ABSTRACT

Context. Active Galactic Nuclei (AGN) are some of the most luminous and extreme environments in the Universe. The central engines of AGN, believed to be super-massive black-holes, are fed by accretion discs threaded by magnetic fields within a dense magneto-ionic

Aims. We report our findings from polarimetric Very-long-baseline Interferometry (VLBI) observations of quasar NRAO 150 taken in October 2022 using a combined network of the Very Long Baseline Array (VLBA) and Effelsberg 100-m Radio Telescope. These observations are the first co-temporal multi-frequency polarimetric VLBI observations of NRAO 150 at frequencies above 15 GHz.

Methods. We use the new VLBI polarization calibration procedure, GPCAL, with polarization observations of frequencies of 12 GHz, 15 GHz, 24 GHz, and 43 GHz of NRAO 150. From these observations, we measure Faraday rotation. Using our measurement of Faraday rotation, we also derive the intrinsic electric vector position angle (EVPA₀) for the source. As a complementary measurement we determine the behavior of polarization as a function of observed frequency.

Results. The polarization from NRAO 150 only comes from the core region, with a peak polarization intensity occurring at 24 GHz. Across the core region of NRAO 150 we see clear gradients in Faraday rotation and $EVPA_0$ values that are aligned with the direction of the jet curving around the core region. We find that for the majority of the polarized region the polarization fraction is greater at higher frequencies, with intrinsic polarization fractions in the core $\approx 3\%$.

Conclusions. The Faraday rotation gradients and circular patterns in EVPA₀ are strong evidence for a helical/toroidal magnetic field, and the presence of low intrinsic polarization fractions indicate that the polarized emission and hence the helical/toroidal magnetic

Introduction** NRAO 150 is a highly variable radio loud quasar with a redshift of z = 1.52 (Acosta-Pulido et al. 2007) and $\theta \approx 0.28^{\circ}$ (Homan et al. 2021). The source has an apparent jet opening angle of $\beta = 8.65$ (Homan et al. 2017), maximum recorded jet speed of $\beta = 8.65$ (Homan et al. 2017), based on the maximum measured jet speed over 42 epochs at 15 GHz, and a variability Doppler factor $\delta_{var} = 13.1$ (Hovatta et al. 2009). Agudo et al. (2007) fourd that the inner it of NRAO 150. Agudo et al. (2007) factor $\delta_{var} = 13.1$ (Hovatta et al. 2009). Agudo et al. (2007) fourd that the inner it of NRAO 150 Nagrae and et al. 2007). jet speed over 42 epochs at 15 GHz, and a variability Doppler jet speed over 42 epocns at 15 G12, and a value $\delta_{var} = 13.1$ (Hovatta et al. 2009). Agudo et al. (2007) found that the inner jet of NRAO 150 swings $\approx 6^{\circ} - 11^{\circ}$ on a timescale of one year using five epochs at 43 and 86 GHz.

The polarization properties of NRAO 150 were studied by Molina et al. (2014) using observations at 8, 15, 22, 43, and 86 GHz observed using the Very Long Baseline Array (VLBA) and Global Millimeter VLBI Array (GMVA) from 2006 to 2009, and a follow-up study was conducted using additional 2008 -2009 observations at 22, 43, and 86 GHz with the VLBA and GMVA (Molina et al. 2016). These studies found that the electric vector polarization angle (EVPA) of the source showed a circular pattern which they concluded was evidence of a magnetic field with helical/toroidal geometry.

Paraschos et al. (2024) used European VLBI Network (EVN) polarimetric data of NRAO 150 at 22 GHz to calibrate their 3C 84 data. These NRAO 150 data will be present in Debbrecht et al. in prep. The EVPA they found shows a circular pattern in the core (similar to that found by Molina et al. 2016) and EVPA values aligned with the direction of the bulk jet flow further downstream. Within the core they measured polarization intensities peaking at ~ 23 mJy/beam.

When polarized emission passes through a magneto-ionic medium, the EVPA is expected to rotate via birefringence. This effect is called "Faraday rotation" and is proportional to the square of the observed wavelength. Typically, we assume that this medium or "screen" is external to the polarized emission region. We quantify the amount of Faraday rotation as the observed rotation measure, RM_{obs} , which we characterize as EVPA = EVPA₀ + RM_{obs} λ^2 . Here, EVPA₀ is the Faraday corrected or "intrinsic" EVPA at the source.

