  $F_\nu(\lambda|\theta, \phi)$  through a filter curve with transmission  $T_i(\lambda)$ :

$$F_i(\theta, \phi) = \frac{\int F_\nu(\lambda|\theta, \phi)T_i(\lambda)\lambda^{-1}d\lambda}{\int S_\nu(\lambda|\theta, \phi)T_i(\lambda)\lambda^{-1}d\lambda} \quad (4)$$

where  $S_\nu(\lambda)$  is the source spectrum used to calibrate the observations. This is the chosen spectrum of Vega in the Vega system and a constant in the AB system. To avoid having to compute integrals “on the fly”, we pre-compute photometry over a large grid of  $T_{\text{eff}}$ ,  $[\text{Fe}/\text{H}]_{\text{surf}}$ ,  $\log g$ ,  $[\alpha/\text{Fe}]$ ,  $A_V$ , and  $R_V$  values in each band, and interpolate over the resulting photometric predictions in each band using a neural network as described in Speagle et al. (2021a, *subm.*). Cross-validation and hold-out testing suggest that the difference between photometry predicted using the neural network versus direct integration is  $\lesssim 0.01$  mag over a large majority of the parameter space.

### 3.3. Application to Data

BRUTUS exploits the nature of the statistical problem to derive *continuous* estimates of the extrinsic stellar parameters  $\phi = \{d, A_V, R_V\}$  over a *grid* of intrinsic stellar parameters  $\theta = \{M_{\text{init}}, [\text{Fe}/\text{H}]_{\text{init}}, \text{EEP}\}$ . While interpolating over an input grid of stellar models allows for smoother probabilistic estimation of underlying parameters (Cargile et al. 2020), this process in general is substantially slower than using pre-computed grids when

the number of parameters being inferred is small ( $\lesssim 4$ ). BRUTUS uses grids to exploit this speedup. This leads to “gridding effects” that will be visible in subsequent plots shown in this work.

In brief, BRUTUS fits each object in three steps:

1. *Magnitude step*: Compute a “quick approximation” of the solution in magnitudes.
2. *Flux density step*: Improve the magnitude solution after converting the data back to flux density.
3. *Prior step*: Incorporate information from the prior (and the parallax) using Monte Carlo sampling.

These steps are then parallelized across all models in the grid, with the final posterior estimated using Monte Carlo integration and resampling. The entire process takes only a few seconds for a typical source with a mildly-informative parallax measurement. The grid of stellar models we use in this work (`grid_mist_v8`) are defined in Table 2 and shown in Figure 4 and available online through the BRUTUS GitHub page.

As discussed in Speagle et al. (2021a, *subm.*) and elsewhere (e.g., Choi et al. 2016), there are known systematics offsets between the MIST models used in this work and the photometric data it is being fit to. To account for some of this additional uncertainty not captured by the empirical corrections described earlier, we apply zeroth order photometric offsets to the observed flux densities and increase the effective errors by adding in error floors in quadrature. A summary of the offsets and error floors applied in this work can be found in Table 1.

**Figure 6.** Estimates of the *statistical* distance uncertainties (i.e. excluding systematic uncertainties) as a function of Pan-STARRS  $r$ -band magnitude ( $r_{\text{PS}}$ ; left), parallax signal-to-noise ratio (SNR; middle), and median estimated distance (right). These are estimated using the distribution of random distance realizations around the median distance estimates, with results from half the width of the 68% credible interval (“ $1\sigma$  average”; solid red) and a quarter the width of the 95% credible (“ $2\sigma$  average”; dashed blue). We find typical uncertainties of 8 – 10% at the faintest magnitudes and lowest parallax SNR, with uncertainties derived from the 95% CIs larger than those derived from the 68% CIs. These differences can become particularly pronounced at larger distances (right panel) due to possible degeneracies between nearby dwarf (Main Sequence) and faraway giant (post-Main Sequence) stellar evolutionary solutions.

We run BRUTUS using this setup over the 170 million sources in the *Augustus* catalog using the default hyperparameters enabled in `v0.7.5`<sup>11</sup>. All computations were performed on the *Cannon* research computing cluster at Harvard University. Including overheads, the final runtime was  $\sim 700,000$  CPU hours.

#### 4. CATALOGS

Using the posterior samples for each object, we post-process the data into two output catalogs:

- a “point” catalog<sup>12</sup> containing various information about each object and summary statistics describing the stellar parameters, and
- a “samples” catalog<sup>13</sup> containing a subset of 25 posterior samples for each object.

We will use results from the former catalog when highlighting results in this paper; the latter is meant to be used as a supplement for users interested in additional error modeling. Detailed descriptions of both catalogs and examples of their usage can be found in Appendix A.

Note that after performing most of the computation, we discovered that BRUTUS `v0.7.5` contained a bug (fixed in more recent versions of the code) that used the wrong sign when sampling from correlations between

$A_V$  and  $R_V$  with distance. We have confirmed this has a negligible impact on the overall posterior distributions and marginal distributions for all parameters and therefore should not impact the quality of the catalog; however, it does affect quantities computed directly from the samples which depend on these quantities (e.g., reddened photometry).

In addition, we found that survey artifacts from the UKIDSS footprint (deeper near-IR photometry changed the distribution of stellar parameter estimated) were prominent when projecting results onto the plane of the sky or Galaxy. As a result, we re-ran all objects in the UKIDSS LAS footprint without UKIDSS photometry (i.e. using 2MASS instead when available) and with the same version of the code (`v0.7.5`) for consistency; the catalogs for this subset of objects are also provided online and described in Appendix A. While this does degrade the quality of the stellar parameter estimates, it makes resulting maps more homogeneous. As a result, we opt to use the “no UKIDSS” versions of our results when highlighting results in this work unless otherwise explicitly stated.

The distribution of a random posterior sample of the distances for each star in *Augustus* is shown in Figure 5. We see that the distribution peaks around a few kpc, with a sharp decline towards larger distances and a shallower decline towards smaller ones. The former behavior can be understood by our  $r = 20$  mag faint magnitude limit in Pan-STARRS, which makes us primarily sensitive to giants at larger distances. The latter behavior is due to a combination of two effects. The

<sup>12</sup> [doi:10.7910/DVN/WYMSXV](https://doi.org/10.7910/DVN/WYMSXV)

<sup>13</sup> [doi:10.7910/DVN/530UYQ](https://doi.org/10.7910/DVN/530UYQ)

**Figure 7.** A “corner” plot showing the collective 1-D and 2-D posterior distributions for the parameters constrained for each of the 125 million *Augustus-Gold* stars. These parameters are (from left to right): the initial mass ( $M_{\text{init}}$ ), initial metallicity ( $[\text{Fe}/\text{H}]_{\text{init}}$ ), equivalent evolutionary point (EEP), age ( $\log t_{\text{age}}$ ), effective temperature ( $\log T_{\text{eff}}$ ), bolometric luminosity ( $\log L_{\text{bol}}$ ), surface gravity ( $\log g$ ), distance  $\log d$ , extinction ( $A_V$ ), and “differential” extinction ( $R_V$ ). The titles of each column show the median and the interval encompassing 95% of the sample. As expected, the majority the sample comprises sources with low extinction ( $A_V \lesssim 1$  mag) and initial masses ranging from  $0.55 < M_{\text{init}} < 1.2$ , with the lower limit imposed by the lower  $M_{\text{init}}$  bound on our underlying grid of stellar models. Gridding effects can be seen in a few panels.

first is the increasing differential volume which goes as  $d^2$ , which increases the raw number of sources available between  $d$  and  $d + \Delta d$  at larger distances. This counteracts the decreasing number density of stars as we move away from the Galactic center and out of the Galactic plane. The second is the  $r \sim 14$  mag saturation limit in Pan-STARRS, which makes us increasingly incomplete at nearby distances.

As part of the catalog we generate two quality flags:

1. **FLAG\_FIT**, which diagnoses problems in the best-fit model spectral energy distribution (SED), including the predicted parallax, and
2. **FLAG\_GRID**, which diagnoses when the output posterior appears to be artificially truncated by the input model parameter grid.

The details of these flags are discussed in Appendix A. There are roughly 14 million sources ( $\sim 8\%$ ) which have **FLAG\_FIT=TRUE** set, 38 million ( $\sim 22\%$ ) with **FLAG\_GRID=TRUE** set, and 47 million ( $\sim 27\%$ ) with either flag set. We consider the set of roughly 125 million sources with neither flag set to have “reliable”, high-quality posteriors that are sufficient for analysis. We utilize this subset of stars in **Augustus** in all subsequent analyses and will henceforth refer to them as the **Augustus-Gold** subset. Objects with **FLAG\_FIT=FALSE** are deemed “acceptable” fits, which will henceforth be referred to as the **Augustus-Silver** subset.

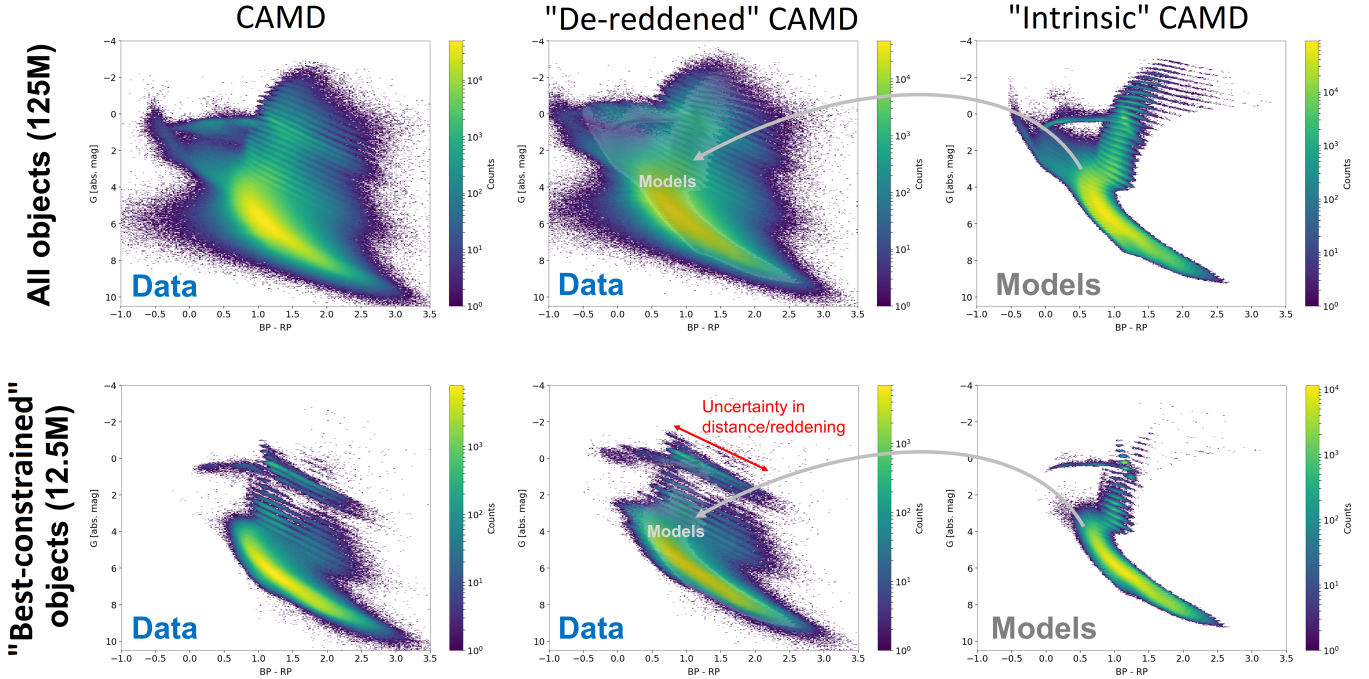

In Figure 5, we show the impact each of these flags has on the distribution of stellar distances. Overall, we find that most poor fits tend to happen preferentially at either small distances ( $\lesssim 5$  kpc) or extremely large ones ( $\gtrsim 15$  kpc). Internal investigation reveals this can be due to a variety of failure modes, some of which are outlined below:

1. *Bad photometry*: One outlying band will lead to extremely poor fits. This is more common near the Pan-STARRS  $r \sim 14$  mag saturation limit.
2. *Failed cross-matching*: Multiple objects within the same 1 arcsec radius can be inappropriately matched, leading to “mixed” SEDs that are difficult to model.
3. *Blending effects*: In crowded regions, significant portions of the flux at a given position may be contributed by nearby objects, which can impact the measured flux densities for any particular source. This becomes stronger at lower  $|b|$  values.
4. *Quasar/galaxy contamination*: As discussed in Green et al. (2019), quasars and other point sources can often contaminate these samples, especially at fainter magnitudes. Since these have very different SEDs compared to our stellar models, they often are poorly fit.

