Abstract

Dimensionality reduction is a fundamental task that aims to simplify complex data by reducing its feature dimensionality while preserving essential patterns, with core applications in data analysis and visualisation. To preserve the underlying data structure, multi-dimensional scaling (MDS) methods focus on preserving pairwise dissimilarities, such as distances. They optimise the embedding to have pairwise distances as close as possible to the data dissimilarities. However, the current standard is limited to embedding data in Riemannian manifolds. Motivated by the lack of asymmetry in the Riemannian metric of the embedding space, this paper extends the MDS problem to a natural asymmetric generalisation of Riemannian manifolds called Finsler manifolds. Inspired by Euclidean space, we define a canonical Finsler space for embedding asymmetric data. Due to its simplicity with respect to geodesics, data representation in this space is both intuitive and simple to analyse. We demonstrate that our generalisation benefits from the same theoretical convergence guarantees. We reveal the effectiveness of our Finsler embedding across various types of non-symmetric data, highlighting its value in applications such as data visualisation, dimensionality reduction, directed graph embedding, and link prediction.

1. Introduction

Dimensionality reduction is a task at the core of data analysis, allowing complex data to be represented in simple low-dimensional forms. In Multi-Dimensional Scaling (MDS), the goal is to preserve pairwise dissimilarities between datapoints, thereby retaining the essential structure of the data. However, the original MDS approach [31, 56, 93] assumes

Figure 1. External fields, such as non-uniform currents, lead to time-wise geodesic curves from A to B (in yellow) that differ from those from B to A (in red). Although asymmetry is impossible in Riemannian manifolds, it is at the core of Finsler geometry.

that data relationships are primarily linear, limiting its ability to capture the non-linear structures often present in high dimensions. Manifold learning extends this approach by assuming that data lies on a low-dimensional manifold, where meaningful relationships are reflected in more complex pairwise dissimilarities. Methods that integrate manifold learning into MDS can capture these structures by focusing on pairwise dissimilarities, such as geodesic distances, which reflect the intrinsic geometry of the manifold and better preserve its continuity in the embedding space.

The MDS community has universally decided to embed data into spaces implicitly equipped with a Riemannian geometry [16, 35], choosing Euclidean [88, 96] or more generally geodesic [15] distances in embedding space. However, such embeddings inherit from the limitations of Riemannian metrics. In particular, Riemannian distances are bound to be symmetric, meaning that they cannot accurately capture the possible asymmetric nature of the original data dissimilarities. Yet, such properties are common in real-world applications across a wide range of fields. In physical systems, external fields such as currents lead to different shortest-time paths whether going upstream or downstream (see Fig. 1). In directed graphs, from social media to road networks, non-symmetric edges lead to non-symmetric pairwise dissimilarities. This inability of Riemannian spaces to account for asymmetry suggests that asymmetric data should be embedded in spaces equipped with other types of metrics than the traditional Riemannian ones. Yet, challenging the Riemannian metric of the em-

bedding space remains largely uncharted.

This strong limitation calls for defining and studying the MDS problem where the embedding space is equipped with a more general metric. Bernard Riemann himself first mentioned generalisations to his own metrics [78], but they were only investigated later by Paul Finsler. In 1918, he proposed a generalisation of Riemannian manifolds [38], which Elie Cartan later named *Finsler manifolds* [18]. The main assumption in Finsler manifolds is that the metric is not symmetric, unlike in Riemannian ones, meaning that distances are sensitive to the direction of motion. Consequently, both local and global distances between two points are asymmetric¹; the distance from A to B is generally different from the distance from B to A . Finsler manifolds have been mostly investigated in theoretical mathematics [4, 90, 91], gravitational physics [3, 17, 45, 75, 76, 99, 100], mechanics [7, 27], current navigation problems [111], and seismic sciences [106]. However, they are largely unexplored in the computer vision and machine learning community.

In this paper, we generalise the MDS problem to account for asymmetric dissimilarities by embedding the data into a Finsler space rather than a symmetric Riemannian one. In particular, our contributions are as follows:

- (a) We revisit multi-dimensional scaling by formulating a new problem, called *Finsler MDS*. The goal is to find an embedding to a Finsler space, allowing asymmetric data dissimilarities. To our knowledge, our framework is the first that goes beyond Riemannian geometry in the field of manifold learning.
- (b) We propose a new canonical Finsler space, that generalises the Euclidean space to incorporate asymmetric distances. Its geodesic simplicity provides embeddings that are intuitive and simple to analyse.
- (c) We extend the popular SMACOF algorithm from traditional MDS to solve the Finsler MDS problem, and prove its theoretical convergence. We also show how to solve Finsler MDS with modern deep learning techniques and neural networks.
- (d) We experimentally highlight the benefits of Finsler MDS for a variety of applications. We perform qualitative data visualisation experiments on various types of data – curved manifolds, flat current maps, and directed graphs. Such asymmetric visualisations are impossible in traditional MDS. We also demonstrate the quantitative superiority of our method for node embedding and link prediction in directed graphs.
- (e) We release our code to facilitate further research: <https://github.com/Tommoo/FinslerMDS>.