^{*} jack.david.livingston+academic@gmail.com

RM relates to the electron number density, n_e , in units of cm⁻³, and the line-of-sight (LOS) magnetic field, B_{\parallel} as,

$$\mathbf{RM} \equiv C \int_{r=0}^{r=d} n_e \, B_{\parallel} d\, \boldsymbol{r} \, (\mathrm{rad} \, \mathrm{m}^{-2}). \tag{1}$$

Here, *d* is the distance to the Faraday rotating medium in pc, *dr* is the incremental displacement along the LOS measured in pc from the observer to the source, and *C* is a conversion constant, C = 0.812 rad m⁻² pc⁻¹ cm³ μ G⁻¹ (Ferrière et al. 2021). We adopt the vector orientation and sign convention for Faraday rotation as outlined by Ferrière et al. (2021).

The Faraday rotation of NRAO 150 was previously measured by Zavala & Taylor (2004), observed in 2001, and in a follow-up analysis of the data by Gabuzda et al. (2015). Zavala & Taylor (2004) found the majority of Faraday rotation to occur near the optically thick core region and found hints of Faraday rotation that appeared to break the λ^2 relation. Gabuzda et al. (2015) re-examined the data from Zavala & Taylor (2004) and found a prominent gradient in Faraday rotation across the core region with a significance of 4.2 σ ; they concluded such a significant gradient was evidence for a helical/toroidal magnetic field. NRAO 150 is a highly variable source; yet, since the 2001 observation from Zavala & Taylor (2004), there has been no new work on the Faraday rotation of NRAO 150. Our work presents the first new Faraday rotation analysis for NRAO 150 in two decades, and also offers a higher frequency range than previously covered, allowing us to better understand the magnetic fields of the source closer to the central engine.

For this work we assume $H_0 = 71 \text{ km s}^{-1} \text{ Mpc}^{-1}$, $\Omega_m = 0.27$, and $\Omega_{\Lambda} = 0.73$ (Komatsu et al. 2009). This corresponds to a luminosity distance for NRAO 150 of 11 193.4 Mpc, with a projected angular scale of 8.55 pc mas⁻¹. Due to the variation in the viewing angles for this source $(0.28^{\circ} \text{ or } 8^{\circ})^{1}$ we keep all physical distances as projected distances.

2. Observations and methods

NRAO 150 was observed on October 1, 2022, using the VLBA and the Effelsberg 100m Radio Telescope (EF) as a joint VLBI network, at central frequencies of 12.168, 15.368, 23.568, and 43.169 GHz, each split into eight intermediate frequencies or IF windows. This observation also included the sources 3C 111, 3C 120, and NGC 1052, as well as a complementary observation of 2023+335, 3C 371, 3C 418, BL Lac and Cygnus-A on October 2, 2022. Eight out of ten VLBA antennas were available for this observation (BR, FD, LA, NL, OV, SC, MK, and HN).

2.1. A-priori and self-calibration

As NRAO 150 is a very bright and compact AGN with typical VLBI peak flux densities exceeding 5 Jy beam⁻¹, it was used as a calibrator source in a-priori calibration using the standard procedures described in the AIPS cookbook² to test for this flux density loss.

After a-priori calibration, we found a lower overall flux density for all sources within our observations compared to MO-JAVE at 15 GHz (Lister et al. 2018) and Boston BEAM-ME 43 GHz (Jorstad & Marscher 2016) measurements of shared sources. We also performed a-priori calibration following using the rPicard/CASA v7.8.1³ pipeline (Janssen et al. 2019). We found that the AIPS a-priori calibrated data shows an overall higher amplitude by 9% than the data processed with rPicard/CASA. A flux density difference of $\sim 10\%$ has been seen in preliminary analysis conducted by the MOJAVE team comparing rPicard/CASA and AIPS and is currently being investigated. It is worth noting that according to the NRAO flux density calibration with the VLBA is only good to ~ $10\%^4$, as such the difference of 9% we see is within that margin. Technical issues as well as weather present challenges for accurate VLBI amplitude calibration. Overall amplitude depends on how bandpass solutions are re-normalized affecting the final values (VLBA Scientific Memo 40^5). For this reason, MOJAVE uses OVRO (Richards et al. 2011) and BEAM-ME uses Metsahovi single dish data⁶ to calibrate the flux density scale.