5. *Unresolved binaries*: A non-negligible fraction of sources in **Augustus** are expected to be in unresolved binaries (see, e.g., Belokurov et al. 2020). These are not modeled in this work.
6. *Missing models*: Since our grid only goes down to  $M_{\text{init}} = 0.5 M_{\odot}$  and only includes stellar models after they reach the Main Sequence (EEP = 202), nearby sources that have  $M_{\text{init}} \lesssim 0.5 M_{\odot}$  or EEP < 202 are not part of our grid and therefore will be mismodeled. This can also occur if sources fall *between* our grid points, which has coarser spacing on the high-mass end.
7. *Strong prior disbelief*: As shown in Speagle et al. (2021a, subm.), BRUTUS can fail to locate the correct solution if it is sufficiently disfavored by the prior. This leads to mismodeling of the SED.
8. *Imprecise photometric parallaxes*: For nearby sources with extremely high signal-to-noise ratio (SNR) astrometric parallax measurements from *Gaia* DR2, the model grid in BRUTUS may be too coarse to estimate distances with the accuracy needed to match the observed parallax measurements within their measurement uncertainties.
9. *Heavily extinguished*: The default modeling used in this work assumes that  $0 \leq A_V \leq 6$ . In nearby regions with large  $A_V$  (and possible large variations in  $R_V$ ), the models will fail to reproduce the heavily extinguished SEDs.

By contrast, we find that the vast majority of cases where **FLAG\_GRID=TRUE** occurs when the initial mass  $M_{\text{init}}$  hits the lower edge of the grid. Imposing this flag therefore imposes a *de facto* cut on initial mass, limiting the catalog to mostly sources above  $M_{\text{init}} \gtrsim 0.55 M_{\odot}$ . This also explains why imposing this cut almost exclusively removes sources at smaller distances, where we are more sensitive to lower-mass objects.

In the right panel of Figure 5, we highlight subsets of **Augustus-Gold** as a function of the probability that a source is classified as a “giant”, which we define as the probability that it has a  $\log g < 3.5$ . The vast majority of stars in our sample ( $\sim 150$  million) are classified as dwarfs with  $P(\text{giant}) \sim 0$ , such that even allowing stars that have only  $P(\text{giant}) > 5\%$  only includes roughly 9 million objects. Imposing even stricter criteria such as  $P(\text{giant}) > 50\%$  or  $P(\text{giant}) > 95\%$  leaves around 5 million and 3.5 million sources, respectively. Given that BRUTUS is inherently biased against classifying sources as giants (Speagle et al. 2022a, subm.), we find these to be likely underestimates of the true number of giants in our catalog. Regardless, a sample of  $> 3$  million giants at high-latitude is already several orders of magnitude larger than targeted spectroscopic surveys such as the HectoChelle in the Halo at High Resolution (H3) survey (Conroy et al. 2019).

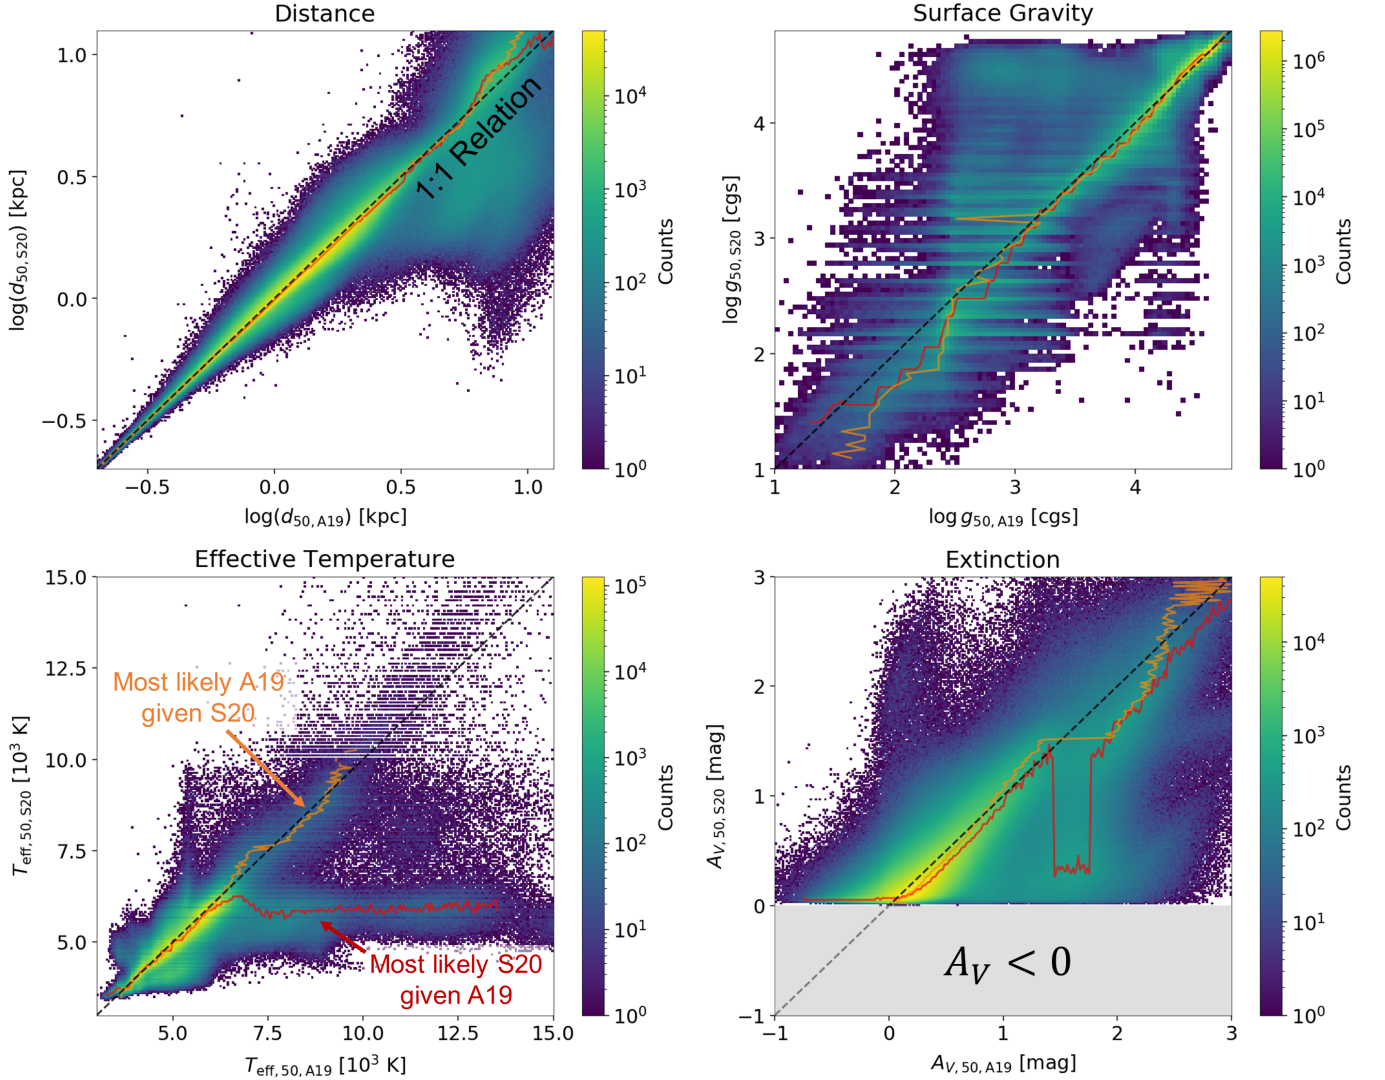

**Figure 8.** The *Gaia*  $G$  vs  $BP - RP$  color-absolute magnitude diagram (CAMD) for all sources in **Augustus-Gold** (125M objects; top) and “best-constrained” sources (12.5 million objects; bottom) which have 10 bands of Pan-STARRS, 2MASS, UKIDSS, and/or unWISE photometry and 95% distance credible intervals that are  $< 30\%$  of the median distance (i.e.  $|(d_{97.5} - d_{2.5})/d_{50}| < 0.3$ ). The left panels show the CAMD after shifting sources to  $d = 10$  pc using a random sample drawn from the stellar posterior. The middle panels show the “de-reddened” CAMD using the  $A_V$  and  $R_V$  values from the same random posterior sample and the predicted linear reddening vector from the stellar parameters associated with them. The right panels show the predicted CAMD *computed directly from the models*; this is also over-plotted as the light gray shaded region in the middle panel for ease of comparison. As the *Gaia* photometry was not used when deriving the stellar posteriors but whose wavelength coverage overlaps with the Pan-STARRS data, this serves as a useful but limited check on the internal self-consistency and overall quality of the results. We find excellent overall agreement between the intrinsic CAMD predicted by the models and the “empirical” CAMD derived from the data, with uncertainties mostly scattered in the direction of the reddening vector. Some exceptions to this include noticeable gridding effects in evolved stellar evolutionary phases (thin overdense regions), issues modeling the horizontal giant branch (upper left regions), and dwarf/giant misclassification (middle right regions).

In Figure 6, we show the *statistical* uncertainties in the estimated distances within **Augustus-Gold** as a function of Pan-STARRS  $r$ -band magnitude, parallax SNR  $\varpi_{\text{SNR}}$ , and median estimated distance. We find typical statistical uncertainties of  $\sim 3 - 5\%$  near  $r \sim 14$  mag that degrade smoothly to  $8 - 10\%$  at  $r \sim 20$  mag and  $\varpi_{\text{SNR}} \lesssim 1$ . Note that these uncertainties *do not* include systematic uncertainties related to issues with the underlying stellar models, the assumed Galactic priors, etc. While in general estimating overall uncertainties from  $1\sigma$  and  $2\sigma$  scatter in the distance realizations give consistent answers, these diverge strongly for median distances  $d_{\text{med}} \gtrsim 10$  kpc, at which point confusion between dwarf and giant solutions lead to multi-modal distance estimates and largely inflated uncertainties in the tails. These estimates, especially on the brighter end, are similar to recent work from Anders et al. (2019) and Bailer-

Jones et al. (2021) and an improvement over the purely geometric uncertainties from Bailer-Jones et al. (2018) and Bailer-Jones et al. (2021) (see §5.3).

The distribution of random posterior samples from all the stars in **Augustus-Gold** is shown in Figure 7. As expected for objects with  $|b| > 10^\circ$ , the vast majority have  $A_V \lesssim 2$  mag with  $> 50\%$  of the sample having  $A_V < 0.4$  mag. The metallicity distribution of the sample peaks around  $[\text{Fe}/\text{H}]_{\text{init}} \sim -0.5$ , similar to that of the thin disk in our prior, although there is a substantial tail out to metallicities as low as  $[\text{Fe}/\text{H}]_{\text{init}} \sim -2.5$ . As expected, most sources have sub-solar initial masses, with 95% having  $0.55 M_\odot \lesssim M_{\text{init}} \lesssim 1.05 M_\odot$ , and are located on the Main Sequence with  $\text{EEP} < 454$ . We do, however, observe a substantial tail of stars up to and beyond the Main Sequence turn-off ( $\text{EEP} > 454$ ).

## 5. RESULTS AND DISCUSSION

**Figure 9.** Comparisons between median distance (top left),  $\log g$  (top right),  $T_{\text{eff}}$  (bottom left), and  $A_V$  (bottom right) in this work (Augustus-Gold; “S20”) and Anders et al. (2019) (“A19”) for 26 million sources present in both catalogs. In each panel, the most common (i.e. likely) associated value in Augustus-Gold given a value from Anders et al. (2019) (i.e.  $y$  given  $x$ ) is shown as a solid red line, and the most common associated value from Anders et al. (2019) given Augustus-Gold (i.e.  $x$  given  $y$ ) is shown as a solid orange line. A 1:1 relationship is also overplotted as a dashed black curve. We see that the estimated distances from both catalogs are extremely consistent with each other across most distances, although this work generally prefers source below a few kpc to be slightly closer. The  $\log g$  values are also consistent with each other (outside of gridding effects), although there is a clear excess of sources that are classified as low-mass dwarfs in Augustus-Gold relative to Anders et al. (2019). The reason for this discrepancy can be seen when examining the estimated  $T_{\text{eff}}$ , which shows that while values are consistent across both datasets below  $T_{\text{eff}} \lesssim 6000$  K, Anders et al. (2019) prefers to make sources substantially hotter than Augustus-Gold for  $T_{\text{eff}} \gtrsim 6000$  K. This leads to a corresponding increase in the number of sources with  $A_V \gtrsim 1$  mag, where the higher reddening combined with the intrinsically bluer (hotter) colors end up giving similar SEDs as intrinsically redder (cooler) sources with less reddening. Note that the naming convention “S20” is based on the fact that the original analysis was included in the lead author’s PhD Thesis, which was accepted in 2020 and can be found online at <https://nrs.harvard.edu/URN-3:HUL.INSTREPOS:37365889>.

We now wish to highlight some preliminary results illustrating the quality of the data from the 125 million stars in *Augustus-Gold*.