¹Asymmetric metrics and distances are sometimes called quasi metrics and quasi distances in the literature.

2. Related Work

Multi-dimensional scaling and manifold learning have a rich history, with many different approaches to find embeddings satisfying different properties. This contrasts with Finsler geometry which has seldom been applied in the computer vision and pattern recognition community.

Multi-Dimensional Scaling. MDS methods aim to preserve data dissimilarities of a low-dimensional embedding by minimising the stress function, which is a weighted sum of the squared difference between the embedded distances and the data dissimilarities [10, 32, 84]. Dissimilarities can be computed using either local [5, 6, 28, 29, 36, 42, 58, 59, 61, 64, 81, 94, 102, 113, 114] or global [13, 40, 104, 105] criteria or a combination of the two [1, 12, 46, 73, 79, 86–88, 96]. Nevertheless, traditional approaches cannot handle asymmetric dissimilarities, which naturally occurs for many features [98] in physical systems and directed graphs. Remarkably, few efforts have tackled asymmetry for MDS, such as ASYMSCAL-like methods [24, 25, 61, 70, 110], slide vector models [33, 43], Gower models [30, 43], the radius-distance model [68, 95], and the hill-climbing model [10, 69]. In brief, these methods use one of the following strategies. The first is to design asymmetric weights, yielding asymmetric importance for fitting to (symmetrised) dissimilarities in the stress function. The second is to design asymmetric embeddings directly by departing from a metric perspective, either by using non metric formula, as in hill-climbing, or by using additional stratagems to display asymmetric visualisations, as in the radius-distance model. To the best of our knowledge, the embedding space has never been equipped with a metric structure that naturally reflects asymmetry, such as Finsler geometry.

Finsler Geometry and Computer Vision. Except for a few notable works in robotics [77], image processing [19–22, 107], and shape analysis [103], Finsler geometry is a largely uncharted topic within the computer vision and machine learning community. For a mathematical introduction to Finsler geometry, see [4, 9, 65, 67].

3. Traditional Multi-Dimensional Scaling

MDS aims to find an embedding $x_1, \dots, x_N \in \mathbb{R}^m$, or in row-stacked format $\mathbf{X} \in \mathbb{R}^{N \times m}$, of N data points $\tilde{\mathbf{X}} \in \mathbb{R}^{N \times n}$ into a canonical space, e.g. the Euclidean space \mathbb{R}^m with $n > m$, while preserving data dissimilarities $\mathbf{D} \in \mathbb{R}_+^{N \times N}$. The points $\tilde{\mathbf{X}}$ often lie on a manifold $\mathcal{X} \subset \mathbb{R}^n$ to be preserved when embedding, which is the goal of *manifold learning*. If \mathcal{X} is equipped with a metric \tilde{L} , given at points $\tilde{x} \in \mathcal{X}$ by $\tilde{L}_{\tilde{x}} : \mathcal{T}_{\tilde{x}}\mathcal{X} \rightarrow \mathbb{R}_+$ where $\mathcal{T}_{\tilde{x}}\mathcal{X}$ is the tangent plane, a manifold preserving strategy is to take geodesic distances as dissimilarities. Let us properly define this notion.

Geodesic Distances. Let \mathcal{X} be a manifold equipped with a metric L given by $L_x : \mathcal{T}_x\mathcal{X} \rightarrow \mathbb{R}_+$. By integrating the length of tangent vectors, we can define the length of a smooth curve $\gamma : [0, 1] \rightarrow \mathcal{X}$ as

$$\mathcal{L}_L(\gamma) = \int_0^1 L_{\gamma(t)}(\gamma'(t))dt. \quad (1)$$

A shortest path, also known as a shortest geodesic, $\gamma_{x \rightarrow y}^L$ between two points $x, y \in \mathcal{X}$ minimises Eq. (1). The geodesic distance from x to y is the length of such shortest paths

$$d_L(x, y) = \mathcal{L}_L(\gamma_{x \rightarrow y}^L). \quad (2)$$

MDS and Riemannian Geometry. In MDS, only the knowledge of \mathbf{D} is needed: the original data $\tilde{\mathbf{X}}$, its dimensionality n , or its manifold $\tilde{\mathcal{X}}$ can be unknown. A key assumption in MDS is that dissimilarities are symmetric, i.e. $\mathbf{D}^\top = \mathbf{D}$, often implying that \mathbf{D} represents Riemannian pairwise distances, e.g. Riemannian geodesic distances in $\tilde{\mathcal{X}}$. The MDS task can then be termed *metric MDS*. In consequence, the embedding space $\mathcal{X} = \mathbb{R}^m$ is viewed as a Riemannian manifold, with metric R , that is the embedding of the Riemannian manifold $\tilde{\mathcal{X}}$, with metric \tilde{R} .