Even accounting for this flux density uncertainty we find additional losses in both the AIPS and rPicard/CASA calibrated data as compared to MOJAVE and BEAM-ME data. This flux density loss comes from erroneous correlation of the VLBA+EF network which is independent of the flux density difference seen between AIPS and rPicard/CASA pipelines. This error occurred due to a mismatch between the EF and VLBA frequency setups which was not accounted for in correlation. This has been confirmed with the operator of EF. This effect remains if we completely flag EF, as such we require a correction to our absolute amplitude based on external data.

We have elected to correct our AIPS calibrated data, due to better overall dynamic range. We also discovered an issue with rPicard/CASA polarization calibration which produces a 45° EVPA offset in our observation due to flipping Stokes Q and U. To correct for overall reduction due to erroneous correlation of the VLBA+EF network, we used TPOL0003 VLA observations of NRAO 150 using the Very Large Array (VLA) conducted on October 10, 2022, across similar frequency bands as our data. We calibrated these observations using the standard VLA CASA calibration pipeline. We then generated images of the calibrated data of NRAO 150, and compared the derived flux density of the VLA images with the flux density of our VLBA+EF images, finding the multiplicative gain factor to correct for. These gain corrections are shown in Table 1.

We performed amplitude and phase self-calibration on NRAO 150 for all frequencies down to 30 s solution intervals. The gains of EF were considerably lower than expected for the 15 and 24 GHz bands, which was seen for all sources within our observation. As such we used the VLBA antennas to anchor the gains of EF before proceeding with amplitude self-calibration to preserve the absolute amplitude of the source.

2.2. Polarization calibration

Between a-priori and absolute EVPA calibration, we used GPCAL⁷ (Park et al. 2021) to solve for polarization leakage or "D-terms". For leakage calibration we selected NRAO 150, 3C 111, and 3C 120 as calibrators, using an iterative self-calibration approach for ten repeated iterations.

⁶ https://www.metsahovi.fi/opendata/

¹ For $\theta \approx 0.28^{\circ}$ the de-projected scale is 1749 pc mas⁻¹, whereas $\theta \approx$

 $^{8^{\}circ}$ results in a scale of 61 pc mas⁻¹.

⁷ https://github.com/jhparkastro/gpcal

Absolute EVPA calibration was done by "anchoring" to an external observation. We used the TPOL0003 VLA observations of NRAO 150. Polarization calibration was done following the methods outlined in the VLA CASA polarization calibration tutorial⁸. We created a point source model of EVPA for the source from 12 to 43 GHz and calculated the EVPA offset between the VLA and the integrated EVPA from our D-term corrected VLBA+EF data of NRAO 150 data for each IF window of each band.

2.3. Imaging and error estimation

The images of Stokes I, Q, and U were generated using the entropy stopping criteria imaging script as outlined by Homan et al. (2024). The script is based on the VLBI imaging software Difmap (Shepherd 1997), and images the data using a variety of visibility weightings - specifically, 10 (ultra-uniform), 2 (uniform), and 0 (natural), to catch any residual structure left in the data. To generate the images shown in this work, we used a common resolving element ("restoring beam") across all frequencies with a major axis of 0.53 mas, a minor axis of 0.35 mas, and a position angle of -22.4° . In Fig. 1 we present the generated linear polarization images and Stokes I contours for each observed frequency.

We estimated the Stokes I uncertainty σ_I by finding the rootmean-squared (RMS) noise of a 300 × 300 pixel region sufficiently far away from Stokes I emission of the source. We further estimated the error introduced from residual D-terms (σ_{dterm}) to the polarized visibilities after calibration using the same approach as shown in Eq. B4 in Hovatta et al. (2012), finding the median scatter of D-terms for each frequency band, and accounting for six scans of NRAO 150, eight spectral windows, and between seven⁹ to eight antennas. The scatter of D-terms are shown in Table 1.