### 5.1. *Reproducing the Gaia Color-Magnitude Diagram*

Given known systematics in the theoretical stellar models used in this and other work (Choi et al. 2016; Anders et al. 2019, Speagle et al. 2022a, subm.), one way to examine the reliability of the results is to examine the ability of the stellar models to reproduce the empirical color-magnitude diagram (CMD). In order to accomplish this, we purposefully *did not* use any of the observed *Gaia* DR2 photometry when computing predictions. Since these bands are so much broader than the underlying Pan-STARRS bands that they overlap with, they can serve as a (limited) *posterior predictive* check on the overall quality of the fits derived using the Pan-STARRS, 2MASS, UKIDSS, and unWISE data. In other words, we can test what the photometry in the *Gaia* bands *should be* (the ‘predictive’) based on the model constraints imposed from the other fitted bands (the ‘posterior’).

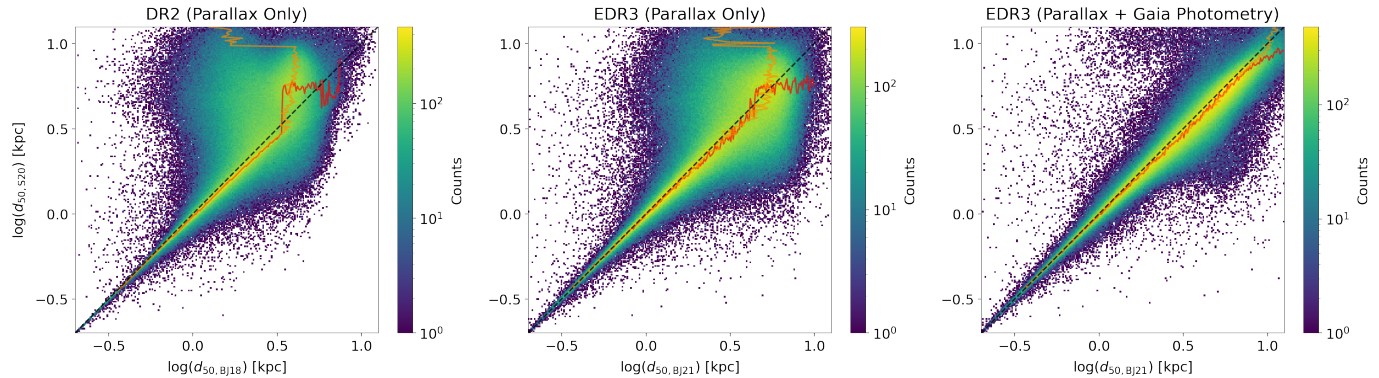

Using the BRUTUS package, we take a random posterior sample of the distance  $d$ , extinction  $A_V$ , and differential reddening  $R_V$  from each object and use it to compute the corresponding distance modulus  $\mu$  and extinctions  $A_G$ ,  $A_{BP}$ ,  $A_{RP}$  in the *Gaia* bands using the filter curves from Maíz Apellániz & Weiler (2018) as described in Speagle et al. (2021a, subm.). We then use these to “de-distance” and “de-redden” the *observed* photometry. We then compare this “empirical” CMD to the “intrinsic” CMD predicted directly from the corresponding model. The results of this exercise for all sources in *Augustus-Gold* along with a subset of 12.5 million sources with full photometric coverage and reasonably-constrained distances ( $< 30\%$   $2\sigma$  errors) are shown in Figure 8. We find excellent overall agreement between the intrinsic CMD predicted by the models and the “empirical” CMD derived from the data, with uncertainties mostly scattered in the direction of the reddening vector. Note that this scatter is expected given the incorrect sign of the covariances between  $A_V$  and  $R_V$  with distance discussed at the beginning of §4. Some exceptions to the excellent overall agreement include noticeable gridding effects in post-Main Sequence stellar evolutionary phases and higher masses as well as clear discrepancies properly modeling the horizontal giant branch.

### 5.2. *Comparison to STARHORSE*

We also compare our results to previous work. In particular, Anders et al. (2019), henceforth “A19”, use a similar approach to derive distances to 270 million sources with *Gaia*  $G < 18$  mag. As in this work, their approach also involved using a set of theoretical isochrones applied to similar photometric and astrometric datasets. The main differences between the two studies are as follows:

1. A19 utilizes the PARSEC 1.2 models (Bressan et al. 2012; Chen et al. 2014; Tang et al. 2014) rather than the (color-corrected) MIST models employed here.
2. A19 uses the empirical dust curve from Schlafly et al. (2016) to model  $A_V$  variation but no  $R_V$  variation. Here we use the dust curve from Fitzpatrick (2004) and models variation in both  $A_V$  and  $R_V$ .
3. A19 uses a different form for the underlying Galactic prior that includes an additional bulge component and different thin disk, thick disk, and halo properties.
4. A19 does not apply a 3-D dust prior to supply additional constraints on  $A_V$ .
5. A19 uses a version of the STARHORSE code (Santiago et al. 2016; Queiroz et al. 2018; Anders et al. 2019) to fit a grid over stellar models,  $d$ , and  $A_V$  and evaluates the prior over these data points. BRUTUS samples  $d$ ,  $A_V$ , and  $R_V$  values and attempts to integrate over the Galactic prior while doing so.
6. A19 fits photometric data from *Gaia*, Pan-STARRS, 2MASS, and AllWISE. This work excludes fitting photometric *Gaia* data and uses unWISE instead of AllWISE.
7. A19 applies different *Gaia* DR2 parallax zero-point corrections and photometric offsets/errors compared to this work.

As A19 performs significant vetting of their associated catalog across a wide range of surveys, we want to confirm that we are able to recover similar results for sources that overlap between the two catalogs. After cross-matching sources based on their *Gaia* object ID and only selecting “high-quality” sources with SH\_GAIAFLAG\_ = 000 and SH\_OUTFLAG = 00000, we find roughly 26 million sources that overlap between the two catalogs. Part of the reason for this small overlap is that A19 only goes down to  $G = 18$  mag rather than the  $r = 20$  mag used in this work; the other main reason is that this work excludes all sources with  $|b| < 10^\circ$  (where the vast majority of stars actually lie) as well as sources in the Southern hemisphere.

**Figure 10.** As Figure 9, but now comparing the median distance from this work with that derived from *Gaia* DR2 parallaxes only from Bailer-Jones et al. (2018) (BJ18; left) and from *Gaia* EDR3 parallaxes from Bailer-Jones et al. (2021) (BJ21) without (middle) and with (right) *Gaia* photometry. The most common (i.e. likely) associated value in *Augustus-Gold* given a value from BJ18 or BJ21 (i.e.  $y$  given  $x$ ) is shown as a solid red line, and the most common associated value from BJ18 or BJ21 given *Augustus-Gold* (i.e.  $x$  given  $y$ ) is shown as a solid orange line. The 1:1 relationship is overplotted as a dashed black curve. Estimated distances from all three catalogs are in excellent agreement with those derived here for stars within a few kpc using only the parallax and agree out to further distances when also considering the BJ21 estimates that also incorporate information from photometry. Disagreements at larger distances compared to the parallax-only estimates generally arise due to stronger distance constraints from photometry overwhelming distance estimates for objects with low parallax signal-to-noise ratios where the Galactic prior tends to dominate the inference. As with A19, this work prefers sources to be slightly closer than BJ18 and BJ21.

Figure 9 shows the comparison between the two datasets in a few parameters of interest including  $d$ ,  $\log g$ ,  $T_{\text{eff}}$ , and  $A_V$ . Overall, we find the estimated distances between the two datasets are extremely consistent with each other, although *Augustus-Gold* generally prefers sources nearer than a few kpc to be slightly closer. This is likely due to small differences in the underlying Galactic prior. We also find strong agreement between predicted  $\log g$  values (outside of gridting effects due to coarse sampling of post-MS evolutionary phases in this work), although there is a clear excess of sources that are classified as low-mass dwarfs in *Augustus-Gold* relative to A19.

The reason for this discrepancy can be seen when examining  $T_{\text{eff}}$ , which shows that while values are consistent across both datasets below  $T_{\text{eff}} \lesssim 6000$  K, sources in *Augustus-Gold* with estimates of  $T_{\text{eff}} \sim 6000$  K are much more likely to have associated estimates of  $T_{\text{eff}} \gtrsim 8000$  K in A19. To reproduce the observed SED, these intrinsically bluer sources need to have more reddening from foreground dust, leading to an expected increase in higher associated values of  $A_V$  for some sources in A19 relative to *Augustus-Gold*. Note that while *Augustus-Gold* strictly enforces  $A_V \geq 0$  mag and A19 does not, we find the impact of this choice does not appear to significantly hamper comparisons other than around  $A_V \sim 0$ . We expect that this will slightly bias distances, intrinsic colors, for stars behind very little dust, but helps to avoid scenarios that can arise when the reddening vector is allowed to compensate for sys-

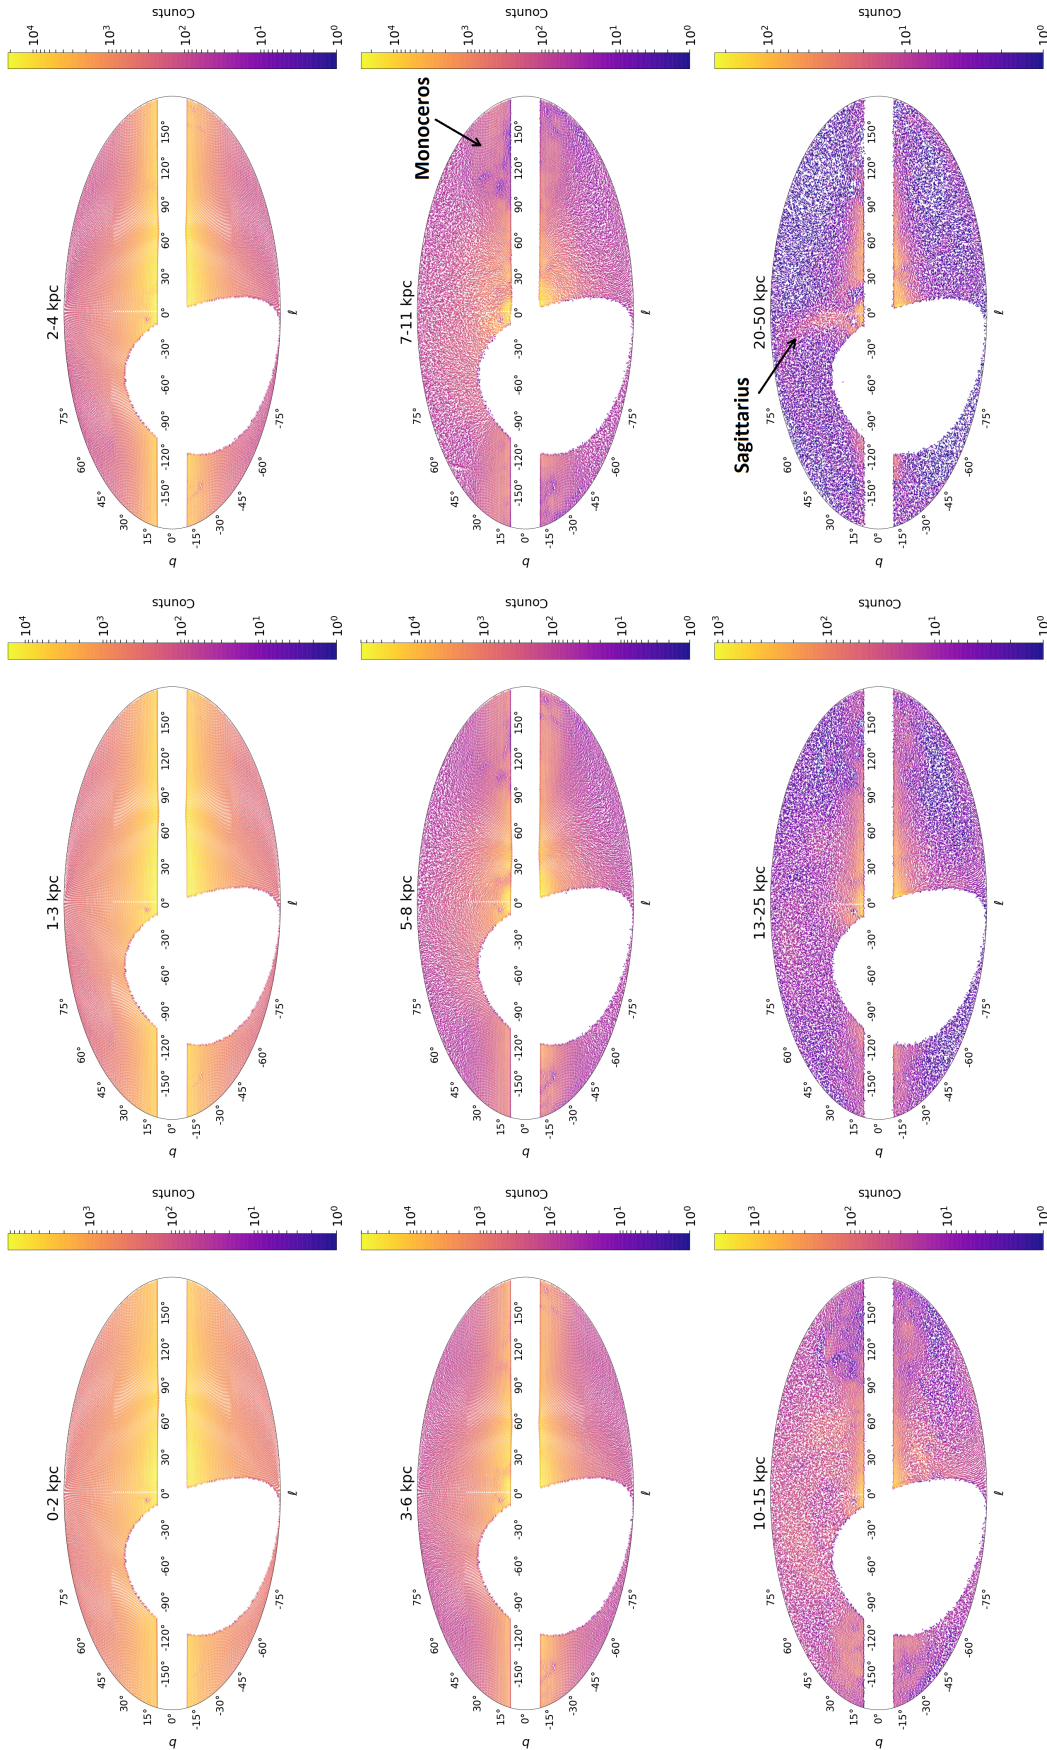

tematic color offsets in the model by exploring non-physical solutions.