Riemannian Manifolds. A Riemannian manifold \mathcal{X} is equipped with a quadratic metric R given by $R_x(u) = \sqrt{u^\top M(x)u}$. The metric tensor $M(x)$ is a symmetric positive definite (SPD) matrix that fully describes R and is abusively called the Riemannian metric. Fundamentally, Riemannian metrics are symmetric as $R_x(-u) = R_x(u)$ for all $u \in \mathcal{T}_x\mathcal{X}$. Thus, traversing a curve in one direction or the other leads to the same distance, implying symmetric geodesic distances, i.e. $d_R(x, y) = d_R(y, x)$.

To reveal the simple intrinsic nature of the Riemannian manifold $\tilde{\mathcal{X}}$, the MDS embedding space \mathcal{X} should be a simple canonical Riemannian space. In particular for the task of *manifold flattening*, geodesics in \mathcal{X} should be the usual Euclidean segment², making the space \mathcal{X} flat. The appropriate canonical Riemannian space is thus the traditional Euclidean space \mathbb{R}^m , corresponding to taking $R_x(u) = \|u\|_2$. We can now formally present the MDS task.

MDS Formulation. The MDS task consists in finding the Euclidean embedding \mathbf{X} that minimises the stress function,

$$\sigma_E^2(\mathbf{X}) = \sum_{i,j} w_{i,j} (d_E(x_i, x_j) - \mathbf{D}_{i,j})^2, \quad (3)$$

where d_E is the Euclidean distance in \mathbb{R}^m of the embedded data \mathbf{X} and \mathbf{D} is a symmetric dissimilarity matrix. The weights $w_{i,j} \geq 0$ are usually taken to be uniform, however other configurations can be useful to better preserve the topology of the manifold, such as when holes are present

²This segment from x_i to x_j is given by $(1-t)x_i + tx_j$ for $t \in [0, 1]$.

due to undersampling or boundaries [12, 14, 15, 79, 87].

Kernel-based [85] closed form solutions exist for uniform weights $w_{i,j}$, and it is called Isomap when Dijkstra's algorithm [34] is used to compute geodesic distances as dissimilarities. This property breaks down for non-uniform weights in which case the stress is minimised using an iterative descent strategy, such as the SMACOF algorithm [32].

MDS Limitations. Traditional MDS requires symmetric dissimilarities, i.e. $\mathbf{D}^\top = \mathbf{D}$. However, in many cases, dissimilarities are naturally non-symmetric, i.e. $\mathbf{D}^\top \neq \mathbf{D}$. For example, this arises with the non-symmetric weights of directed graphs, but it can also occur in real-world systems (see Fig. 1). Yet, to the best of our knowledge, none of these methods fully address a core limitation of traditional MDS: its reliance on a Riemannian embedding space, which imposes symmetric distances between points. Thus, even with various adjustments, embedding into a Riemannian space \mathcal{X} cannot capture the non-symmetric structure of the data. We address this by introducing metric tools that move beyond Riemannian geometry and support *asymmetric* distances. Specifically, we consider Finsler geometry as it offers a refined, asymmetric generalisation of Riemannian geometry. Our goal is to embed data with non-symmetric dissimilarities \mathbf{D} into a Finsler space.

4. Finsler Geometry

Finsler manifolds [4] are a generalisation of Riemannian manifolds that incorporates distance asymmetry [23]. A Finsler manifold \mathcal{X} is equipped with a Finsler metric F satisfying at all points $x \in \mathcal{X}$ the following properties.

Definition 1 (Finsler metric). *A Finsler metric F , given by $F_x : \mathcal{T}_x\mathcal{X} \rightarrow \mathbb{R}_+$, is smooth, positive definite (i), positive homogeneous (ii), and satisfies the triangle inequality (iii):*

- (i) $F_x(u) \geq 0$ and $F_x(u) = 0 \iff u = 0, \quad \forall u \in \mathcal{T}_x\mathcal{X}$,
- (ii) $F_x(\lambda u) = \lambda F_x(u), \quad \forall u \in \mathcal{T}_x\mathcal{X}, \lambda > 0$,
- (iii) $F_x(u+v) \leq F_x(u) + F_x(v), \quad \forall u, v \in \mathcal{T}_x\mathcal{X}$.