The uncertainty of the polarized signal was determined by finding the RMS of a 300 × 300 square pixel area away from the source of the Stokes Q and U images ($\sigma_{\rm rms}$) and combining this uncertainty estimate with that from $\sigma_{\rm dterm}$ following equation B5 of Hovatta et al. (2012). The uncertainty of the polarization data (σ_p) is the combination of the uncertainties from Stokes Q and U such that $\sigma_P = \sqrt{\sigma_Q^2 + \sigma_U^2}$.

To estimate the uncertainty of our EVPA measurements, we take the uncertainty assumed from σ_P , which is $\sigma_{\text{EVPA}} = \sigma_P/(2P)$ and add an additional error based on the scatter of the VLA data around the model of EVPA used for absolute EVPA calibration. This scatter of EVPA values are shown in Table 1.

For image alignment between observed frequencies we implemented a 2D cross-correlation approach on optically thin Stokes I emission similar to that outlined by Molina et al. (2014). We use the Python package phase_cross_correlation from skimage.registration¹⁰, but we found that the overall displacement is consistent with zero across all frequencies. Hovatta et al. (2012) showed that the measurement of RM is robust against a small misalignment between frequencies up to 0.15 mas for the VLBA at 15 GHz, as such we expect image alignment errors to not affect our work.

2.4. Faraday rotation

Following Sarala & Jain (2001) we use a circular statistics approach to fitting RM_{obs} with a fit minimization parameter, χ^2_{circ} defined as,

$$\chi_{\rm circ}^2 = \sum_{i}^{n_v} \frac{1 - \cos\left(2\left[{\rm EVPA} - {\rm RM}_{\rm obs}\lambda^2 - {\rm EVPA}_0\right]\right)}{1 - \cos\left(2\sigma_{\rm EVPA}\right)}.$$
 (2)

Here, n_v is the number of frequencies we have polarization information for. By minimizing Eq. (2) we are able to solve for EVPA₀ (Sarala & Jain 2001),

$$EVPA_0 = \frac{1}{2} \arctan\left(\frac{\sum_i^n (\sin(E)/[1 - \cos(2\sigma_{EVPA})])}{\sum_i^n (\cos(E)/[1 - \cos(2\sigma_{EVPA})])}\right),\tag{3}$$

where $E = 2(\text{EVPA} - \text{RM}_{obs}\lambda^2)$. In this formulation we only require RM_{obs} to model EVPA, without needing to fit the EVPA₀ directly, reducing the number of fitted parameters.

We model RM_{obs} for all pixels with a polarized signal greater than $3\sigma_P$ and $5\sigma_I$ for at least two frequencies. For pixels with polarization information for more than two frequencies we reject any fits for which the χ^2_{circ} of the fit exceeds the 95% confidence limit. For these pixels, they may have non- λ^2 dependent Faraday rotation, which occurs when there are complex Faraday rotation effects present (Hovatta et al. 2012).

When we measure RM_{obs} in the direction of an extra-galactic source we are measuring the combination of different contributions of Faraday rotation such that,

$$\mathbf{RM}_{\rm obs} = \mathbf{RM}_{\rm int} \left(1 + z\right)^{-2} + \mathbf{RM}_{\rm IGM} + \mathbf{RM}_{\rm MW}.$$
 (4)

Here, RM_{int} is the intrinsic Faraday rotation of the source which needs to be corrected for the redshift, *z*; RM_{IGM} and RM_{MW} are the Intergalactic Medium (IGM) and the Milky Way (MW) contributions to RM_{obs}. The magnitude of RM_{IGM} is typically between 1 and 10 rad m⁻² (O'Sullivan et al. 2017) and as such we ignore the contribution of RM_{IGM}. We estimate RM_{MW} using the RM catalog of Van Eck et al. (2023) taking the median RM of a 2° area around the phase center of NRAO 150 which is RM_{MW} = 52 rad m⁻² with a standard deviation of 65 rad m⁻².

2.5. Depolarization

Measuring depolarization as a function of frequency can help to determine where the RM_{int} originates within the source. We model depolarization following the method outlined by Hovatta et al. (2012),

$$\log m = \log m_0 + b\lambda^4.$$
⁽⁵⁾

Here m is the measured polarization degree (as a percentage), m_0 is the intrinsic degree of polarization at $\lambda = 0$, and b is the depolarization in units of m⁻⁴.