### 5.3. Comparison to Bailer-Jones et al. (2018, 2021)

In addition to Anders et al. (2019), we also compare our distances to those derived purely from *Gaia* data based on both DR2 (Bailer-Jones et al. 2018) (BJ18) and EDR3 (Bailer-Jones et al. 2021) (BJ21), which was released between constructing the initial catalog and writing up this manuscript. While BJ18 utilize only parallax information when deriving their distances, BJ21 include both parallax-only estimates and ones that also include contributions from an empirical model that incorporates *Gaia* photometry. After cross-matching with both catalogs, we find roughly 126 million sources in common between those samples and the *Augustus-Gold* sample.

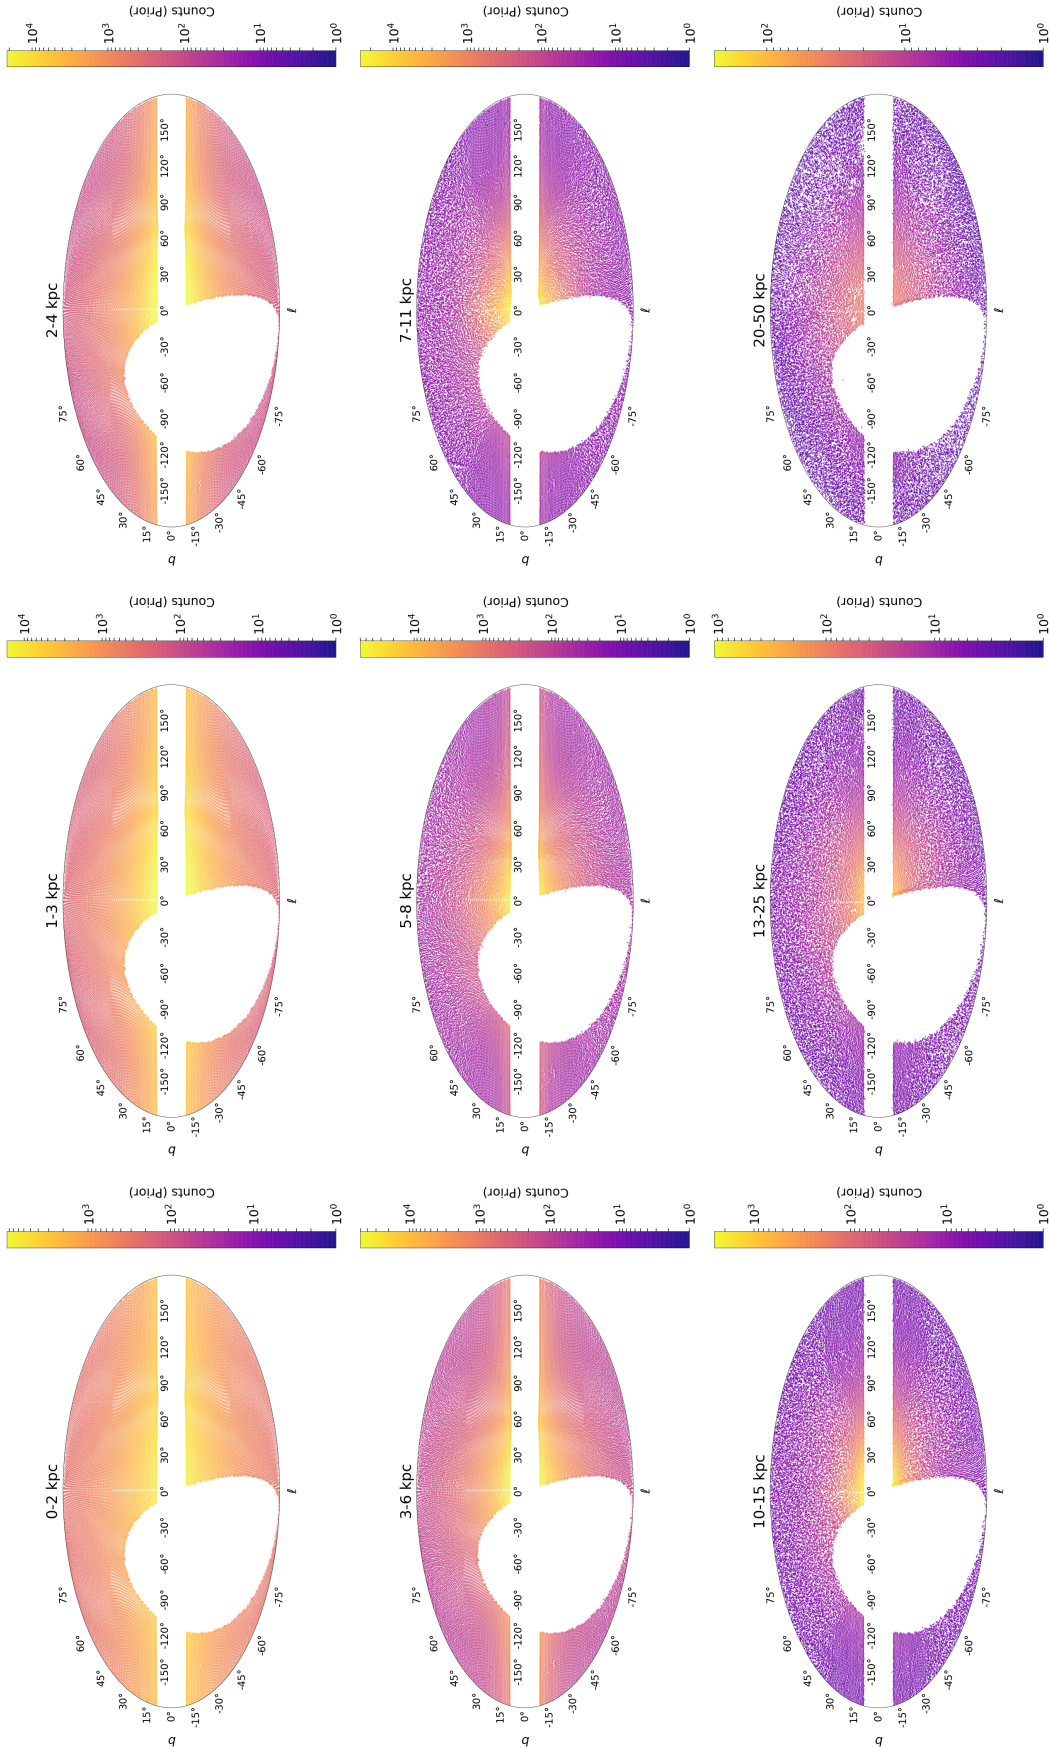

In Figure 10, we compare the distance estimates from BJ18 and BJ21 to those from *Augustus-Gold*. Overall, we find that excellent agreement between *Augustus-Gold*, BJ18, and BJ21 within a few kpc, which further improves when considering estimates the BJ21 estimates derived including *Gaia* photometry. Given that the BJ18 and BJ21 estimates were derived using substantially different prior assumptions from our model and, in the case of BJ21, mutually exclusive photometric datasets (as no *Gaia* photometry was used to derive any stellar properties reported in this work), this agreement lends further confidence to the overall accuracy of our distance estimates.

### 5.4. Galactic Substructure seen in *Augustus*

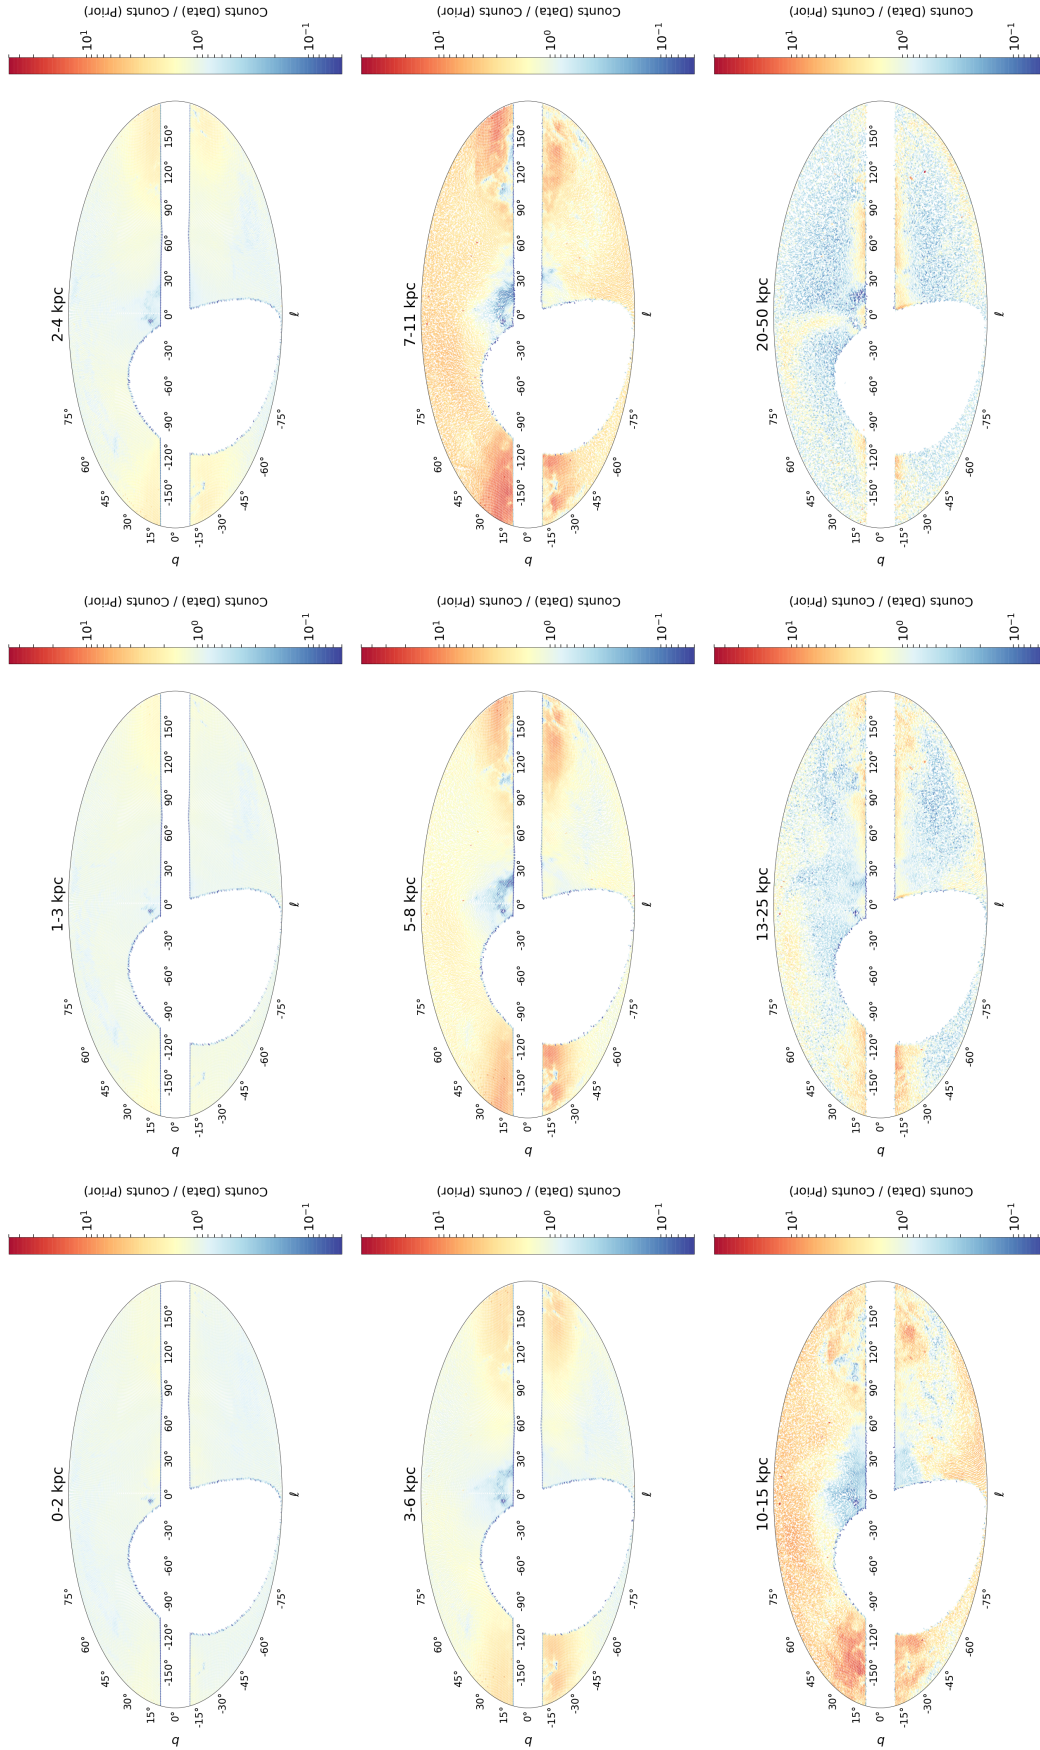

**Figure 11.** The mean number density of stars in (overlapping) distance bins ranging from  $d = 0 - 50$  kpc at a `healpix` resolution of `nside = 64` (see Figure 2). The bulk motion of stars within each `healpix` pixel (corrected for Solar reflex motion) are indicated by small arrows and estimated using the mean proper motion. We can see clear evidence of large-scale features in our maps, including evidence of the Sagittarius stream (bottom right) and the Monoceros Ring (middle right) along with “missing regions” where substantial foreground dust extinction removes stars from our catalog. An interactive version of this figure is available online at [this link](#).