In contrast to Riemannian metrics, Finsler metrics are no longer homogeneous, leading to metric asymmetry as $F_x(-u) \neq F_x(u)$ in general. This asymmetry is impossible for Riemannian metrics. Additionally, Finsler metrics are no longer given by a quadratic form in general [23] and do not share a universal parametric description. However, several parametric families of Finsler metrics exist [48], such as the (α, β) metrics [62], which induce Randers [76], Matsumoto [63] or Kropina metrics [55]. Due to the simplicity of its explicit formulation, we consider in the following the Randers metric which generalises the Riemannian metric.

Definition 2 (Randers metric). *A Randers metric F is parametrised by a tensor field M of symmetric positive definite matrices and a drift vector field ω with $\|\omega(x)\|_{M^{-1}(x)} < 1$ such that $F_x(u) = \sqrt{u^\top M(x)u} + \omega(x)^\top u$.*

In particular, the Randers metric is the sum of a Riemannian metric associated to the tensor field M and an asymmetric linear part due to the vector field ω . Note that the positivity of the metric stems from $\|\omega(x)\|_{M(x)^{-1}} < 1$. Riemannian metrics are Randers metrics, and thus also Finsler, and correspond to $\omega \equiv 0$. We can now present the novel Finsler multi-dimensional scaling problem.

5. Finsler Multi-Dimensional Scaling

We aim to embed non-symmetric data into \mathbb{R}^m viewed as a Finsler space. This task requires the formulation of the general Finsler MDS problem (Sec. 5.1) and the establishment of a canonical Finsler space (Sec. 5.2) that generalises the canonical Riemannian space of traditional MDS.

5.1. Problem Statement

We formalise Finsler manifold learning, or *Finsler MDS*, as the minimisation of the Finsler stress function

$$\sigma_F^2(\mathbf{X}) = \sum_{i,j} w_{i,j} (d_F(x_i, x_j) - \mathbf{D}_{i,j})^2, \quad (4)$$

where d_F is the Finsler distance in $\mathcal{X} = \mathbb{R}^m$ with chosen Finsler metric F . In general, unlike in classical scaling, data distances need not be symmetric, $\mathbf{D}_{j,i} \neq \mathbf{D}_{i,j}$, nor the embedding distance, $d_F(x_i, x_j) \neq d_F(x_j, x_i)$.

As in traditional MDS, it is often desirable for the embedding space to have a straightforward, canonical metric, ensuring that the embedding space $\mathcal{X} = \mathbb{R}^m$ remains flat. In this context, the embedding space \mathbb{R}^m is said to be flat when its geodesic curves are simply straight Euclidean segments. For the Riemannian case, this is achieved with the Euclidean metric. However, in Finsler spaces, we need to establish an appropriate canonical metric. In this paper, we develop a canonical Finsler space that extends the Euclidean space, allowing for asymmetric distances. This approach enables us to maintain the simplicity and flatness while accommodating the asymmetric structure of Finsler geometry.

5.2. Canonical Randers Space

We propose using \mathbb{R}^m as the canonical Finsler space equipped with the following Randers metric.

Definition 3 (Canonical Randers space). *The space \mathbb{R}^m is a canonical Randers space if it is equipped with the canonical Randers metric F^C , with Euclidean Riemannian component and a constant drift vector ω with $\alpha \equiv \|\omega\|_2 < 1$.*

The canonical Randers metric F^C is uniform as

$$F_x^C(u) = \|u\|_2 + \omega^\top u, \quad \forall x \in \mathbb{R}^m. \quad (5)$$

The canonical Randers space is Euclidean along hyperplanes orthogonal to ω , with an additional dimension along ω to capture asymmetry. The parameter α controls the influence of asymmetry: when $\omega \equiv 0$, i.e. $\alpha = 0$, asymmetry

is discarded, and the metric reduces to the Euclidean one. As α increases, asymmetry takes on a greater role.

In Euclidean space, geodesics are given by usual straight segments. The following theorem shows that this property also holds in the canonical Randers space.

Theorem 1 (Flatness of the canonical Randers space). *The shortest path between any points $x, y \in \mathbb{R}^m$ for the canonical Randers metric F^C is the Euclidean straight segment between x, y , i.e. $\gamma_{x \rightarrow y}^{F^C}(t) = (1-t)x + ty$ for $t \in [0, 1]$.*

We provide a proof in Appendix A.1. Theorem 1 means that the canonical Randers space is *flat*, as geodesic paths are not curved. This peculiarity results from the uniformity of the drift component. While geodesic paths in the canonical Randers space are identical to those in Euclidean space, their lengths vary depending on the direction of traversal.