There are two main causes of depolarization we consider: external and internal Faraday dispersion. If there is magneto-ionic turbulence within an external medium, this causes an EVPA decoherence across the size of the beam, which results in a reduction in the overall linear polarization fraction. This depolarization increases with the observed wavelength as the size of the resolving beam increases and the variation in RM_{int} is more prominent for greater λ^2 .

For internal Faraday dispersion, we assume that the polarized emission is co-spatial with the Faraday rotating medium.

⁸ https://casaguides.nrao.edu/index.php/CASA_Guides

⁹ The FD antenna was not present for the 43 GHz observation.

¹⁰ https://scikit-image.org/docs/stable/api/skimage.registration.html

Fig. 1. Panels (1) to (4) show the Stokes I contours and linear polarization intensity (shown in gray-scale) of NRAO 150 for 12 (1), 15 (2), 24 (3), and 43 GHz (4). The purple ellipse in panel (4) shows the restoring beam used for all four frequencies. The contours start at $5\sigma_1$ up to the peak increasing by a factor of 2. The blue ticks in panels (1) to (4) show the average EVPA across a 5 × 5 pixel region for each frequency.

Emission from the source undergoes differential Faraday rotation depending on where in the medium the emission is generated, which can cause a de-coherence of EVPA and subsequent depolarization.

Depending on the morphology of the emission region it is also possible to re-align EVPA values, causing "inverse" depolarization (Homan 2012). If we see positive values of b, this indicates the presence of inverse depolarization, which is suggestive of internal Faraday dispersion. The internal Faraday dispersion effect is dependent on the magnitude of RM such that $b \sim 2RM^2$. If $|b|/(2RM^2) \leq 1$, especially when the magnitude of RM is large, we expect the depolarization observed to be attributed to co-spatial polarized emission and Faraday rotation (Hovatta et al. 2012). If we see large negative values of b that are larger in magnitude than $2 \times RM^2$, this suggests that the depolarization comes from external Faraday dispersion, resulting from random fluctuations in RM causing EVPA de-coherence.

3. Results and discussion

In this section we will discuss the linear polarization, Faraday rotation, EVPA₀, and depolarization properties of NRAO 150, in order to understand the geometry of its magnetic field.

Fig. 2. Panels (1) to (4) show the fractional linear polarization for each frequency. The contours are the lowest Stokes I contour levels for all frequencies from Fig. 1.

3.1. Linear polarization

In panels (1) to (4) of Fig. 1 we show the linear polarization intensity maps for the four frequency bands in conjunction with Stokes I contours. From these maps we can see that the linear polarization is present near the VLBI 'core' position of the source, with a some log magnitude polarized emission extending outwards towards the jet for the 12 and 15 GHz maps. The peak polarization is greatest at 24 GHz, decreasing from 225 mJy beam⁻¹ to 181 mJy beam⁻¹ at 43 GHz, shown in Table 1. Molina et al. (2014) found for a number of epochs of 22 and 43 GHz similar linear polarization intensity as shown in panels (3) and (4). Paraschos et al. (2024), shows considerably lower peak polarization intensity at ~ 22 GHz than our findings (~ 23 mJy beam⁻¹ compared to 225 mJy beam⁻¹). This discrepancy may come from the fact that the source is intrinsically variable (also supported by the finding that the peak Stokes I reported in Paraschos et al. (2024) is 2.5 Jy beam⁻¹).

In panels (1) to (4) of Fig. 2 we show the fractional linear polarization for each frequency. We can see that the fractional linear polarization is greater throughout the 12 GHz map, with sections of the jet exceeding 20%, while the fraction near the core is around ~ 5%. For panels (2) to (4) we can see that the fractional polarization does not exceed ~ 10% in the core. We expect polarization of optically thick regions to not exceed 10 – 15% and within these regions EVPA runs parallel to the pro-

Notes: Columns are; (column 1) the band name used in the text, (column 2) the observed central frequency, (column 3) range of observed frequencies, (column 4) the major axis of the nominal beam at each frequency, (column 5) the minor axis of the nominal beam, (column 6) the position angle of the nominal beam, (column 7) the gain corrections discussed in Sect. 2.1, (column 8) scatter of D-terms, (column 9) absolute EVPA correction from VLA observations at v_c , (column 10) scatter of the model of EVPA, (column 11) the peak Stokes I, (column 12) the noise in Stokes I based on the RMS of the map, (column 13) the peak linear polarization, (column 14) the noise in linear polarization calculated using the method outlined in Sect. 2.2.