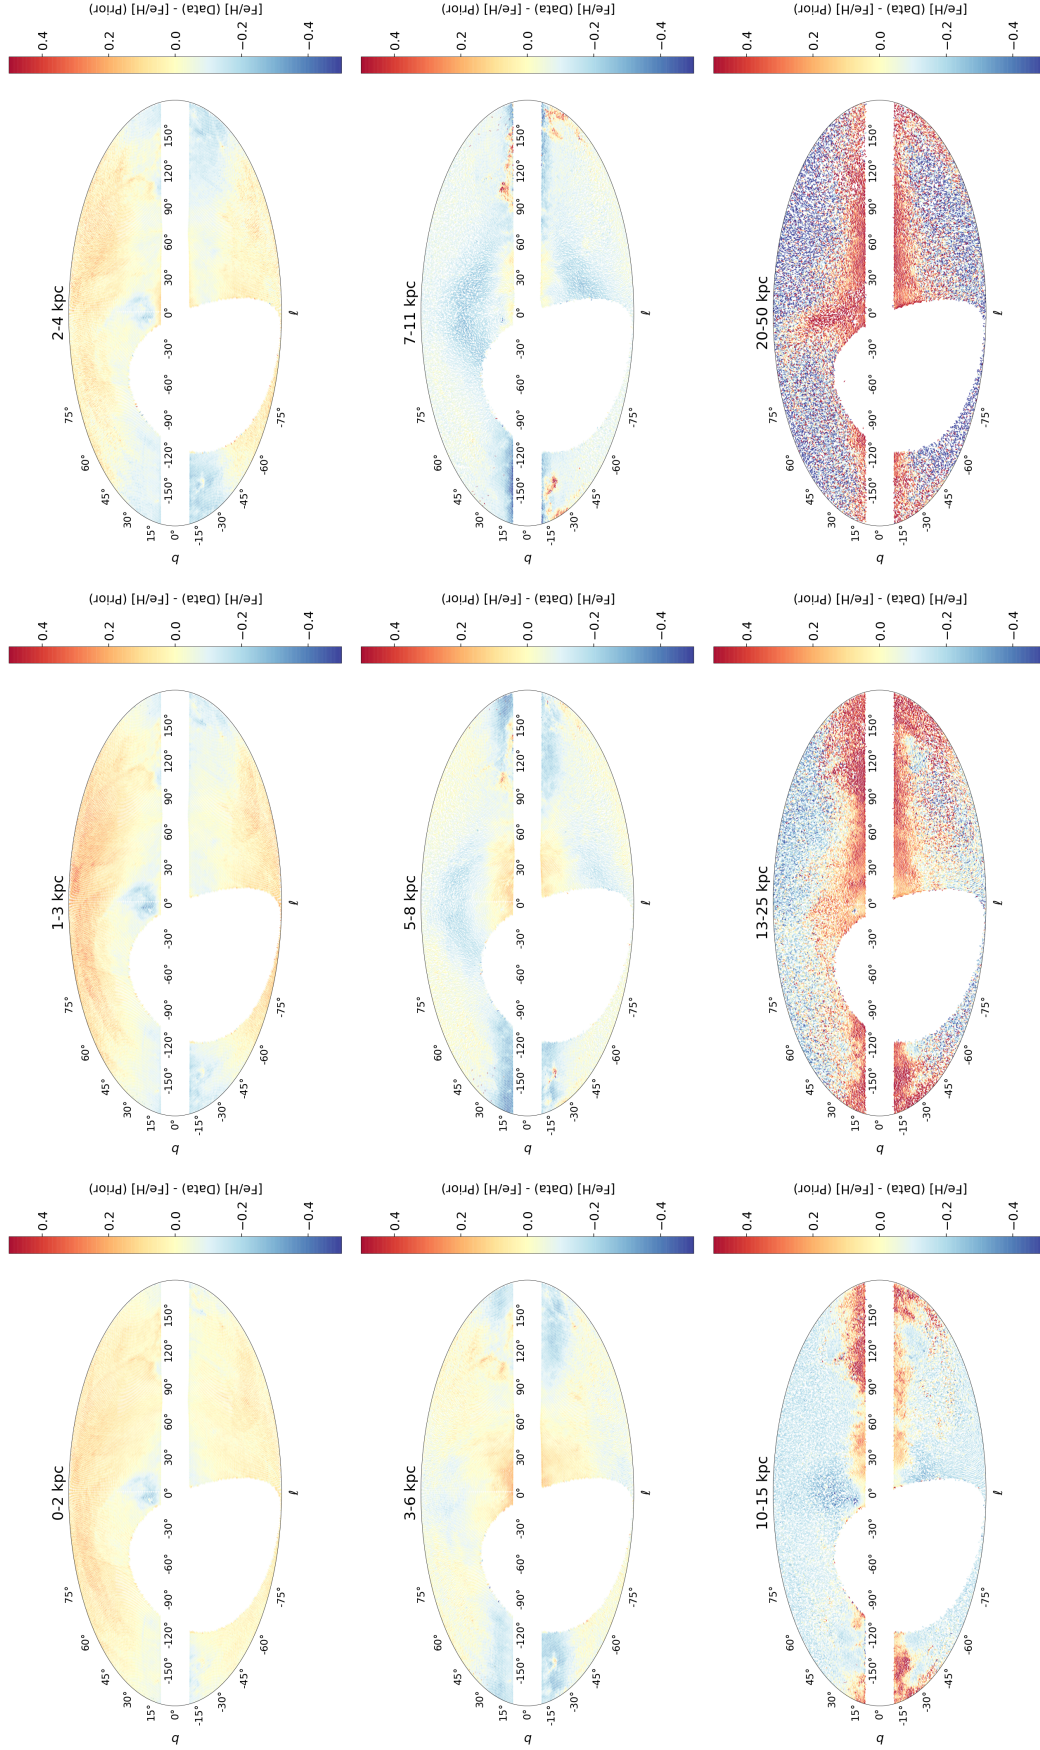

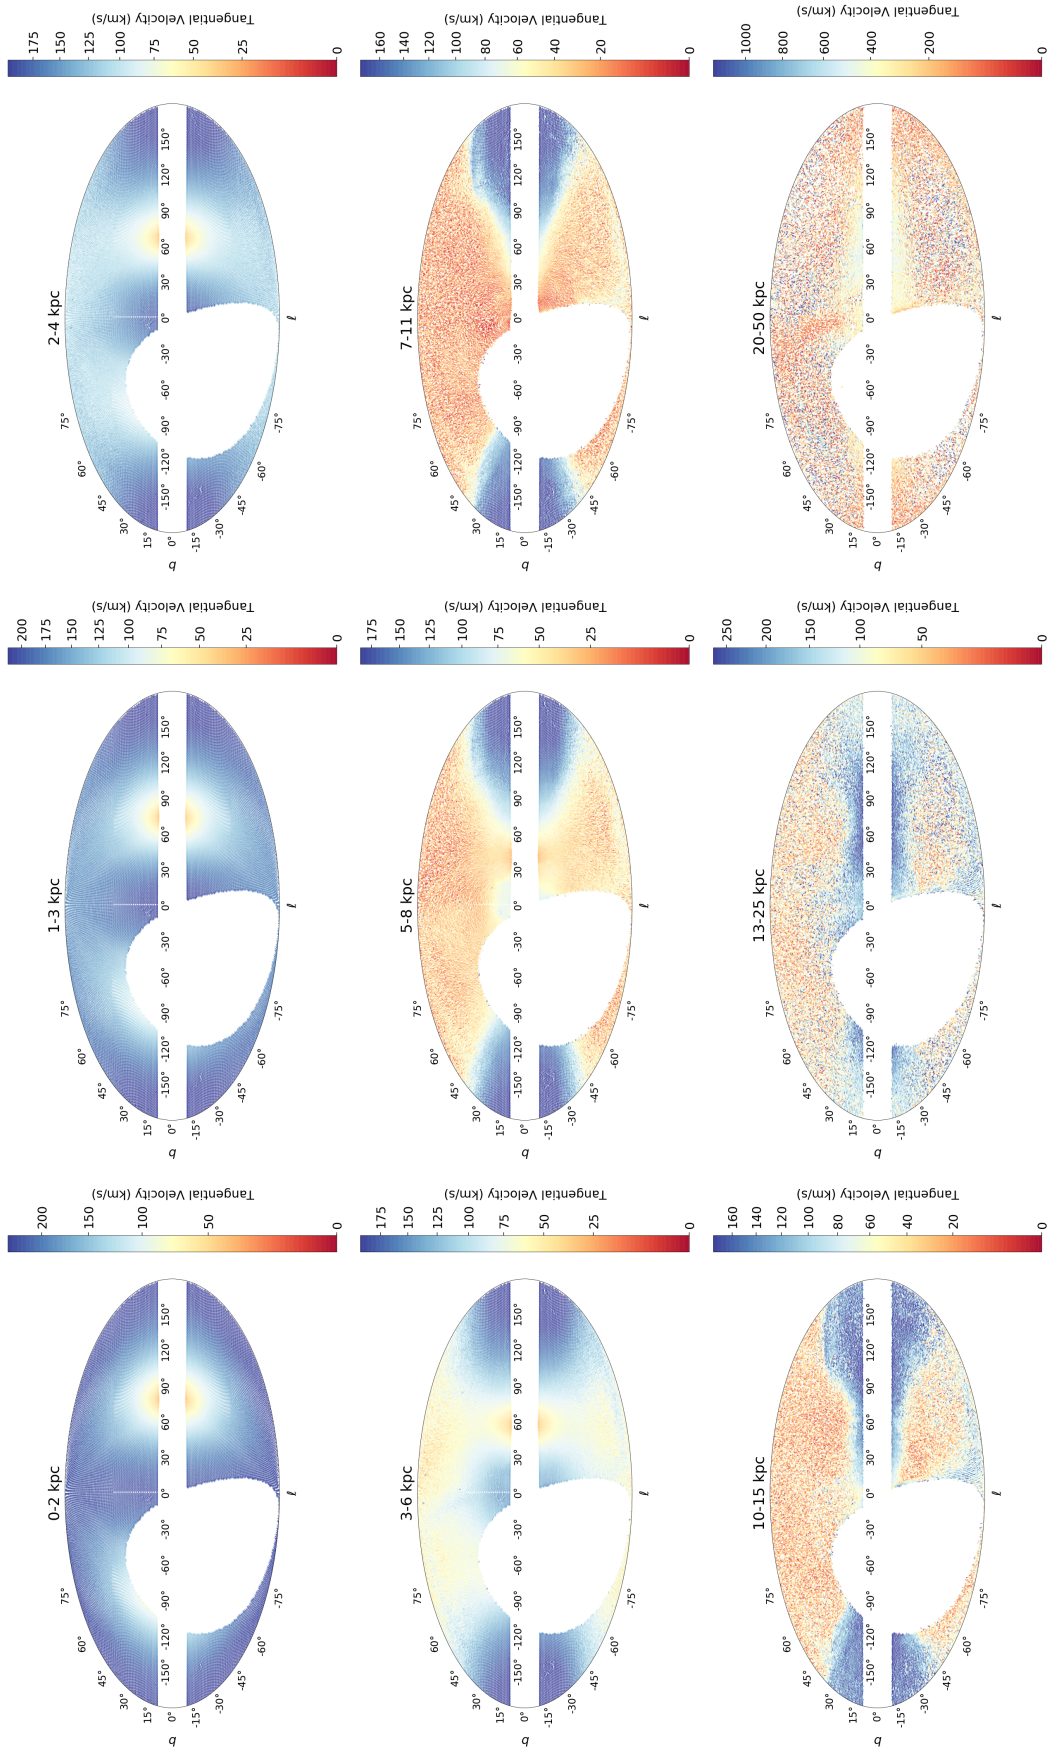

**Figure 12.** As Figure 11, but now showing the expected distribution of sources from the Galactic prior. These have been normalized so that the total number of sources in each distance bin are the same in both figures. Since the prior contains only smooth components, it does not show any evidence for additional substructure compared to Figure 11. *An interactive version of this figure is available online at [this link](#).*