Proposition 1 (Canonical Randers distance). *The canonical Randers distance d_{FC} between points $x, y \in \mathbb{R}^m$ is*

$$d_{FC}(x, y) = \|y - x\|_2 + \omega^\top(y - x). \quad (6)$$

See Appendix A.2 for a proof. When $\omega \equiv 0$, we recover the Euclidean distance. However, for $\omega \neq 0$, this distance becomes *asymmetric*: $d_{FC}(y, x) \neq d_{FC}(x, y)$. Remarkably, geodesic distances in the canonical Randers metric have a straightforward closed-form solution. It is composed of the Euclidean distance $\|y - x\|_2$ and an additional asymmetric term $\omega^\top(y - x)$, that is the projection of $(y - x)$ along ω . Thus, in the canonical Randers space, both shortest paths and geodesic distances are known and easy to compute, providing an intuitive visual understanding of the asymmetric structure of \mathbb{R}^m viewed as a canonical Randers space.

Riemannian Generalisations. As noted above, the canonical Randers space generalises the Euclidean space in many aspects. When $\omega \equiv 0$, it becomes Euclidean. When $\omega \neq 0$, it still shares the same geodesic paths as the Euclidean space, and a similar simplicity for computing their length. Moreover, for symmetric data and non-zero ω , the canonical Randers space also extends the traditional MDS embedding, as formalised in the following theorem.

Theorem 2. *Assume that the data is symmetric, $\mathbf{D} = \mathbf{D}^\top$, and that it can be accurately embedded into a Euclidean space \mathbb{R}^m , i.e. we can find $\mathbf{X} \in \mathbb{R}^m$ such that $d_E(x_i, x_j) = \mathbf{D}_{i,j}$ for all (i, j) . The solution to the Finsler MDS problem (Eq. (4)) using the canonical Randers space $\mathcal{X} = \mathbb{R}^{m+1}$ with $\omega \neq 0$ is given by the traditional MDS embedding in a m -dimensional hyperplane orthogonal to ω .*

A proof is provided in Appendix A.3. Theorem 2 implies that the canonical Randers space can thus be seen as an extension of the Euclidean space, adding an extra dimension to encode asymmetry. Within hyperplanes orthogonal

to this direction, the metric remains Euclidean. When there is no asymmetry, Finsler MDS preserves the Euclidean embedding in the m -dimensional hyperplane.

6. Solving Finsler Multi-Dimensional Scaling

We first solve the Finsler MDS problem by revisiting the SMACOF algorithm for the canonical Randers metric (Sec. 6.1). In addition, we show how to adapt the Finsler MDS problem to modern deep learning for node embedding and link prediction in digraphs (Sec. 6.2). These two methods show the simplicity and versatility of Finsler MDS.

6.1. Finsler SMACOF

The traditional MDS task in Eq. (3) is a non-linear least-squares problem that can be solved with the SMACOF algorithm [10]. We propose to extend this approach for solving the Finsler MDS task in Eq. (4). We call this method the *Finsler SMACOF algorithm*.

Denoting W the weight matrix with entries w_{ij} , we assume a symmetric weighting scheme $W = W^\top$, even if the data dissimilarities \mathbf{D} are not. This is a natural assumption meaning that the (i, j) and (j, i) pairs are as important for the embedding. We can then rewrite Eq. (4) as

$$\begin{aligned} \sigma_F^2(\mathbf{X}) = & \text{tr}(\mathbf{X}^\top V \mathbf{X}) + \text{tr}(\mathbf{X}^\top V \mathbf{X} \omega \omega^\top) \\ & + 2 \text{tr}((W \odot \mathbf{D} - W^\top \odot \mathbf{D}^\top) \mathbb{1}_m \omega^\top \mathbf{X}^\top) \\ & - 2 \text{tr}(\mathbf{X}^\top B(\mathbf{X}) \mathbf{X}) + \text{tr}(\mathbf{D} W \mathbf{D}^\top), \end{aligned} \quad (7)$$

where tr is the trace operator, \odot is the Hadamard product, $\mathbb{1}_m \in \mathbb{R}^m$ is the vector with all entries equal to 1, and

$$V_{ij} = \begin{cases} -w_{ij} & \text{if } i \neq j, \\ \sum_{k \neq i} w_{ik} & \text{if } i = j. \end{cases} \quad (8)$$

$$B_{ij}(\mathbf{X}) = \begin{cases} -w_{ij} \frac{D_{i,j}}{d_{FC}(x_i, x_j)} & \text{if } i \neq j \\ -\sum_{k \neq i} B_{ik}(\mathbf{X}) & \text{if } i = j. \end{cases} \quad (9)$$