Fig. 3. Map of RM_{int} and EVPA₀. The tick markers show the average EVPA₀ across a 3×3 pixel region. The contours are the lowest Stokes I contour levels for all frequencies from Fig. 1. The observed EVPA against λ^2 for the three pixels marked by numbers 1,2 and 3 are plotted in Fig. 4. The purple ellipse in panel shows the restoring beam used for all four frequencies.

jection of the magnetic field on the plane-of-sky, \mathbf{B}_{\perp} (Pacholczyk 1970). Molina et al. (2014) found fractional polarization of $\approx 5\%$, 10%, 15% for 15, 22, and 43 GHz observations respectively, and Molina et al. (2016) found a fractional polarization of $\approx 14\%$ around the northern edge of the central region of the source for both frequencies.

3.2. Rotation measure

In Fig. 3 we show the RM_{int} map (corrected for the *z* of NRAO 150) with ticks showing EVPA₀. Most of the RM_{int} of NRAO 150 is negative with the positive peak of RM_{int} = $(3.0 \pm 0.7) \times 10^4$ rad m⁻² and a negative peak of RM_{int} = $(-2.0 \pm 0.7) \times 10^4$ rad m⁻². Towards the jet there is a

gradient in RM_{int}. In Fig. 4 we show the observed EVPA against λ^2 for the three pixels marked by numbers 1, 2, and 3 in Fig. 3. For the pixels the observed EVPA values fit well to the model for RM_{obs}.

The EVPA₀ shown in Fig. 3 run towards the direction of the jet, gradually bending around the core. We also note that the EVPA₀ values run perpendicular to the gradient in RM_{int} in the north of the core. In the optically thick regions of a source, we expect EVPA₀ to be aligned with \mathbf{B}_{\perp} ; the alignment of EVPA₀ is suggestive of a \mathbf{B}_{\perp} pointing in the direction of the jet curving around the core region. Both Molina et al. (2014) and Molina et al. (2016) found a similar circular geometry of EVPA for NRAO 150, however this was not Faraday rotation corrected.

3.3. Depolarization and maximum polarization

In Fig. 5 we show the map of redshift-corrected b_{int} . Here b_{int} is the depolarization constant b (discussed in Sect. 2.5) scaled by $(1 + z)^2$ to account for the redshift of NRAO 150. Most of the core region has large negative values of b_{int} , which reflects depolarization that increases as a function of increasing observed λ .

In Fig. 6 we show the intrinsic polarization degree, m_0 . Across the entire region, m_0 is around 3%, with an increase to 6% on the northern side of the core region. In the small emission we see further down the jet the m_0 increases to $\geq 10\%$. This preferential increase in polarization degree is similar to that seen in the fractional linear polarization maps (Fig. 2), and the findings of Molina et al. (2014) and Molina et al. (2016). Values of m_0 around a few percent hint that the emission we are probing is likely optically thick for which we expect lower fractional polarization (Pacholczyk 1970).

In the map of ratios of $b_{int}/(2 RM_{int}^2)$ shown in Fig. 7, 31% of pixels have ratios greater than -1, indicating that the majority of pixels show $b_{int}/(2 RM_{int}^2) < -1$. The pixels with negative ratio values are spatially close to the point at which the gradient seen in Fig. 3 passes through zero. We can see that the ratio of $b_{int}/(2 RM_{int}^2)$ decreases in magnitude away from this transition going towards $b_{int}/(2 RM_{int}^2) > -1$. Ratios ≥ -1 indicate that the depolarization we see is explainable by the magnitude of RM causing internal Faraday rotation, without needing to invoke magneto-ionic turbulence as is required in the external Faraday dispersion case.