**Figure 13.** As Figure 11, but now showing the ratio between the data and the prior. This highlights deviations from the assumed Galactic model (i.e. “the background”) in order to emphasize substructure present in the data. The Monoceros Ring in the Galactic anti-center can be clearly seen as a  $\gtrsim 10$  times overdensity relative to the background from  $d \sim 5 - 15$  kpc. We also observe broad flaring in the disk, which is not modeled in our prior. At  $d > 20$  kpc, the Sagittarius stream is also clearly visible, with number densities also  $\gtrsim 10$  times higher than the background. *An interactive version of this figure is available online at [this link](#).*

**Figure 14.** As Figure 13, but now showing the difference between the mean  $[\text{Fe}/\text{H}]_{\text{init}}$  from the data and the prior. Deviations can be seen in all distance bins, although the size of the deviations increases as a function of distance. Clear systematics in  $[\text{Fe}/\text{H}]_{\text{init}}$  estimation aligned with foreground dust extinction features and objects near the Galactic plane are visible. We see evidence for lower-than-expected  $[\text{Fe}/\text{H}]_{\text{init}}$  values (compared to the prior) for stars in the Monoceros Ring and higher-than-expected  $[\text{Fe}/\text{H}]_{\text{init}}$  values for stars in the Sagittarius stream. *An interactive version of this figure is available online at [this link](#).*

**Figure 15.** As Figure 11, but now showing the mean tangential velocity (in km/s) corrected for the Solar reflex motion. The overall structure in the observed velocities at  $d \lesssim 6$  kpc is due to pointing directly along/opposite the expected motion of stars orbiting in the disk. Kinematically coherent structures associated with known clusters (which show up as “outliers” relative to the background motion of nearby sources) as well as more extended structures are easily visible.

As discussed in Speagle et al. (2021a, subm.), inference from photometry alone is strongly influenced by the underlying Galactic priors and even including strong constraints from parallaxes can still lead to biases in inferred stellar properties without tight constraints on  $A_V$  (i.e. some knowledge of the intrinsic SED). As such, it is important to investigate just how much information we are able to recover relative to the prior.

It has been demonstrated in Green et al. (2015), Chen et al. (2019), Anders et al. (2019), and other work that there is enough information in stellar photometry to recover distance and extinction estimates to stars with enough precision to construct detailed, accurate 3-D dust maps. Anders et al. (2019) show that these estimates may also be detailed enough to begin resolving large-scale features such as the Galactic bar. Given that our map targets high-latitude regions and goes substantially deeper than that work, we want to investigate whether we too can (in principle) recover large-scale substructure purely from astro-photometry alone.

In Figure 11, we plot the mean proper motion directions for all the sources in *Augustus-Gold* with `nside` = 64 `healpix` resolution, split into (overlapping) median distance bins ranging from  $d_{50} = 0$  kpc to  $d_{50} = 50$  kpc and colored by counts in each pixel. Overall, we see clear evidence of large-scale features in our maps, including evidence of the Sagittarius stream (bottom right) and the “Monoceros Ring” (middle right) (Newberg et al. 2002; Jurić et al. 2008; Purcell et al. 2011; Gómez et al. 2013; Laporte et al. 2018a,b). We also observe issues where systematics clearly play a role in the inferred stellar properties, especially near the Galactic center and the Galactic plane as well as in regions of substantial foreground extinction (where we either miss stars entirely or likely somewhat mismodel them).

To get a sense for how significant these features are, we need to compare them against what we expect given our Galactic prior. In Figure 12, we show the exact same plot except this time colored by the *expected* number of counts in each pixel, normalized so that each distance bin contains the same total number of stars. In this version, we see no evidence for any substructure in density alone (since our prior includes no kinematic information). This makes sense, since our prior was, by construction, a *smooth* model of the Galaxy that did not account for any small-scale structure.

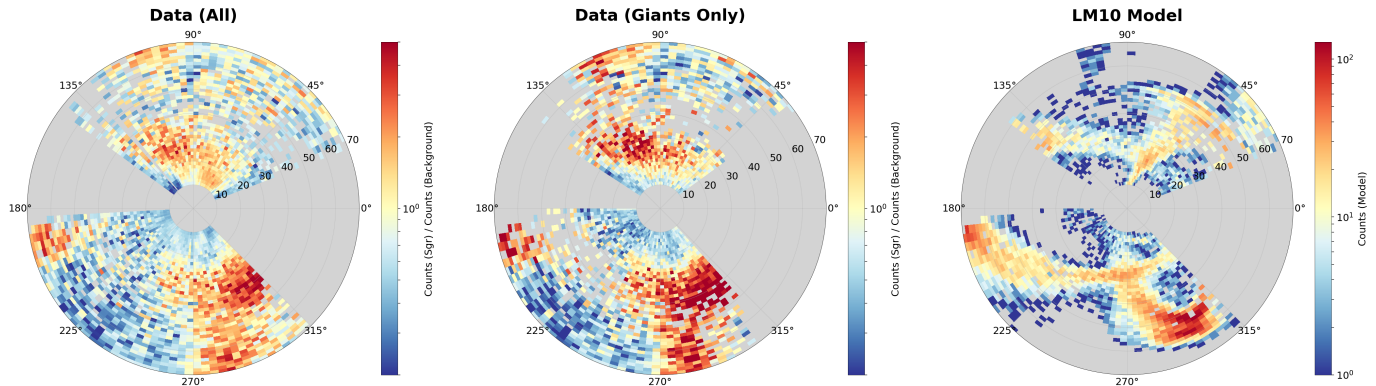

In Figure 13 we compare the *ratio* of the observed number of counts to the expected number of counts. As expected, we have an under-density of sources in the direction of the Galactic center, where there is a substantial amount of dust extinction and we are likely incomplete. We can clearly see the overdensity corresponding to the Monoceros Ring appears as early as  $d \sim 3$  kpc, peaks at  $d \sim 9$  kpc, and extends out to  $d \sim 13$  kpc. While there are strong asymmetries as a function of  $\ell$  and  $b$ , it is difficult to interpret these differences since these regions have dust clouds along the line of sight.

Beyond  $d \sim 15$  kpc, we see clear evidence for the Sagittarius stream, which has densities at high-latitudes similar to those near the plane. These densities are in fact so large that they dominate the normalization of the expected number of counts, leading to these structures being considered “normal” with ratios  $\sim 1$  while the rest of the halo is considered “underdense”.

In Figure 14, we now highlight differences between the predicted mean  $[\text{Fe}/\text{H}]_{\text{init}}$  from the Galactic prior (which is spatially-independent within each component of our prior) and the mean  $[\text{Fe}/\text{H}]_{\text{init},50}$  derived from the data. Deviations can be seen in all distance bins, although the size of the deviations increases as a function of distance. Here we see clear evidence for issues related to survey coverage at nearby distances with visible survey stripes and at far distance near the Galactic plane. There are also clear systematics in  $[\text{Fe}/\text{H}]_{\text{init}}$  estimation correlated with foreground dust extinction, with regions with large  $A_V$  having discrepant  $[\text{Fe}/\text{H}]_{\text{init}}$  relative to background sources. That said, we do see strong, correlated evidence for lower-than-expected  $[\text{Fe}/\text{H}]_{\text{init}}$  values for stars in the Monoceros Ring and higher-than-expected  $[\text{Fe}/\text{H}]_{\text{init}}$  values for stars in the Sagittarius stream. These findings suggest that we should be able to use photometric metallicities to explore kinematic and chemical origins of these structures, such as to follow up on kinematic and chemical separations with other structures from the Monoceros Ring (e.g., Laporte et al. 2020).

In Figure 15 we plot the associated mean tangential velocities in each pixel derived from the median distances in *Augustus-Gold* and measured proper motions from *Gaia*, corrected for the Solar reflex motion using *ASTROPY* (Astropy Collaboration et al. 2013; Price-Whelan et al. 2018). The overall structure in velocities observed at  $d \lesssim 6$  kpc agrees with what we would expect from geometry, where sources orbiting in the disk are moving directly along/opposite our line of sight. Kinetically coherent large-scale structure associated with the Monoceros Ring and Sagittarius stream are clearly visible. We also clearly see the presence of known large open/globular clusters, which show up as “outliers” in tangential velocity in a given distance bin relative to the underlying background. Both of these results are encouraging.

Finally, we examine our detection of the Sagittarius stream in more detail. We transform the coordinates from our sources from Galactic coordinates ( $\ell, b$ ) to coordinates aligned with the orbital plane of the Sagittarius stream ( $\Lambda, \beta$ ) from Law & Majewski (2010). In Figure 16 we try to directly compare these results with those from simulations taken from Law & Majewski (2010) by using the density contrast for sources with  $|\beta| < 10$  compared with those with  $10 < |\beta| < 30$  as a tracer of the Sagittarius stream as a function of  $d$  and  $\Lambda$ . We find our results to be qualitatively consistent regardless of whether we use all sources or limit ourselves to only

**Figure 16.** The ratio of the observed number density for objects with  $|\beta| < 10$  (“Sagittarius”) and with  $10 < |\beta| < 40$  (“Background”) as a function of distance and  $\Lambda_{\text{Sgr}}$ , where  $(\Lambda, \beta)$  are coordinates in the Sagittarius orbital plane. The results for all stars with median distances  $10 \text{ kpc} < d_{50} < 70 \text{ kpc}$  and the subset with  $P(\text{giant}) > 95\%$  are shown in the left and middle panels, respectively. The stellar density from stars taken from the Law & Majewski (2010) simulations with  $|\beta| < 10$  are shown in the right panel. The broad correspondence in overall structure between the astro-photometric distances derived in this work and the results from the simulations lends confidence that our distances and stellar classifications are reliable even out to large distances.

those with  $P(\text{giant}) > 95\%$ . This broad correspondence in overall structure between the astro-photometric distances in Augustus-Gold and the results from the simulations lends confidence that our distances and stellar classifications are reliable even out to large distances.

### 5.5. Visualizing 5-D Substructure with ALLSKY

As a final tool to aid exploration and characterization of the data presented in this work, we modify the public, open source code EARTH<sup>14</sup> used to visualize wind and ocean currents on the surface of the Earth to handle the similar types of structure present in 2-D velocities in a given set of 3-D distance bins. Our public, open source code ALLSKY<sup>15</sup> is able to illustrate velocity motion as moving “streamlines” following simple non-linear trajectories and allows users to explore various underlying properties of the data (velocity, number density, metallicity, etc.) in various projections (Atlantis, orthographic, equirectangular, etc.) for each of the nine distance bins shown in this work. A screenshot illustrating the code is shown in Figure 1. The full interactive visualization can be accessed online at <http://allsky.s3-website-us-east-2.amazonaws.com> and the data can be downloaded from the ALLSKY GitHub repository.

