(Dated: March 11, 2025)

We calculate the shift current response in twisted double bilayer graphenes (TDBG) by applying the perturbative approach to the effective continuum Hamiltonian. We have performed a systematic study of the shift current in AB-AB and AB-BA stacked TDBG, where we have investigated the dependence of the signal on the twist angle, the vertical bias voltage and the Fermi level. The numerical analyses demonstrate that a large signal is generated from the formation of the moiré minibands. Notably, we also found that there is a systematic sign reversal of the signal in the two stacking configurations below the charge neutrality point for large bias voltages. We qualitatively explain the origin of this sign reversal by studying the shift current response in AB-stacked bilayer graphene.

I. INTRODUCTION

The study of moiré systems has been one of the major focusses of modern condensed matter physics. By stacking two sheets with a relative twist angle, the total system shows a moiré pattern originating from the lattice mismatch between the two layers. This moiré pattern leads to a modification of the band structure of the system, where the most notable example is the flat band formation and the experimental observation of superconductivity in twisted bilayer graphene (TBG) at an angle known as the magic angle $\theta \sim 1.1^{\circ}$ [1–3]. Studies has expanded to other graphene-based moiré systems, such as twisted monolayer-bilayer [4–13], twisted trilayer [14–20], and other twisted multilayer graphene [21–24].

Twisted double bilayer graphene (TDBG) is a moiré system where two sheets of AB-stacked bilayer graphene (BLG) are stacked with a relative twist angle, as shown in Fig. 1. A variety of studies on TDBG has been performed, such as the observation of strongly correlated phenomena [25-40], owing to its highly tuneable band structure, where a band gap can be opened through the application of a vertical bias voltage. Importantly, TDBG can be fabricated in two distinct stacking structures, known as AB-AB and AB-BA, respectively shown in Fig. 1 (a) and (b). The AB-AB stacking is composed of two bilayer sheets stacked and twisted with the same orientation, while the AB-BA stacking introduces a 180° offset on the second layer. A schematic diagram of the respective variants are shown in Fig. 1 (a) and (b). It is known that the two variants have completely different valley Chern numbers while hosting very similar band structures [21, 25, 26].

Simultaneously, the shift current response has been under intense investigation due to its potential to probe the topology, quantum geometry and the symmetry of a variety of materials [41–47]. This is a second order nonlinear optical response where light is rectified into dc current in noncentrosymmetric materials [48–50]. It is characterised by a quantity known as the shift vector, which is expressed in terms of the difference between the Berry connection of the initial and final band of the optical excitation. The shift current response has been experimentally measured in various 2D materials [43, 51–58], where the two main types which have been actively studied are the family of transition metal dichalcogenides [59–69] and ferroelectric 2D materials, such as transition metal monochalcogenides [52, 55, 70] and CuInP₂S₆ [54, 71].

Nowadays, the scope of investigation of the shift current has expanded to moiré materials [31, 38, 72–76] where there is no need to rely on the polarisation of the monolayer to observe a finite shift current; for example, two non-polar materials with a lattice mismatch can be stacked in order to create an interface with broken inversion symmetry. The shift current response in TBG, being one of the simplest moiré system, has been studied theoretically [31, 73, 77, 78]. However, the C_{2z} symmetry renders the in-plane shift current to vanish [78], thus, an extra term is required in the TBG Hamiltonian to break such symmetry. This is achieved by introducing an asymmetric potential between the A and B sites which can be experimentally realised through the alignment with hBN. There have also been studies of the shift current in other graphitic systems [31, 38, 74] and heterostrucutres [53, 63, 72], such as WSe₂/black phosphorene heterostructure [53] and twisted TMD heterobilayers [72, 79].

In the present work, we theoretically study the shift current response in AB-AB and AB-BA stacked TDBG. This is motivated by the fact that TDBG is composed of AB-stacked BLG, which has broken C_{2z} symmetry, allowing for a finite in-plane shift current response without the need for any substrate or external field unlike TBG. Furthermore, the band structure of TDBG is highly tuneable through the application of a vertical bias voltage, giving an extra degree of freedom to investigate the behaviour of the shift current. The fact that the two variants of TDBG exhibit similar band structures with distinct topologies [21, 25, 26] offers a platform to study how this contrast influences the shift current response. One previous work has studied the shift current response in AB-AB and AB-BA stacked TDBG for fixed values of the twist angle, Fermi level and vertical bias voltage [31], however, the relationship between the two variants was unclear. Here, we systematically investigate the twist angle, Fermi level and vertical bias voltage dependence on the TDBG shift

current to study its relation to the stacking configuration. In particular, we have found a systematic sign reversal in the signals of the AB-AB and AB-BA variants when a large vertical bias voltage is applied. We further give a qualitative explanation on the origin of this sign reversal by studying the shift current in AB-stacked BLG.