Fig. 4. Observed EVPA against λ^2 for the three pixels marked by numbers 1, 2, and 3 in Fig. 3. Above each plot is the RM_{int} (corrected for red-shift and foreground contribution as discussed in Sect. 2.4) and EVPA₀ for that pixel.

3.4. Faraday rotation gradients

In Fig. 8 we show the longest North-South (N-S), panel (1) shown in panel (2). Taylor & Zavala (2010) first proposed a list of criteria for Faraday rotation gradients to be considered significant, which was followed up by Hovatta et al. (2012) who extensively tested the validity of RM_{int} gradients, finding that if a gradient has a δ RM with $\geq 3\sigma$ confidence and is $\geq 1.4 \times$ the beam full-width half-maximum (FWHM) in the direction of the gradient it is significant. The gradient shown in Fig. 8 has a confidence in δ RM_{int} of 5.7 σ and and is 2× the beam FWHM in the direction of the slice at 0.9 mas in length corresponding to a projected size of ~ 7.7 pc.

Broderick & McKinney (2010) conducted parsec-scale general relativistic magnetohydrodynamic simulations of AGN jets testing the expected morphology of Faraday rotation. One of their primary findings was that the presence of a significant Faraday rotation gradient indicates the presence of a helically/toroidal magnetic field located within the jet or core of the AGN. This is because foreground clouds, while contributing

the the overall Faraday rotation of some AGN, should not show Faraday rotation gradients that are correlated with jet structures (Broderick & McKinney 2010).

In their study of Faraday rotation gradients, Gabuzda et al. (2015) found a gradient across the core region of NRAO 150 (observed in 2001 between 8.1 - 15.2 GHz) with a significance of 4.2σ ($\Delta RM_{int} = 3944 \pm 934 \text{ rad m}^{-2}$) with a length of 1.5 mas. Following the findings of Broderick & McKinney (2010), Gabuzda et al. (2015) concluded that the presence of a

Fig. 8. Slice of RM_{int} of NRAO 150 of the longest North-South (N-S) slice (1). Panel (2) is an illustration of slice locations on RM map from Fig. 3. The black dashed line shows the beam full-width half maximum (FWHM) in the direction of the slice.

Article number, page 8 of 9

significant gradient in the core of NRAO 150 is indicative of the presence of a helical/toroidal magnetic field within the innermost jet of the AGN, even if the region is not optically thin, given the significance and continuity of the RM gradients seen for NRAO 150. We see similar significant and continuous gradients across the core region of NRAO 150. We conclude that the Faraday rotation gradients we see, especially our longest Faraday rotation gradient with $\Delta RM_{int} = (15954 \pm 2661)$ rad m⁻² across a angular distance of 0.9 mas (~ 7.7 pc), indicate a helical/toroidal magnetic field is present within the innermost jet of NRAO 150.

3.5. The magnetic field strength in NRAO 150

In Fig. 8 we see that RM_{int} varies across the source, with a gradient in RM_{int} of Δ RM_{int} = (17274 ± 3039) rad m⁻² with a maximum magnitude value of |RM_{int}| = (9453 ± 2737) rad m⁻². This occurs over an apparent size scale of ~ 7.7 pc. Assuming an apparent opening angle of 19.4° (Pushkarev et al. 2017) this results in an apparent distance from the jet base of ~ 23 pc across the gradient. If we further assume that at 1 pc from the core the free electron number density is between 10² and 10⁴ cm⁻³ (Lobanov 1998), the magnetic field strength and electron number density both go as ~ r^{-1} (Lobanov 1998; Pushkarev et al. 2012; Nokhrina & Pushkarev 2024), and we are integrating along a path-length of 22 pc, the relationship between RM_{int} and B_{\parallel} from Eq. (1) becomes,

$$B_{\parallel,r=1} \sim 13 \left(\frac{\text{RM}_{\text{int}}}{1000 \,\text{rad}\,\text{m}^{-2}} \right) \left(\frac{n_{r=1}}{100 \,\text{cm}^{-3}} \right)^{-1} \mu\text{G},$$
 (6)

where $n_{r=1}$ is the electron density at 1 pc from the core. Setting RM_{int} = (9453 ± 2737) rad m⁻² we get a lower limit of $B_{\parallel,0} \sim 1.2 \,\mu\text{G}$ (assuming $n_0 = 10^4 \text{ cm}^{-3}$) and an upper limit of $B_{\parallel,0} \sim 122 \mu\text{G}$ ($n_0 = 10^2 \text{ cm}^{-3}$). This is similar to the LOS magnetic field strength estimated by Hovatta et al. (2019) for 3C 273 of 62 μ G assuming an electron number density of 1000 cm⁻³ coming from the narrow line region (Zavala & Taylor 2004).