### 5.6. Additional Remarks

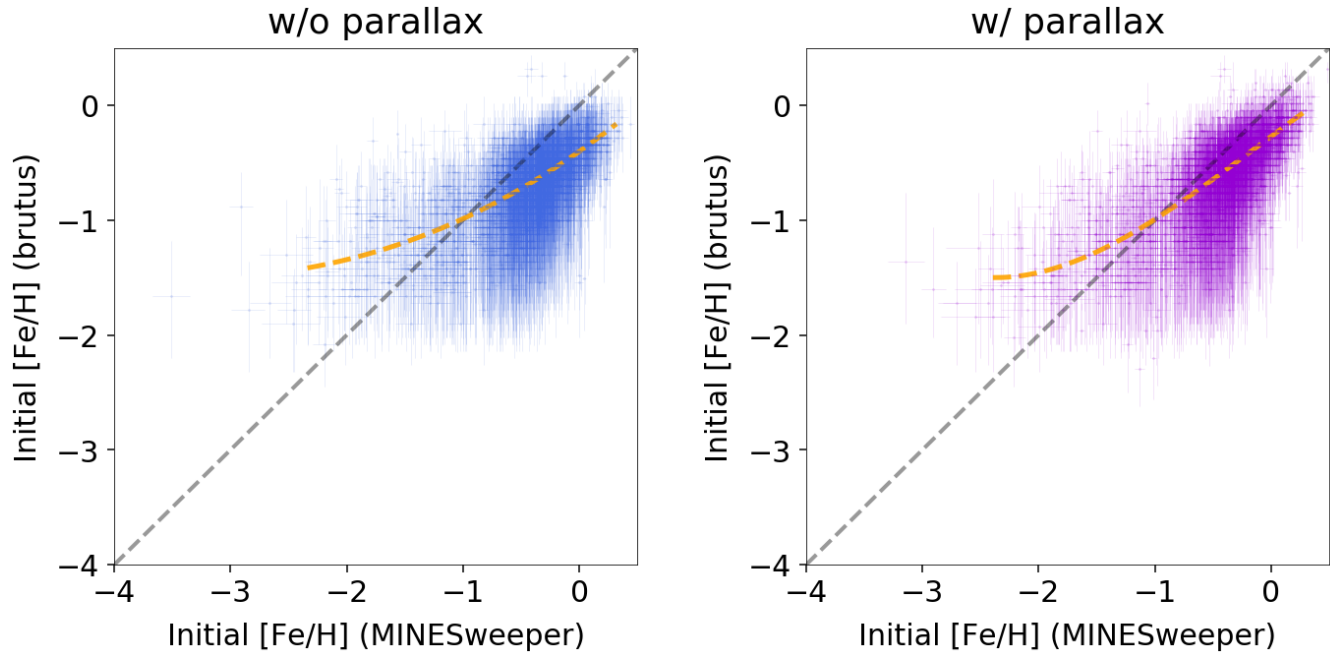

While the results described in this section highlight some of the successes of BRUTUS and the overall quality of the Augustus-Gold sub-sample, we also want to take some time to explicitly mention limitations as well as

future directions for improvement. These fall under a few broad categories:

- *Limited spatial coverage and depth:* For practical reasons, Augustus is limited to only covering the Northern sky that overlaps with the 3-D dust prior from Green et al. (2019), does not include the large amount of objects at  $|b| \leq 10^\circ$ , and only extends down to  $r < 20$ . We aim to break away from these limitations in future work by removing our reliance on a previously-estimated 3-D dust prior, improving the computational efficiency the underlying BRUTUS code, using larger all-sky datasets such as Gaia EDR3 as a base to expand off of, and using a broader set of surveys to provide deeper optical and (near-)IR photometry in both the North and the South.
- *Overly simplistic priors:* The current set of priors (see Speagle et al. (2021a, subm.) for additional details) includes simple models for a 3-component model that includes a thin disk, thick disk, and halo. Not only are all components overly simplistic smooth models (with no substructure, warps, etc.) with spatially-independent metallicity and age constraints, but there is no prior for a bulge or bar. We aim to improve on these in future work.
- *Low  $A_V$  limits:* While the Augustus catalog targeted the halo, there are still regions where extremely high  $A_V$  values occur. Stars in these regions are inherently mismodeled due to the default maximum value of  $A_V = 6$  imposed in the catalog. This will be raised to much higher values in future work.

<sup>14</sup> <https://earth.nullschool.net/>

<sup>15</sup> <https://github.com/joshspeagle/allsky>

**Figure 17.** A comparison of the metallicities derived from BRUTUS (used in this work with photometry only) and MINESWEEPER (including both photometry and spectroscopy) for a sample of  $n \sim 5100$  objects shown from the H3 Survey using similar isochrones and photometry without (left, blue) and with (right, purple) *Gaia* parallax constraints. 1-sigma errors from both sources are plotted for each point and the one-to-one relation is shown with a dashed gray line along with a sliding median (orange dashed line). In both cases, the metallicities derived from photometry only are found to be substantially biased, although they broadly follow the same trend as those derived using both spectra and photometry. As discussed in §5.6, this is due to a fundamental degeneracy where changes in the estimated reddening can be accounted for with corresponding changes to the underlying stellar properties, which leads to increased reliance on the metallicity prior from our Galactic model. These results suggest our metallicities, along with other derived quantities without good external constraints, should be used with caution.

- *Mass limits:* The theoretical MIST isochrones we are using have large systematic biases in the predicted photometric colors below  $M \lesssim 0.5M_{\odot}$ , even with some of the empirical corrections implemented in Speagle et al. (2021a, subm.). This primarily affects our ability to model  $M$  dwarfs/giants. We hope to use improved isochrone models in future work to extend our modeling to lower masses.
- *Model-data mismatch:* Offsets between the predicted photometry vary systematically across the CMD for our given set of isochrones. This imposes systematic limits on parameter recovery above the statistical errors present in the photometric measurements. We hope the incorporation of new data-driven stellar models such as those from Green et al. (2021) will help to alleviate these issues.
- *Gridding effects:* As shown most clearly in Figure 9, the current grid does sample a range of surface gravities and effective temperatures but still contains visible gridding effects that could impact inference. We hope to alleviate this in future work through approaches that can apply iterative adaptive refinements.
- *Non-Normal errors:* It is possible that the assumption of strictly Normal uncertainties is not valid for the assumed photometric uncertainties in both magnitude and flux density, leading to incorrect (likely underestimated) statistical uncertainties in derived properties. While systematic effects from survey photometric pipelines may lead to empirical error distributions with broader tails (e.g., such as the complex photometric processing for data in *Gaia* DR2; Gaia Collaboration et al. 2018), in general most reported uncertainties in derived properties are dominated by the effects of model-data mismatch. Similarly, while distribution of statistical parallax uncertainties for *Gaia* DR2 appear to follow a Normal distribution out to several standard deviations, the applied zero-point corrections can lead to systematic offsets that are distinctly non-Normal in nature (Lindgren et al. 2018).
- *No kinematic constraints:* As can be seen in some panels in Figure 15, the predicted tangential veloc-

ities for some sources indicate clear mismodeling of the distance. Especially given the recent improved parallaxes and proper motions from *Gaia* EDR3, in future work we hope to incorporate additional kinematic constraints to better resolve some of these degeneracies.

Although the primary purpose of this catalog is to provide distance and reddening estimates, we also want to explicitly highlight possible deficiencies in secondary derived quantities, namely photometric metallicities. In Figure 17, we show the metallicity recovery for a subset of  $n \sim 5100$  stars from the H3 survey (Conroy et al. 2019). In brief, the H3 Survey is a high-latitude ( $|b| > 30^\circ$ ), high-resolution ( $R = 32,000$ ) spectroscopic survey of the distant ( $d \gtrsim 2$  kpc Galaxy. Targets are selected purely on their Gaia parallax ( $\varpi < 0.4\text{--}0.5$  mas), brightness ( $15 < r_{\text{PS1}} < 18$ ), and accessibility to the 6.5 m MMT in Arizona, USA ( $\text{dec} > -20^\circ$ ). The survey measures radial velocities to 0.1 km/s precision, surface abundances ( $[\text{Fe}/\text{H}]_{\text{surf}}$  and  $[\alpha/\text{Fe}]_{\text{surf}}$ ) to 0.1 dex precision, and spectrophotometric distances to 10% precision using MINESWEEPER (Cargile et al. 2020). In addition to being a representative, low-reddening subsample of sources, all derived quantities were estimated using the same underlying MIST isochrones (excluding the empirical corrections and photometric offsets derived in this work). This makes the estimated metallicities comparisons both independent (derived using different codebases and with/without spectra) while still remaining internally consistent (using similar photometry and underlying stellar models).

As seen in Figure 17, the parameter recovery is substantially biased and prior-dominated, even with reasonable signal-to-noise photometry and parallax measurements. As discussed in Speagle et al. (2022a, subm.), this is because there is an intrinsic degeneracy in reddened stellar colors that only can be broken if the dust attenuation is known to high precision. Without this, it is possible to shift the brightness and colors of stars by adjusting dust attenuation (which affects the observed star colors) along with metallicity and other stellar properties (which affects the intrinsic star colors). As a result, estimates are generally dragged towards our prior means for both the thin/thick disk and halo populations, which shows up as a bias for both high and low-metallicity objects. Since distance estimates don't break these color degeneracies, this effect is present when modelling objects with or without parallax constraints, emphasizing the prior is actually dominating much of the inference. While internal tests and comparisons presented here imply this bias doesn't substantially impact our distance estimates, it does mean that our metallicity estimates, and other prior-dominated derived quantities, should be used with caution in any downstream analyses.

## 6. CONCLUSION

As large-area surveys such as SDSS (York et al. 2000), Pan-STARRS (Chambers et al. 2016), *Gaia* (Gaia Collaboration et al. 2016), and the Legacy Survey of Space and Time (LSST; Ivezić et al. 2008) continue to or promise to soon provide provide measurements to billions of stars, the challenge of transforming observations of the projected 2-D positions of sources on the sky into full 3-D maps becomes ever more pressing when trying to study the Milky Way. In this work, we presented results applying BRUTUS (Speagle et al. 2022a, subm.) – a public, open-source PYTHON package that uses a combination of statistical approaches to infer stellar properties, distances, and extinctions for sources using photometry and astrometry – to a catalog of 170 million sources (Augustus) at high Galactic latitudes ( $|b| > 10$  mag) down to  $r < 20$  mag with data from Pan-STARRS, *Gaia*, 2MASS, UKIDSS, and unWISE.

We find 125 million objects (Augustus-Gold) have good fits and reliable posteriors with estimated *statistical* distance uncertainties of  $\sim 3\text{--}5\%$  at  $r = 14$  mag to  $\sim 8\text{--}10\%$  at  $r = 20$  mag. We show that our results are able to *predict* the “empirical”, de-reddened *Gaia* CMD based on astro-photometric modeling in other bands, and that the derived stellar parameters are in excellent agreement with similar results derived in Anders et al. (2019). We then illustrate the quality of the data by highlighting its ability to recover large and small-scale Galactic substructure such as the Monoceros Ring at  $d \sim 10$  kpc and the Sagittarius Stream at  $d \sim 25$  kpc in density, metallicity, and kinematics relative to expectations from the underlying Galactic prior. Finally, we present an interactive visualization (ALLSKY) that is able to highlighted limited 5-D distance and tangential velocity structure present in our data.

Catalogs summarizing our results are publicly available at the Harvard Dataverse<sup>16</sup> and summarized in Appendix A. Overall, we hope that our results serve as a useful value-added catalog that highlight the power of combined astro-photometric constraints to estimate stellar properties.

## ACKNOWLEDGMENTS

### *Contributions:*

The author list is divided up into 3 groups:

1. a list of primary authors who made direct contributions to the construction, computation, and analysis of the catalog (JSS to BDJ),
2. an alphabetized secondary list of authors who made direct or indirect contributions to project and/or data products (AB to EFS), and

<sup>16</sup> [https://dataverse.harvard.edu/dataverse/brutus\\_augustus](https://dataverse.harvard.edu/dataverse/brutus_augustus)

3. an alphabetized tertiary list of authors who provided useful feedback during the development process and/or on the paper itself (AD to IAZ).

*Personal:*

JSS would like to thank Rebecca Bleich for her truly incredible support – mental, physical, emotional, and spiritual – during these difficult times. Without it, this paper (along with a great many other things) would likely never have seen the light of day. JSS would also like to thank Jan Rybizki, Seth Gossage, and Nayantara Mudur for insightful discussions that improved the quality of this work and Blakesley Burkhart for providing feedback on earlier versions of the catalog.

*Funding:*

JSS and CZ were partially supported by the Harvard Data Science Initiative. HMK acknowledges support from the DOE CSGF under grant number DE-FG02-97ER25308. AD received support from the National Aeronautics and Space Administration (NASA) under Contract No. NNG16PJ26C issued through the WFIRST Science Investigation Teams Program. CZ and DPF acknowledge support from NSF grant AST-1614941, “Exploring the Galaxy: 3-Dimensional Structure and Stellar Streams.” AKS gratefully acknowledges support by a National Science Foundation Graduate Research Fellowship (DGE-1745303). YST acknowledges financial support from the Australian Research Council through DECRA Fellowship DE220101520.

*Data:*

The Pan-STARRS1 Surveys and the public science archive have been made possible through contributions by the Institute for Astronomy, the University of Hawaii, the Pan-STARRS Project Office, the Max Planck Society and its participating institutes, the Max Planck Institute for Astronomy, Heidelberg and the Max Planck Institute for Extraterrestrial Physics, Garching, The Johns Hopkins University, Durham University, the University of Edinburgh, the Queen’s University Belfast, the Center for Astrophysics | Harvard & Smithsonian, the Las Cumbres Observatory Global Telescope Network Incorporated, the National Central University of Taiwan, the Space Telescope Science Institute, the National Aeronautics and Space Administration under Grant No. NNX08AR22G issued through the Planetary Science Division of the NASA Science Mission Directorate, the National Science Foundation Grant No. AST-1238877,

the University of Maryland, Eotvos Lorand University (ELTE), the Los Alamos National Laboratory, and the Gordon and Betty Moore Foundation.

This publication makes use of data products from the Two Micron All Sky Survey, which is a joint project of the University of Massachusetts and the Infrared Processing and Analysis Center/California Institute of Technology, funded by the National Aeronautics and Space Administration and the National Science Foundation.