The present paper is organised as follows. In Section II, we introduce the effective continuum Hamiltonian for TDBG and the theoretical expression of the shift current. Then, in Section III, we present our results of the shift current response in TDBG and provide a discussion on the interpretation on the results in Section IV. Finally, we will conclude the present paper in Section V.

II. MODEL AND METHODS

A. Twisted double bilayer graphene

The primitive lattice vectors of the graphene lattice are chosen to be $a_1 = a(1,0)$ and $a_2 = a(1/2,\sqrt{3}/2)$, where a = 0.246nm is the lattice constant. Then, the corresponding reciprocal lattice vectors are $b_1 = 4\pi/\sqrt{3}a(\sqrt{3}/2, -1/2)$ and $b_2 = 4\pi/\sqrt{3}a(0, 1)$. AB-stacked bilayer graphene (BLG), which can be prepared by stacking two graphene sheets with the A and B sites of the upper and lower layers aligned, shares the same primitive lattice vectors with monolayer graphene, thus, the Brillouin zones are also common. A schematic diagram is shown on the left side of Fig. 1 (a), where there are four atomic sites labelled A_1 , B_1 , A_2 and B_2 . Sites (B_1, A_2) , which are vertically aligned, are referred to as the dimerised sites and experience an energy offset of $\Delta' = 0.050$ eV.

Twisted double bilayer graphene (TDBG) is a system where two sheets of AB-stacked BLG are stacked and twisted with a relative twist angle, as shown in Fig. 1 (a), (b). To fabricate a sample of TDBG, we first stack the two BLG without twisting. There are two ways to perform this operation: one is to simply stack the two BLG sheets with the same orientation and the other is to perform a 180° rotation about the z-axis on one sheet and then stacking the two. Then, a relative twist angle between the two BLG sheets is introduced to form a sample of TDBG. Here, the first variant is known as AB-AB stacking, while the second is known as AB-BA stacking. Their respective structures are shown in Fig. 1 (a) and (b), and the difference in their moiré patterns can be seen. Hence, the extra 180° rotation leads to a different environment at the twist interface between the two stacking configurations, resulting in different band topologies [25]. It should also be noted that the AB-AB variant has the in-plane three-fold rotational symmetry C_{3z} inherited from monolayer graphene and a two-fold rotational symmetry along C_{2x} along the x-axis. Similarly, the AB-BA variant has C_{3z} and C_{2y} rotational symmetries.

In cases when the moiré lattice constant is much

FIG. 1: (a) We show a schematic diagram of AB-stacked BLG and the stacking configuration in AB-AB stacked TDBG on the top. The corresponding moré pattern is shown in the bottom. In (b), we shows the same diagrams, but for AB-BA stacked TDBG, where the blue layer gains a 180° offset.

greater than the graphene lattice constant, *i.e.* when the twist angle is small, we can construct an effective continuum Hamiltonian for TDBG around the K_{\pm} valleys. When the lower layer (l = 1) and the upper layer (l = 2) are rotated by an angle $\pm \theta/2$, the reciprocal lattice vectors in the respective layers are given as $\boldsymbol{b}_{i}^{(l)} = R\left[(-1)^{l}\theta/2\right]\boldsymbol{b}_{i}$, where $R(\theta)$ is the two dimensional rotation matrix. This allows us to define the moiré reciprocal lattice vectors $\boldsymbol{G}_{i}^{\mathrm{M}} = \boldsymbol{b}_{i}^{(1)} - \boldsymbol{b}_{i}^{(2)}$.

The Hamiltonians for AB-AB and AB-BA TDBG are written as

$$H_{AB-AB} = \begin{pmatrix} H(\mathbf{k}_{1}) & g^{\dagger}(\mathbf{k}_{1}) & & \\ g(\mathbf{k}_{1}) & H'(\mathbf{k}_{1}) & U^{\dagger}(\mathbf{r}) & \\ & U(\mathbf{r}) & H(\mathbf{k}_{2}) & g^{\dagger}(\mathbf{k}_{2}) \\ & & g(\mathbf{k}_{2}) & H'(\mathbf{k}_{2}) \end{pmatrix} + V,$$

$$H_{AB-BA} = \begin{pmatrix} H(\mathbf{k}_{1}) & g^{\dagger}(\mathbf{k}_{1}) & & \\ g(\mathbf{k}_{1}) & H'(\mathbf{k}_{1}) & U^{\dagger}(\mathbf{r}) & \\ & U(\mathbf{r}) & H'(\mathbf{k}_{2}) & g(\mathbf{k}_{2}) \\ & & g^{\dagger}(\mathbf{k}_{2}) & H(\mathbf{k}_{2}) \end{pmatrix} + V,$$
(1)

where we have defined

$$H(\mathbf{k}) = \begin{pmatrix} 0 & -\hbar v_0 k_- \\ -\hbar v_0 k_+ & \Delta' \end{pmatrix},$$

$$H'(\mathbf{k}) = \begin{pmatrix} \Delta' & -\hbar v_0 k_- \\ -\hbar v_0 k_+ & 0 \end{pmatrix},$$

$$g(\mathbf{k}) = \begin{pmatrix} \hbar v_4 k_+ & \gamma_1 \\ \hbar v_3 k_- & \hbar v_4 k_+ \end{pmatrix}.$$
(2)