See Appendix A.4 for a detailed derivation. Denote $\text{vec}(A)$ the vectorisation of matrix A by stacking its columns, A^\dagger the Moore-Penrose pseudo-inverse of A , and \otimes the Kronecker product. Let $K \in \mathbb{R}^{mN \times mN}$ and $C \in \mathbb{R}^{N \times m}$ be $K = (I_m + \omega \omega^\top) \otimes V$ and $C = (W \odot \mathbf{D} - W^\top \odot \mathbf{D}^\top) \mathbb{1}_m \omega^\top$. By deriving first-order optimality conditions, σ_F can be iteratively minimised. Denoting $\mathbf{X}^{(k)}$ the k -th iterate of the embedding, we have the following.

Proposition 2 (Finsler SMACOF). *A local minimum of the Finsler stress with symmetric weights is reached by iterating*

$$\text{vec}(\mathbf{X}^{(k+1)}) = K^\dagger \text{vec}(B(\mathbf{X}^{(k)}) \mathbf{X}^{(k)} - C).$$

We refer the reader to Appendix A.5 for a proof. Note that when $\omega \equiv 0$, we retrieve the iterates of the traditional SMACOF algorithm [10]: $\mathbf{X}^{(k+1)} = V^\dagger B(\mathbf{X}^{(k)}) \mathbf{X}^{(k)}$.

6.2. Finsler Representation Learning

To scale our approach, we present a Finsler representation learning method leveraging modern deep learning. This approach enables the canonical Randers embedding to be learned directly from data through neural networks, allowing applications to large digraph datasets [49]. Rather than training on σ_F , we adopt it as an evaluation metric, optimizing our model with alternative objectives while still maintaining effective embeddings. Such replacements of the stress with alternative losses are standard in the field.

To bridge Finsler MDS with Finsler representation learning for graph tasks, we introduce the concept of a *digraph* (directed graph) and its relationship to an asymmetrical pairwise distance matrix. Let $\mathcal{G} = (\mathcal{V}, \mathcal{E}, \mathbf{A})$ be a digraph, where \mathcal{V} is the set of $|\mathcal{V}| = N$ nodes, $\mathcal{E} \subset \mathcal{V} \times \mathcal{V}$ represents directed edges, and $\mathbf{A} \in \mathbb{R}^{N \times N}$ is the weighted adjacency matrix. The directed graph distance $d_{\mathcal{G}}$ is the length of shortest paths on \mathcal{G} . This results in an asymmetrical pairwise distance matrix \mathbf{D} , where $D_{i,j} = d_{\mathcal{G}}(i, j)$ for nodes $i, j \in \mathcal{V}$, inherently satisfying $\mathbf{D}^\top \neq \mathbf{D}$ due to the directed nature of \mathcal{G} . It aligns with our asymmetrical setup in Finsler MDS (see Sec. 5). Given a digraph \mathcal{G} , we aim to represent each node $i \in \mathcal{V}$ by a m -dimensional Finsler embedding $x_i \in \mathbb{R}^m$ such that the stress function in Eq. (4) is minimised and the learned embedding supports various graph generalisations, such as link prediction.

To learn the canonical Randers embedding, we use the Fermi-Dirac decoder [54, 66] to model probability scores of directed edges, given by

$$p((i, j) \in \mathcal{E} | \mathbf{X}) = \frac{1}{1 + \exp\left(\frac{d_{FC}^2(x_i, x_j) - r}{t}\right)}, \quad (10)$$

with d_{FC} is the canonical Randers distance, and $r, t > 0$ are hyperparameters. We train the Finsler embeddings on the weighted cross-entropy loss with negative sampling [41].

7. Experimental Results

Our new problem and its resolution open new perspectives, as we demonstrate with two types of applications. The first is data visualisation via low dimensional embeddings (Sec. 7.1). The second is the representation learning for node embedding and link prediction for directed graphs (Sec. 7.2), which are prevalent tasks in graph theory. The implementation details, including experimental setup, dataset details, and hyperparameters, along with additional results can be found in Appendix D.

7.1. Data Visualisation

We demonstrate not only how our method is capable of handling asymmetric input dissimilarities, but also how the canonical Randers embedding space provides an intuitive asymmetric embedding space suitable for visualisations.

We show on several types of synthetic data the strength of our method for many visualisation applications.