This work has made use of data from the European Space Agency (ESA) mission Gaia (<https://www.cosmos.esa.int/gaia>), processed by the Gaia Data Processing and Analysis Consortium (DPAC; <https://www.cosmos.esa.int/web/gaia/dpac/consortium>). Funding for the DPAC has been provided by national institutions, in particular the institutions participating in the Gaia Multilateral Agreement.

This publication makes use of data products from the Wide-field Infrared Survey Explorer, which is a joint project of the University of California, Los Angeles, and the Jet Propulsion Laboratory/California Institute of Technology, and NEOWISE, which is a project of the Jet Propulsion Laboratory/California Institute of Technology. WISE and NEOWISE are funded by the National Aeronautics and Space Administration.

*Computation:*

The bulk of the computation in this paper was done on the *Cannon* cluster, which is supported by the Research Computing Group in the FAS Division of Science at Harvard University.

*Code:*

This work has benefited from the following packages:

- ASTROPY (Astropy Collaboration et al. 2013; Price-Whelan et al. 2018)
- NUMPY (van der Walt et al. 2011)
- SCIPY (Virtanen et al. 2020)
- MATPLOTLIB (Hunter 2007)
- HEALPY (Górski et al. 2005; Zonca et al. 2019)
- GALA (Price-Whelan 2017)

## APPENDIX

## A. DATA PRODUCTS

The output **Augustus** stellar parameter catalogs can be found online through the [Harvard Dataverse](#). Two types of data products are made available:

1. a “point” catalog that contains information about each object along with summary statistics describing the results ([doi:10.7910/DVN/WYMSXV](#)) and
2. a “samples” catalog that contains 25 random posterior samples for each object ([doi:10.7910/DVN/530UYQ](#)).

A summary of the column names, the data format, and a brief description of each catalog can be found in Tables 3 and 4. Note that the “samples” catalogs is strictly meant to be supplementary to the “point” catalog and is matched to the latter row-wise.<sup>17</sup> Catalogs are made available for sources modeled using all bands as well as excluding UKIDSS data for sources that have them (which have the `_noukidss` suffix). The `_noukidss` data products are available for download at the same [Harvard Dataverse](#) repository as their UKIDSS-included counterpart files. Additional information on the columns provided in these catalogs are described below.

Information on sources is provided through their corresponding Pan-STARRS ID (`PS_ID`) and *Gaia* DR2 ID (`GAIA_ID`) as well as by their 2-D coordinates, in units of right ascension and declination (`SKY_COORDS`) as well as Galactic longitude and latitude (`GAL_COORDS`). In addition, we also include astrometric measurements from *Gaia* including parallaxes (`PARALLAX`, `PARALLAX_ERROR`) and proper motions (`PROPER_MOTION`, `PROPER_MOTION_ERROR`) as well as multi-band photometry from *Gaia*, Pan-STARRS, 2MASS, UKIDSS, and unWISE (`MAGNITUDES`, `MAGNITUDES_ERROR`). Note that the parallaxes and magnitudes contain *none* of the offsets or additional systematic corrections/errors described in §2 outside of the 0.005 mag photometric error floor.

Information on the overall quality of the fit can be assessed in a few ways. One metric is the log-evidence (`LOG_EVID`), defined as

$$\ln \mathcal{Z} \equiv \ln \left( \int \mathcal{L}_{\text{phot}}(\boldsymbol{\theta}, \boldsymbol{\phi}) \mathcal{L}_{\text{astr}}(\boldsymbol{\phi}) \pi(\boldsymbol{\theta}, \boldsymbol{\phi}) \, d\boldsymbol{\theta} \, d\boldsymbol{\phi} \right) \quad (\text{A1})$$

We estimate this for each object by summing over the final (weighted) subset of models before applying the posterior resampling scheme described in Speagle et al. (2021a, *subm.*). This provides information on the *overall* quality of the fit across all the models *including* the influence of the prior.

Another metric is simply the best-fit  $\chi^2_{\text{best}}$  (`BEST_CHI2`) from all the models before applying the posterior resampling scheme. This provides information on the quality of the *best* possible fit *ignoring* the impact of the prior, thereby serving as a useful supplement to the log-evidence.

Combined with the number of bands  $b$  used in the fit (`NBANDS_IN_FIT`), we use this information to derive a flag for rejecting sources that fail to achieve even a single reasonable fit:

$$\text{FLAG\_FIT} = \begin{cases} \text{TRUE} & \text{if } P(\chi^2 > \chi^2_{\text{best}} | b-3) < 10^{-3} \\ \text{FALSE} & \text{otherwise} \end{cases} \quad (\text{A2})$$

where  $P(\chi^2 > \chi^2_{\text{best}} | b-3)$  is the probability of observing a  $\chi^2$  value larger than  $\chi^2_{\text{best}}$  assuming  $b-3$  degrees of freedom. Note that we use  $b-3$  rather than  $b$  due to the fact that BRUTUS “optimizes” over 3 parameters ( $d$ ,  $A_V$ ,  $R_V$ ) before the posterior weighting and resampling step.

For every parameter we compute the 2.5th, 50th, and 97.5th percentiles (i.e. the median and the  $2\sigma$  errors) for each parameter by rank-ordering the final set of  $n = 250$  posterior samples. We choose to report  $2\sigma$  rather than  $1\sigma$  errors here since they better reflect intuitive understanding of uncertainty (i.e. objects are “unlikely” to be outside the error bars) and better highlight possible degeneracies in the fits (e.g., between dwarf and giant solutions) when they occur. We provide these percentiles along with a random sample taken from the posterior for the object for each parameter in our model (see Table 3 for a full list). Since all the parameters from this random sample are correlated, it can be useful in certain contexts.

<sup>17</sup> As described in §4, BRUTUS v0.7.5 contained a bug (fixed in more recent versions of the code) that used the wrong sign when sampling from correlations between  $A_V$  and  $R_V$  with distance  $d$ . While this has a negligible impact on the quality of the point catalog outside of the provided random draw, it does affect quantities computed directly from the “samples” catalog which jointly depend on  $d$  and  $A_V$  or  $R_V$  (e.g., reddened photometry).

We use these percentiles to define a second flag `FLAG_GRID` that we set to `TRUE` if any of the 2.5th or 97.5th percentiles for each parameter that defines the grid of models ( $M_{\text{init}}$ ,  $[\text{Fe}/\text{H}]_{\text{init}}$ ,  $\text{EEP}$ ) are equal to the minimum or maximum possible value of that parameter, respectively, and `FALSE` otherwise. This flags posteriors that may be biased due to the hard edges present in our input model grid. This mainly flags sources with lower initial masses since our model grid only goes down to  $M_{\text{init}} = 0.5 M_{\odot}$ .

Finally, as part of the “point” catalog we also provide the probability `PROB_GIANT` that a source is a giant, which we define as

$$\text{PROB\_GIANT} \equiv P(\log g < 3.5) \quad (\text{A3})$$

following the definition used in the H3 survey (Conroy et al. 2019). We estimate this using the final set of posterior samples, which gives us a resolution of  $1/n_{\text{samp}} = 1/250 = 0.4\%$  in probability.

In the “samples” catalog, we provide 25 samples from the posterior for the distance  $d$  (`SAMPLES_DISTANCE`), extinction  $A_V$  (`SAMPLES_A_V`), differential reddening  $R_V$  (`SAMPLES_R_V`), and “model index” (`SAMPLES_MODEL_IDX`). The model index can be used to grab the corresponding models from the input parameter grid, which can then be used to construct output predictions for associated quantities.

An example showing how to use these samples within `BRUTUS` is shown below:

```
import numpy as np
import h5py
from brutus import utils as butils
from brutus.filters import gaia, ps, tmass, ukidss, wise

# grab quality flags
cat = h5py.File('point_cat.h5', mode='r') # load h5 file
flag_fit, flag_grid = cat['FLAG_FIT'][:100], cat['FLAG_GRID'][:100] # first 100 elements
good = np.where(~flag_fit & ~flag_grid)[0] # no flags (good fits, good posteriors)

# load samples catalog
samples = h5py.File('samples_cat.h5', mode='r') # load h5 file
samples_idx = samples['SAMPLES_MODEL_IDX'][:100][good] # first 100 elements + no flags

# load MIST grid
flts = gaia + ps[:-2] + tmass + ukidss + wise[:-2] # define filterset
mags, labels, _ = butils.load_models('grid_mist_v8.h5', filters=flts) # read file

# get effective temperatures of corresponding models
logt = labels['logt'][samples_idx] # log(Teff)
teff = 10**logt # convert from log to linear

# compute percentiles (median, +/- 1 sigma, +/- 2 sigma)
teff_vals = np.percentile(teff, [2.5, 16, 50, 84, 97.5], axis=1)

# compute mean and standard deviation of predicted intrinsic Gaia G magnitude at 1 kpc
G = mags[:, 0, 0][samples_idx]
G_mean, G_std = np.mean(G, axis=1), np.std(G, axis=1)
```

**Table 3.** Summary of the *Augustus* “point” catalog that includes object information and summary statistics description results from the BRUTUS fits. See Appendix A for additional details. The table is available for download at [doi:10.7910/DVN/WYMSXV](https://doi.org/10.7910/DVN/WYMSXV).

Name	Data Format	Description
<b>Object Information</b>		
PS_ID	64-bit uint	Pan-STARRS object ID
GAIA_ID	64-bit uint	<i>Gaia</i> DR2 object ID
SKY_COORDS	64-bit float (x2)	Sky coordinates ( $\alpha, \delta$ ) in degrees
GAL_COORDS	64-bit float (x2)	Galactic coordinates ( $l, b$ ) in degrees
PARALLAX	32-bit float	Parallax from <i>Gaia</i> DR2 in mas
PARALLAX_ERROR	32-bit float	Parallax error from <i>Gaia</i> DR2 in mas
PROPER_MOTION	32-bit float (x2)	Proper motion in sky coordinates from <i>Gaia</i> DR2 in mas/yr
PROPER_MOTION_ERROR	32-bit float (x2)	Proper motion error in sky coordinates from <i>Gaia</i> DR2 in mas/yr
MAGNITUDES	32-bit float (x16)	Magnitudes from <i>Gaia</i> DR2, Pan-STARRS, 2MASS, UKIDSS, and unWISE
MAGNITUDES_ERROR	32-bit float (x16)	Magnitude errors from <i>Gaia</i> DR2, Pan-STARRS, 2MASS, UKIDSS, and unWISE
<b>Fit Information</b>		
LOG_EVID	32-bit float	Log-evidence (base $e$ ) from models used in the fit
BEST_CHI2	32-bit float	Best-fit $\chi^2$ value (photometry and parallax) from models used in the fit
NBANDS_IN_FIT	8-bit uint	Number of bands (photometry and parallax) included in the fit
FLAG_FIT	1-bit bool	Whether there was an issue with the fit (TRUE = yes)
FLAG_GRID	1-bit bool	Whether the posterior hits the edge of the grid (TRUE = yes)
<b>Stellar Properties</b>		
PROB_GIANT	16-bit float	Probability that $\log g < 3.5$ from models used in the fit
INIT_MASS	16-bit float (x4)	2.5th, 50th, and 97.5th percentiles and a random sample of $M_{\text{init}}$ in $M_{\odot}$
INIT_FEH	16-bit float (x4)	2.5th, 50th, and 97.5th percentiles and a random sample of $[\text{Fe}/\text{H}]_{\text{init}}$
EEP	16-bit int (x4)	2.5th, 50th, and 97.5th percentiles and a random sample of EEP
LOG10_AGE	16-bit float (x4)	2.5th, 50th, and 97.5th percentiles and a random sample of $\log t_{\text{age}}$ in yr
LOG10_TEMP_EFF	16-bit float (x4)	2.5th, 50th, and 97.5th percentiles and a random sample of $\log T_{\text{eff}}$ in K
LOG10_LBOL	16-bit float (x4)	2.5th, 50th, and 97.5th percentiles and a random sample of $\log L_{\text{bol}}$ in $L_{\odot}$
LOG10_SURF_GRAV	16-bit float (x4)	2.5th, 50th, and 97.5th percentiles and a random sample of $\log g$ in cgs
DISTANCE	32-bit float (x4)	2.5th, 50th, and 97.5th percentiles and a random sample of $d$ in kpc
A_V	16-bit float (x4)	2.5th, 50th, and 97.5th percentiles and a random sample of $A_V$ in mag
R_V	16-bit float (x4)	2.5th, 50th, and 97.5th percentiles and a random sample of $R_V$

**Table 4.** Summary of the *Augustus* “samples” catalog that includes random posterior samples from the BRUTUS fits. See Appendix A for additional details. The table is available for download at [doi:10.7910/DVN/530UYQ](https://doi.org/10.7910/DVN/530UYQ).

Name	Data Format	Description
SAMPLES_MODEL_IDX	32-bit int (x25)	25 posterior samples of the model index in the input grid
SAMPLES_DISTANCE	32-bit float (x25)	25 posterior samples of $d$ in kpc
SAMPLES_A_V	16-bit float (x25)	25 posterior samples of $A_V$ in mag
SAMPLES_R_V	16-bit float (x25)	25 posterior samples of $R_V$ in mag