The velocities are defined as $v_i = \sqrt{3}a|\gamma_i|/(2\hbar)$, γ_i being hopping integrals, and $k_{\pm} = \xi k_x \pm i k_y$, ξ being the valley index K_{ξ} . Namely, $\gamma_0 = -2.4657$ eV is the intralayer nearest neighbouring hopping, $\gamma_1 = 0.4$ eV is the hopping between the dimerised sites, $\gamma_3 = 0.32$ eV and $\gamma_4 = 0.044$ eV are the diagonal hopping between the (A_1, B_2) and (B_1, B_2) sites, respectively. Also, $k_l = R\left[(-1)^l \theta/2\right] (\mathbf{k} - \mathbf{K}_{\xi}^{(l)})$ and $\mathbf{K}_{\xi}^{(l)}$ are the \mathbf{K}_{ξ} valleys in the respective layers. By inspecting the Hamiltonianans, we can see that the top left block corresponds to the 4×4 Hamiltonian for AB-stacked BLG. We have the same Hamiltonian in the bottom right block for $H_{\text{AB-AB}}$, however, for $H_{\text{AB-BA}}$, we can see that the pairs $[H(\mathbf{k}_2), H'(\mathbf{k}_2)]$ and $[g(\mathbf{k}_2), g^{\dagger}(\mathbf{k}_2)]$ are interchanged, reflecting the difference in stacking configuration. The interlayer moiré potential $U(\mathbf{r})$ is given by

$$U(\mathbf{r}) = \begin{pmatrix} u & u' \\ u' & u \end{pmatrix} + \begin{pmatrix} u & u' \omega^{-\xi} \\ u' \omega^{\xi} & u \end{pmatrix} e^{i\xi \mathbf{G}_{1}^{\mathrm{M}} \cdot \mathbf{r}}$$
(3)
+
$$\begin{pmatrix} u & u' \omega^{\xi} \\ u' \omega^{-\xi} & u \end{pmatrix} e^{i\xi (\mathbf{G}_{1}^{\mathrm{M}} + \mathbf{G}_{2}^{\mathrm{M}}) \cdot \mathbf{r}},$$

where u = 0.0797 eV, u' = 0.0975 eV [25, 80] and $\omega = \exp(2\pi i/3)$ is the cube root of unity. The final term V is the diagonal matrix modelling the vertical bias voltage

$$V = \begin{pmatrix} \frac{3}{2}\Delta \mathbb{I} & & \\ & \frac{1}{2}\Delta \mathbb{I} & \\ & & -\frac{1}{2}\Delta \mathbb{I} \\ & & & -\frac{3}{2}\Delta \mathbb{I} \end{pmatrix}.$$
 (4)

We note that a finite Δ breaks the C_{2x}/C_{2y} rotational symmetries in the AB-AB/AB-BA stacked TDBG. In this system, the twist angle θ and the vertical bias voltage Δ are the parameters that can be modified experimentally.

The numerical evaluation of Hamiltonians in Eq. (1) involves expanding $U(\mathbf{r})$ in term of the Fourier components with respect to $\mathbf{G} = n_1 \mathbf{G}_1^{\mathrm{M}} + n_2 \mathbf{G}_2^{\mathrm{M}}$, with integers n_1 and n_2 . This Fourier expansion entails the introduction of a cutoff in \mathbf{k} space, and in this study, we have adopted a cutoff of $||\mathbf{k}|| \leq 4G^{\mathrm{M}}$.

B. Shift current

When two rays of light, $E_{\alpha}(\omega_{\alpha})$ and $E_{\beta}(\omega_{\beta})$ polarised in the α , β direction with frequency ω_{α} , ω_{β} respectively, are shone to a sample, we expect a current density in the μ direction j_{μ} resulting from a second order nonlinear optical (NLO) response. Here, $\mu, \alpha, \beta = x, y$ in the present 2D set-up. Adopting the Einstein summation convention over repeated indices, the second order NLO response is expressed as

$$j_{\mu}(\omega_{\Sigma}) = \sigma^{\mu}_{\alpha\beta}(\omega_{\Sigma};\omega_{\alpha},\omega_{\beta}) E_{\alpha}(\omega_{\alpha}) E_{\beta}(\omega_{\beta}), \qquad (5)$$

where $\sigma^{\mu}_{\alpha\beta}$ is the second order NLO conductivity tensor and $\omega_{\Sigma} = \omega_{\alpha} + \omega_{\beta}$. It should be noted that $\sigma^{\mu}_{\alpha\beta}$ will be finite only when the system lacks inversion symmetry [48, 49], which can be checked by inspecting the inversion symmetry of both sides of Eq. (5).