The drift component of the canonical Randers embedding space ω is chosen to be along the last axis, i.e. \vec{z} (resp. \vec{y}) in 3D (resp. 2D). The distance between two points going upwards is then greater than the downwards distance, leading to intuitive visualisations. Results are shown using the Finsler SMACOF algorithm (Sec. 6.1) on data dissimilarities computed from geodesic distances via Dijkstra’s algorithm [34]. Full details are provided in Appendix D.1.1.

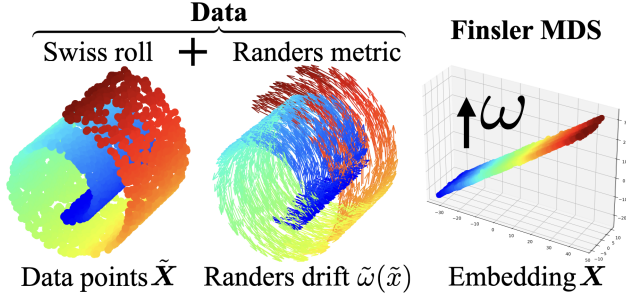

Figure 2. Flattening the Swiss roll (left) equipped with a Randers metric (middle) in the 3D canonical Randers space with Finsler MDS (right). The plotted arrows on the manifold are the linear drift components $\tilde{\omega}$ of the Randers metric. While Finsler MDS manages to flatten the Swiss roll, it preserves the asymmetry along ω , e.g. the height difference between blue and red points implies asymmetric distances between them.

Asymmetric Manifold Flattening. We flatten the Swiss roll $\tilde{\mathcal{X}} \in \mathbb{R}^3$, a reference shape in Manifold learning. To make it asymmetric, we equip $\tilde{\mathcal{X}}$ with the Randers metric $\tilde{F}^{\tilde{\alpha}}$ given by $\tilde{F}^{\tilde{\alpha}}(u) = \|u\|_2 + \tilde{\alpha}\tilde{\omega}^\top u$, with chosen $\tilde{\omega} \in \mathcal{T}_{\tilde{x}}\tilde{\mathcal{X}}$ having $\|\tilde{\omega}\|_2 = 1$ and hyperparameter $\tilde{\alpha} < 1$ controlling the input amount of asymmetry on $\tilde{\mathcal{X}}$. We plot in Fig. 2 the Finsler Smacof embedding to the canonical Randers space $\mathcal{X} = \mathbb{R}^3$, which is well-suited for embedding two-dimensional asymmetric manifolds (see Theorem 2). For more embeddings with different levels of input asymmetry $\tilde{\alpha}$, and in particular an illustration of Theorem 2 when data is symmetric $\tilde{\alpha} = 0$, see Appendix D.1.2. Our Finsler embedding demonstrates both the intuitive flat structure of the Swiss roll $\tilde{\mathcal{X}}$ and its asymmetry between points. In fact, our visualisation is significantly clearer than when artificially plotting arrows on top of the manifold $\tilde{\mathcal{X}}$, as the asymmetry can be difficult to discern for numerous samples or low magnitudes of the Randers drift component. To the best of our knowledge, our method is the only metric approach capable of naturally revealing and preserving these asymmetric structures, thanks to Finsler geometry.

Robustness to Holes. Most Manifold learning approaches suffer from topological changes due to missing parts. To increase robustness, the weights $w_{i,j}$ of the stress can be tuned

Figure 3. Swiss roll embeddings to the canonical Randers space \mathbb{R}^2 . Our Finsler MDS can generalise current SOTA approaches for providing embeddings robust to missing parts. Note that Finsler MDS accurately embeds the Swiss roll to \mathbb{R}^2 , but Isomap would not be able to accurately embed the symmetric version to \mathbb{R}^1 .

to filter out perturbed data dissimilarities, by focusing on local [87] or non-local criteria [12, 79]. Our Finsler MDS is compatible with such approaches. We propose a Finsler wormhole criterion, generalising the SOTA non-heuristic criterion for symmetric distances [12], and prove that it recovers consistent geodesic pairs on a Finsler manifold in Appendix C. We showcase in Fig. 3 the strength of the Finsler wormhole criterion to provide robust embeddings preserving the geometry of the underlying Finsler manifold.

Figure 4. Unflattening a current map (left) by Finsler MDS embedding to the 3D canonical Randers space (right). Dissimilarities are shortest-time distances given the current. The 3D map reveals the asymmetry, where timewise distances are easy to read based on the measurements on the straight Euclidean 3D line between points, and with local maxima (resp. minima), plotted in black (resp. gray), corresponding to source (resp. sink) points.