Nokhrina & Pushkarev (2024) using a relationship between core-shift (Lobanov 1998) and the energy equipartition assumption found that the typical total magnetic field strength at 1 pc from the core of AGN is ~ 84 mG. If we instead assume that the LOS magnetic field strength and the plane-of-sky magnetic field strength are the same, i.e. $B_{\parallel,r=1} \sim 59$ mG, this results in an electron number density of $n_{r=1} \sim 2 \times 10^{-1}$ cm⁻³. To differentiate between the scenarios of a weak magnetic field (1.2 – 122 μ G) and a small electron number density we plan to conduct simulations in a future publication similar to those done by MacDonald & Nishikawa (2021).

4. Summary and conclusions

In this work we presented multi-frequency polarimetric observations of quasar NRAO 150 taken using the VLBA+EF telescopes at 12, 15, 24, and 43 GHz. This work builds on previous studies of the source, with the unique quality of having high-frequency (between 12 - 43 GHz) polarimetric observations that are quasisimultaneous. From the linearly polarized emission, we calculated the Faraday rotation, intrinsic electric vector position angle (EVPA₀), and depolarization properties of the source.

We find a circular pattern of EVPA₀ and the presence of Faraday rotation gradients across the core region of NRAO 150, both of which are consistent with a helical/toroidal magnetic field. The predicted maximum polarization fraction, m_0 , for this region is $\approx 3\%$, consistent with emission from optically thick regions in AGN. Together with the magnitude of Faraday rotation in this region, we conclude that the observed polarized emission is produced within the jet, opposed to an external medium.

The results of this study, in conjunction with previous findings from Molina et al. (2014), Gabuzda et al. (2015), and Molina et al. (2016), show there is a helical/toroidal magnetic field within the innermost jet region of NRAO 150.

Appendix: Alternative polarization calibration using CASA/PolSolve

As part of this work, the rPicard/CASA calibrated data (discussed in Sect. 2.1) was also polarization leakage calibrated using PolSolve v2¹¹ (Martí-Vidal et al. 2021) and absolute EVPA corrected using CASA function polcal. After D-term and absolute EVPA correction the 15 GHz, 24 GHz, and 43 GHz linear polarization and EVPA maps were similar to those seen in Fig. 1, however we saw significant differences for the 12 GHz band. In Fig. 9 we show the 12 GHz linear polarization and EVPA distribution using these alternative methods. Compared to what we see for the 12 GHz band in Fig. 1, we can see a flip in EVPA values of $\sim 90^{\circ}$ in the core region and a significant difference in overall linear polarization morphology. We also see a much larger polarized intensity with a peak of 520 mJy beam⁻¹.

The D-terms derived by PolSolve took 16 iterations to converge for the 12 GHz band, whereas it took 2, 5, and 4 iterations for the 15 GHz, 24 GHz, and 43 GHz bands, indicating that the polarization leakage was not well characterized for the 12 GHz band. The significant differences in linear polarization of the 12 GHz band using these CASA based methods may be due to a bug we found in the rPicard/CASA pipeline, which flips Stokes Q and U, resulting in a rotation of the EVPA distribution by 45°, an issue with D-term characterization using PolSolve, or the application of CASA function polcal in absolute EVPA calibration for VLBI data. Due to this reason we elected to use GPCAL and AIPS function CLCOR to correct for polarization leakage and perform absolute EVPA correction.

Fig. 9. Stokes I contours and linear polarization intensity (shown in gray-scale) of NRAO 150 for the 12 GHz band derived using a-priori calibration from rPicard/CASA, polarization leakage calibration from PolSolve, and absolute EVPA correction using CASA.