The shift current corresponds to the case where $\omega_{\alpha} = -\omega_{\beta} = \omega$, resulting in a dc response $j_{\mu}(0)$. If we choose to focus on the case where the incoming light is of a single polarisation α , the shift current conductivity in 2D is given by the following expression [49, 50]

$$\sigma^{\mu}_{\alpha\alpha}(\omega) = \frac{2\pi q^3}{\hbar\omega^2} \int \frac{d^2 \mathbf{k}}{(2\pi)^2} \sum_{a,b} f_{ab} |v^{\alpha}_{ba}|^2 R^{\mu(\alpha)}_{ba} \delta(\hbar\omega - \varepsilon_{ba}).$$
⁽⁶⁾

Here, q is the charge of the carrier, $\varepsilon_{ba} = \varepsilon_b - \varepsilon_a$, where ε_a is the eigenenergy of the Bloch state $|a\rangle$, $f_{ab} = f(\varepsilon_a) - f(\varepsilon_b)$, where $f(\varepsilon)$ is the Fermi-Dirac occupation function, $v^{\alpha} = \hbar^{-1}\partial_{\alpha}H$ is the velocity operator, where ∂_{α} is used as a shorthand for $\partial/\partial k_{\alpha}$. We also introduce the shift vector $R_{ba}^{\mu(\alpha)}(\mathbf{k}) = A_{bb}^{\mu} - A_{aa}^{\mu} - \partial_{\mu}\varphi_{ba}^{(\alpha)}$, defined using the intraband Berry connection $A_{aa}^{\alpha} = i\langle a|\partial_{\alpha}|a\rangle$ and the phase of the velocity matrix element $\varphi_{ba}^{(\alpha)} = \arg(v_{ba}^{\alpha})$. A close inspection of Eq. (6) allows us to deduce

A close inspection of Eq. (6) allows us to deduce a couple of key features of the shift current. First, $f_{ab} \,\delta(\hbar\omega - \varepsilon_{ba})$ is the joint density of states (JDoS) which counts the number of states that are separated by energy $\hbar\omega$, and $|v_{ba}^{\alpha}|^2$ is the dipole matrix element which dictates the transition rules at each k-point. Thus, we can conclude that a and b respectively labels the initial and final state of the optical transition and that the magnitude of the current is proportional to the number of states available for the transition. Second, the shift current is characterised by the shift vector $R_{ba}^{\mu(\alpha)}$. It is expressed as the difference between the intraband Berry connections A^{μ}_{nn} of the initial and final bands of the optical transition, and we can understand this as being the difference in the centre-of-mass coordinate of the electron wavepacket in the initial and the final band [81–83]. The final $\partial_{\mu}\varphi^{(\alpha)}_{ba}$ term is present to ensure that $R^{\mu(\alpha)}_{ba}$ is gauge invariant. In the present paper, we only work with Hamiltonians

In the present paper, we only work with Hamiltonians which are linear in k. This allows us to rewrite Eq. (6) as [73]

$$\sigma^{\mu}_{\alpha\alpha}(\omega) = -\frac{\hbar^2 e^3}{2\pi} \int d^2 \mathbf{k} \sum_{a,b} \frac{f_{ab}}{\varepsilon_{ba}^2} \times \\ \operatorname{Im}\left[\sum_{c\neq a} \frac{v^{\mu}_{ac} v^{\alpha}_{cb} v^{\alpha}_{ba}}{\varepsilon_{ac}} + \sum_{c\neq b} \frac{v^{\mu}_{cb} v^{\alpha}_{ba} v^{\alpha}_{ac}}{\varepsilon_{bc}}\right] \delta(\hbar\omega - \varepsilon_{ba}),$$
(7)

where we have set q = -e, where e is the elemental charge. Here, we can view the states a and b as the initial and final states of the real optical transition, while state c corresponds to some intermediate state that is reached through virtual transitions. The numerical evaluation of the shift current response in the present work was performed using this expression. We replace the integral over the moiré Brillouin zone by a summation over a mesh of 50×50 and employ a Lorentzian function $\eta/[(\hbar\omega - \varepsilon_{ba})^2 + \eta^2]$ with a broadening $\eta = 1$ meV in place of $\delta(\hbar\omega - \varepsilon_{ba})$.

In applying Eq. (7) to our system, we can perform a simple symmetry analysis on the $\sigma^{\mu}_{\alpha\beta}$ tensor to find its independent components. To do so, we return to Eq. (5) and consider a transformation from coordinates $\mathbf{r}' = (x', y')$ to a new set of coordinates $\mathbf{r} = (x, y)$ given by a rotation matrix $\mathbf{r}' = R(\psi) \mathbf{r}$. In this new frame, we can rewrite Eq. (5) as

$$j_{\mu'} = \sigma_{\alpha'\beta'}^{\mu'} E_{\alpha'} E_{\beta'}$$
$$R_{\mu'\mu} j_{\mu} = \sigma_{\alpha'\beta'}^{\mu'} R_{\alpha'\alpha} E_{\alpha} R_{\beta'\beta} E_{\beta}$$
$$j_{\mu} = \left(R_{\mu\mu'}^{-1} \sigma_{\alpha'\beta'}^{\mu'} R_{\alpha'\alpha} R_{\beta'\beta} \right) E_{\alpha} E_{\beta}, \qquad (8)$$

leading us to the following transformation law

$$\sigma^{\mu}_{\alpha\beta} = R^{-1}_{\mu\mu'} \sigma^{\mu'}_{\alpha'\beta'} R_{\alpha'\alpha} R_{\beta'\beta}. \tag{9}$$

Imposing C_{3z} symmetry, in which we set $\sigma^{\mu}_{\alpha\beta} = \sigma^{\mu'}_{\alpha'\beta'}$ with $\psi = 2\pi/3$, we find [31]

$$\sigma_{xx}^{x} = -\sigma_{xy}^{y} = -\sigma_{yx}^{y} = -\sigma_{yy}^{x},$$

$$\sigma_{yy}^{y} = -\sigma_{xy}^{x} = -\sigma_{yx}^{x} = -\sigma_{xx}^{y}.$$
(10)

Therefore, $\sigma_{\alpha\beta}^{\mu}$ only contains two independent components, σ_{xx}^{x} and σ_{yy}^{y} . Since any signal can be expressed in terms of σ_{xx}^{x} and σ_{yy}^{y} , in the subsequent sections, we solely focus on these two components. We further note that in the case where the vertical bias voltage is absent, AB-AB (AB-BA) configuration recovers the C_{2x}

 (C_{2y}) rotational symmetry [25], further rendering $\sigma_{yy}^y = 0$ $(\sigma_{xx}^x = 0).$

We finally note that in the present system, the two valleys K_{\pm} are connected by time-reversal symmetry. This ensures that the contributions to the shift current from each valley are equal [73, 77] and the following results have taken this degeneracy into account.

III. RESULTS

A. Intrinsic shift current response

We compute the shift current response in twisted double bilayer graphene (TDBG) at a twist angle of $\theta = 0.8^{\circ}$. We specifically focus on the intrinsic signal in the absence of any bias voltage $\Delta = 0$.

The results for the σ_{xx}^{x} response in AB-AB and AB-BA stacked TDBG are shown on the leftmost panels in Fig. 2 (a) and (b) respectively. Focussing on the AB-AB variant, we show the band structure on the left panel and $\sigma_{xx}^{x}(\omega; E_{\rm F})$ as a colour density plot on the right panel. The shift current is plotted with frequency $\omega = 0 \sim 70$ meV on the horizontal and Fermi level $E_{\rm F} = -50 \sim 50$ meV on the vertical axis. Therefore, each horizontal strip of the density plot corresponds to a σ_{xx}^{x} - ω plot for a certain value of $E_{\rm F}$. We note that the scale of the vertical axis is adjusted to match that of the band structure plot. In Fig. 2 (b), we show the corresponding plots for AB-BA TDBG, however, due the the C_{2y} symmetry, σ_{xx}^{x} is completely suppressed.

If we inspect the σ_{xx}^{x} density plot in AB-AB TDBG, we see that there is a strong signal in the low frequency region which gradually tails off as we move to higher frequencies. This behaviour is seen throughout the plotted $E_{\rm F}$ range and is due to the $1/\omega^2$ prefactor in Eq. (6). This prefactor acts to enhance the signal when the gap is small and to cause a suppression for high frequencies. The enhancement is especially strong near the charge neutrality point (CNP), indicated by the grey arrow, where bands are concentrated giving rise to very small energy gaps. A similar enhancement of the shift current is reported other moiré materials [31, 72–74]. We also notice that the low frequency signal is not of a single sign but a series of sign changes is observed as the Fermi level is swept. Note that the signal should technically vanish as $\omega \to 0$, however, due to to the finite broadening and the colour scale of the density plot, it appears that there is a finite response in the dc limit.

The results for the σ_{yy}^{y} response are shown in Fig. 3 in a similar fashion. In this case, the (b) AB-BA variant gives a finite response while it vanishes in the (a) AB-AB case due to the C_{2x} symmetry. Although there are differences between the σ_{xx}^{x} and σ_{yy}^{y} responses, we find that their overall behaviour, such as the strong enhancement at low frequencies, are common.

B. Effect of vertical bias voltage

Having studied the behaviour of the intrinsic shift current response, we now move our attention to the evolution of the response as a result of the application of Δ . We begin with the σ_{xx}^x response at values of $\Delta = 10, 20$ and 50 meV and show the band structures of AB-AB and AB-BA stacked TDBG in Fig. 2 (a) and (b) respectively.

Focussing on the AB-AB configuration, where σ_{xx}^{x} is always non-zero, as Δ is increased, we see that the overall size of the signal is suppressed. This is due to the fact that the bias voltage increases the gap size, which in turn suppresses the signal via the $1/\omega^2$ factor. On the other hand, in the AB-BA variant, as soon as the vertical bias voltage begins to break the C_{2y} symmetry, we observe a finite response. From here, the signal continues to grow in magnitude until $\Delta \sim 10$ meV, from which the signal follows the same pattern with the $1/\omega^2$ suppression for stronger Δ . A similar pattern between the signal strength and the band gap can be seen when the twist angle θ is increased. The results for $\theta = 0.4^{\circ}$ and 2.0° at $\Delta = 50$ meV are given in Appendix A.

We further notice that there is a large insulating region, represented in white, near the CNP as Δ increases. This behaviour can be simply inferred from the large band gap that opens at the CNP. We see similar trends in the σ_{yy}^{y} response show in in Fig. 3 (a) and (b).

C. Comparison between AB-AB and AB-BA stacked TDBG

We find that there is a visible relationship between the signals of the two variants when Δ is large and the bands are well separated. To allow for a systematic comparison of the shift current response between the two stacking configurations, we consider the case where a finite vertical bias voltage of $\Delta = 50$ meV is applied. On the rightmost side of Fig. 2, we show the band structure and the corresponding σ_{xx}^{x} plots for (a) AB-AB and (b) AB-BA stacked TDBG.

If we begin to compare the density plots between the two stacking configurations, we notice that there is a general positive/negative correlation in the sign of the signal above/below the CNP. The negative correlation is illustrated in Fig. 4 where we show a close-up view of the four density plots below the CNP, indicated by the grey dashed boxes in Fig. 2 and 3. Focussing first on the σ_{xx}^{x} response shown in Fig. 4 (a) and (b), we have labelled four regions from A to D where a sign reversal can be seen. For example, in the AB-AB variant, region A has a positive signal, while the corresponding signal in the AB-BA variant is negative. A similar pattern is seen for the other three regions. Likewise, in Fig. 4 (c) and (d), where show the density plots for σ_{yy}^{y} , we find that regions with the same label have opposite signs. We note that this positive/negative correlation is overshadowed as we turn down Δ and the bands begin to cluster.

IV. UNDERSTANDING SIGN REVERSAL IN TDBG SHIFT CURRENT

In order to understand the sign reversal seen in the AB-AB and AB-BA stacked TDBG, we consider the shift current response in AB-stacked bilayer graphene (BLG). We note that BLG is intrinsically centrosymmetric, hence, requires some external symmetry breaking for a finite response. In the present case, we apply a vertical bias voltage of $\Delta = 50$ meV to match the value of Δ in the previous section. It should also be noted that BLG has M_x mirror symmetry across the y-z plane, which renders σ_{xx}^x to zero. Therefore, it will suffice to study σ_{yy}^y to describe its shift current response.

The continuum Hamiltonian for BLG around the K_{\pm} valleys is given by the top left 4×4 matrix in Eq. (1),

$$H_{\rm AB} = \begin{pmatrix} H(\mathbf{k}) & g^{\dagger}(\mathbf{k}) \\ g(\mathbf{k}) & H'(\mathbf{k}) \end{pmatrix} + V_{\rm AB}, \tag{11}$$

where V_{AB} represents the vertical bias voltage

$$V_{\rm AB} = \begin{pmatrix} \frac{1}{2}\Delta \mathbb{I} & \\ & -\frac{1}{2}\Delta \mathbb{I} \end{pmatrix}.$$
 (12)

Using this Hamiltonian, we show the band structure (left panel) and the corresponding σ_{yy}^{y} response (right panel) of BLG in Fig. 5. The band structure computed from the Hamiltonian in Eq. (11) shows a slice through k_x at $k_y = 0$ around the K_+ (K_-) point, plotted in the black solid (red dashed) line. The vertical bias voltage allows for a gap-opening of around 50 meV. On the right panel, we show the shift current response as a colour density plot with frequency ω on the horizontal and Fermi level $E_{\rm F}$ on the vertical axis. The numerical evaluation of Eq. (7) was performed with a broadening of $\eta = 1$ meV. We can initially see that there is very little or no response at frequencies below 50 meV, which is a reflection of the fact that there are no possible optical transitions in this frequency range due to the gap opened via the bias voltage. As we move up to $\omega = 50$ meV, we start to see a large response when the Fermi level is set within the gap. This sharp response corresponds to the optical transition from the band edge of the valence to that of the conduction band, where a large joint density of states (JDoS) is realised. We also note that the size of the signal is in the range of 10 mA nm V^{-2} , which is an order of magnitude smaller compared to the signal seen in TDBG. This result suggests that the effect of the moiré reconstruction of the band structure indeed enhances the shift current response.

We next move on to the case where two AB-stacked BLG are stacked and twisted with no coupling at the twist interface, which we will refer to as uncoupled TDBG. Since the two sheets of BLG are uncoupled, the shift current response of the total system is given by the sum of the responses from each BLG.

The results of the shift current shown in Fig. 5 are given with respect to coordinates aligned with the lattice orientation of the BLG, which we will denote using

6

FIG. 2: The band structure and σ_{xx}^{x} density plots of (a) AB-AB and (b) AB-BA stacked TDBG for various strength of the vertical bias voltage Δ . Here, we used $\Delta = 0, 10, 20$ and 50 meV. The grey arrows indicate the respective charge neutral gaps. We also show the moiré Brillouin zone in the top right corner.

primed coordinates $\sigma_{y'y'}^{y'}$. However, once we begin to rotate the BLG sheets, we are in need to compute the components of the shift current, σ_{xx}^{x} and σ_{yy}^{y} , with respect to the fixed coordinates denoted by unprimed coordinates. A schematic diagram of the set-up under consideration is shown in Fig. 6. Using the transformation law in Eq. (9),

the relationship between the conductivities are given as

$$\sigma_{xx}^{x}(\psi) = \sigma_{y'y'}^{y'} \sin(3\psi),$$

$$\sigma_{yy}^{y}(\psi) = \sigma_{y'y'}^{y'} \cos(3\psi),$$
(13)

where we have used the fact that $\sigma_{x'x'}^{x'} = 0$. The detail of the derivation is described in Appendix. B. We note that, now, both σ_{xx}^{x} and σ_{yy}^{y} are finite since M_x symmetry is broken as the two BLG sheets are twisted relative to each

7

FIG. 3: The band structure and σ_{yy}^{y} density plots of (a) AB-AB and (b) AB-BA stacked TDBG for various strength of the vertical bias voltage Δ . Here, we used $\Delta = 0$, 10, 20 and 50 meV. The grey arrows indicate the respective charge neutral gaps.

other.

Now, that we have an expression for σ_{xx}^x and σ_{yy}^y , we will apply this to the uncoupled TDBG. Here, we use the parameters $\theta = 0.8^{\circ}$ and $\Delta = 50$ meV. In Fig. 7, we show the schematic band structures of (a) AB-AB and (b) AB-BA uncoupled TDBG at the K_+ point, which simply corresponds to having two copies of the band structure shown in Fig. 5 with a shift in the Fermi energy. On the right panels, we show the density plots for the shift current conductivities σ_{xx}^x and σ_{yy}^y . Fist, we note that

the magnitudes of σ_{xx}^x is much smaller than σ_{yy}^y , which stems from the fact that σ_{xx}^x grows linearly with θ for small twist angles.

If we focus on the signs of the σ_{xx}^x signal on the centre panels, we can see that there is a positive/negative correlation above/below the charge neutrality point between the two variants. This can be understood from the fact that the relative orientation of the BLG sheets are aligned/antialigned in the AB-AB/AB-BA variant. As the shift current is related to the polarisation of the ma-

FIG. 4: A close-up view of the $\sigma_{xx}^x/\sigma_{yy}^y$ responses in (a)/(c) AB-AB and (b)/(d) AB-BA TDBG shown in Fig. 2 and 3. We have labelled regions where a sign reversal between the two stacking configurations can be seen.

terial, the 180° rotation of the second layer leads to a sign reversal of the signal. The same effect is seen in the σ_{yy}^{y} signal on the right panels. This qualitatively explains the sign reversal that was seen in the TDBG calculation, and it reveals that this relationship is retained even after the effect of the moiré coupling.

V. CONCLUSION

In the present paper, we have studied the shift current response in AB-AB and AB-BA stacked twisted double bilayer graphene (TDBG). We have studied the intrinsic signal and the effect on the signal as we turn on the vertical bias voltage and their dependence on the Fermi level. In the low frequency regime, we have found a strong signal and a series of sign flips across band edges. We have further found a positive/negative correlation in the sign of the signal between the AB-AB and AB-BA variants above/below the charge neutrality point at large values of the vertical bias voltage. To understand the origin of

FIG. 5: The band structure of AB-stacked BLG from the K_+ (K_-) is plotted in the solid black (dashed red) lines in the left panel; a vertical bias voltage of 50 meV is applied across the layers. The shift current σ_{yy}^{y} is plotted as a density plot in the right panel.

the sign relationship between the two variants, we used a simplified model for TDBG with no moiré coupling at the twist interface. By studying the response in this system, we have found that the sign reversal originated from the 180° rotation of one of the bilayer and that the relative sign between the variants is retained even after the effects of the moiré reconstruction of the bands.

Appendix A: Results for $\theta = 0.4^{\circ}$ and 2.0°

Here, we show the band structures and shift current plots for AB-AB and AB-BA TDBG for $\theta = 0.4^{\circ}$ and 2.0° with $\Delta = 50$ meV. The results for $\theta = 0.4^{\circ}$ and 2.0° are shown in Fig. 8 and Fig. 9, respectively. We can see that the signal strength is strong at $\theta = 0.4^{\circ}$, while it is suppressed at $\theta = 2.0^{\circ}$. This is a similar behaviour to what was seen when the vertical bias voltage Δ was increased, in which, the widened band gap suppressed the signal strength via the $1/\omega^2$ factor. We further note

FIG. 6: A schematic diagram of the set up of the shift current conductivities (a) $\sigma_{x'x'}^{x'}$, (b) $\sigma_{y'y'}^{y'}$ in the coordinates aligned with the BLG lattice orientation and (c) σ_{xx}^{x} , (d) σ_{yy}^{y} in the fixed coordinates, where the BLG sheet is rotated through an angle ψ .

that the sign reversal that was seen below the charge

neutrality point in the $(\theta, \Delta) = (0.8^{\circ}, 50 \text{ meV})$ case is overshadowed at $\theta = 2.0^{\circ}$, which is mainly due to the fact that the bands are much more dispersive compared to the $\theta = 0.8^{\circ}$ case.

Appendix B: Transformation of the conductivity tensor in non-moiré TDBG

In this appendix, we show the detail of the calculation that was performed to obtain Eq. (13). Using the explicit forms for the rotation matrix

$$R(\psi) = \begin{pmatrix} \cos(\psi) & \sin(\psi) \\ -\sin(\psi) & \cos(\psi) \end{pmatrix},$$
 (B1)

and the conductivity tensor in the coordinates aligned with the BLG lattice

$$\sigma' = \begin{pmatrix} \sigma_{x'x'}^{x'} & -\sigma_{y'y'}^{y'} & -\sigma_{y'y'}^{y'} & -\sigma_{x'x'}^{x'} \\ -\sigma_{y'y'}^{y'} & -\sigma_{x'x'}^{x'} & -\sigma_{x'x'}^{x'} & \sigma_{y'y'}^{y'} \end{pmatrix},$$
(B2)

we can perform the matrix multiplication in Eq. (13) to obtain the σ tensor in the unprimed coordinates. It reads

$$\sigma = R^{-1} \sigma' (R \otimes R), \tag{B3}$$

where the 4×4 matrix $R(\psi) \otimes R(\psi)$ is explicitly given as

$$R(\psi) \otimes R(\psi) = \begin{pmatrix} \cos(\psi) & \sin(\psi) \\ -\sin(\psi) & \cos(\psi) \end{pmatrix} \otimes R(\psi)$$
$$= \begin{pmatrix} \cos(\psi) R(\psi) & \sin(\psi) R(\psi) \\ -\sin(\psi) R(\psi) & \cos(\psi) R(\psi) \end{pmatrix}$$
$$= \begin{pmatrix} \cos^2(\psi) & \cos(\psi) \sin(\psi) & \cos(\psi) \sin(\psi) & \sin^2(\psi) \\ -\cos(\psi) \sin(\psi) & \cos^2(\psi) & -\sin^2(\psi) & \cos(\psi) \sin(\psi) \\ -\cos(\psi) \sin(\psi) & -\sin^2(\psi) & \cos^2(\psi) & \cos(\psi) \sin(\psi) \\ \sin^2(\psi) & -\cos(\psi) \sin(\psi) & -\cos^2(\psi) & \cos^2(\psi) \end{pmatrix}.$$
(B4)

Then, the σ_{xx}^{x} and σ_{yy}^{y} components are given as

$$\sigma_{xx}^{x}(\psi) = \sigma_{x'x'}^{x'}\cos(3\psi) + \sigma_{y'y'}^{y'}\sin(3\psi),
\sigma_{yy}^{y}(\psi) = -\sigma_{x'x'}^{x'}\sin(3\psi) + \sigma_{y'y'}^{y'}\cos(3\psi).$$
(B5)

Recalling that $\sigma_{x'x'}^{x'}=0$ from the M_x mirror symmetry, we finally end with

$$\begin{aligned} \sigma_{xx}^{x}(\psi) &= \sigma_{y'y'}^{y'} \sin(3\psi), \\ \sigma_{yy}^{y}(\psi) &= \sigma_{y'y'}^{y'} \cos(3\psi), \end{aligned} \tag{B6}$$

FIG. 7: The band structure of (a) AB-AB and (b) AB-BA stacked uncoupled TDBG is shown in the left panels. The plot is around the K_+ point, the twist angle is set to $\theta = 0.8^{\circ}$ and a vertical bias voltage of $\Delta = 50$ meV is applied. The contribution from the first (second) BLG is plotted in the solid (dotted) black lines. The corresponding moiré reciprocal lattice vector is also labelled. On the centre and right panels, we show the corresponding σ_{xx}^x and σ_{yy}^y plots, plotting frequency ω and Fermi energy $E_{\rm F}$ on the horizontal and vertical axes respectively.