Unflattening Current Maps. We aim to visualise current maps such as surface currents in a sea. The data points lie on the 2D plane $\tilde{\mathcal{X}} \subset \mathbb{R}^2$, with current at their location $\tilde{v}(\tilde{x}) \in \mathcal{T}_{\tilde{x}}\tilde{\mathcal{X}} = \mathbb{R}^2$. The 2D map displays the correct spatial flatness of the surface, and it can be used to measure spatial distances. However, due to complex non-uniform currents \tilde{v} , the time-shortest paths for a boat with a fixed speed motor will be particularly complex and we cannot measure on the 2D map the time of these journeys. In fact, these times are given by the Zermelo metric \tilde{F} , which is Randers, that we approximate here as $\tilde{F}_x(u) = \|u\|_2 - \tilde{v}(\tilde{x})^\top u$ (see Appendix B). We propose to embed the data into the 3D canonical Randers space $\mathcal{X} = \mathbb{R}^3$, yielding a 3D map where height levels represent asymmetry in shortest-time travel (see Fig. 4 and Appendix D.1.2). Shortest travel time is

then easily measurable (see Proposition 1) from Euclidean segments. Additionally, extracting local extrema from the embedding space yields the source and sink points of the current. The curved Finsler embedding is thus intuitive.

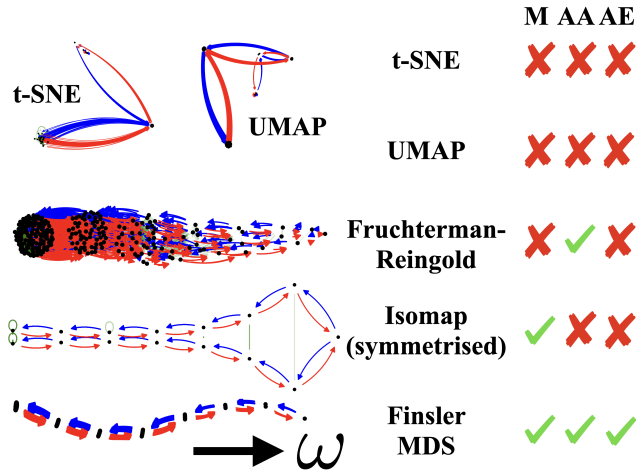

Figure 5. Manually rotated embeddings of modified directed binary trees of various depth, with small symmetric edges between equally deep nodes. The reference works, t-SNE [101] and UMAP [64] fail to provide a meaningful embedding. The Fruchterman-Reingold [39] algorithm fails to clearly reveal the hierarchy, unlike Isomap [88, 96]. The latter heavily distorts distances between equally deep nodes, due to node collapse to two nodes and large separations at the top of the structure. Neither method provides the direction of the hierarchy. In contrast, the Finsler MDS embedding clearly reveals the hierarchy and its direction by construction while highly preserving all distances. The symbols mean: M – Metric, AA – Asymmetric algorithm, and AE – Asymmetric Embedding.

Revealing Graph Hierarchies. Directed graphs are common and asymmetric, yet lack any embedding. In this experiment, we aim to reveal the node hierarchy by embedding directed graphs into a 2D canonical Randers space. Nodes embedded higher in \vec{y} have greater importance than those embedded below. Our synthetic graph is a modified directed binary tree. Children are close from their parents but not vice versa, and small symmetric edges have been added between nodes at the same depth. This simulates a proximity graph in a pyramidal company between managers (parents) and employees (children). The Finsler embedding (see Fig. 5) naturally reveals the graph hierarchy between nodes, with nodes at different depths embedded to different heights. In contrast, the traditional symmetrised MDS embedding collapses and the proximity between nodes at the same depth is not consistent throughout the graph.

7.2. Digraph Embedding and Link Prediction

We demonstrate the power of the proposed Finsler representation learning (Sec. 6.2) for digraph embedding and link prediction tasks [71, 74]. Various approaches have

been proposed to preserve the asymmetry information in graph data [26, 37, 52, 80, 112, 115, 116], capturing essential properties of directed structures. These methods explore ways to encode the directionality inherent in directed graphs, often through adjustments in learning algorithms or spectral properties that reflect asymmetrical relationships. Nevertheless, to the best of our knowledge, none of these approaches have considered Finsler geometry for digraphs.

Digraph Embedding for Asymmetric Distance Reconstruction. To assess the quality of learned Finsler embeddings, we first compare embedding results on the full graph, i.e. all nodes, using either the canonical Randers distance or the Euclidean distance in the embedding space \mathbb{R}^m of various dimensions $m \in \{2, 5, 10, 50\}$. The reconstruction errors, analysed with respect to m , provide an indication of the strength of Finsler embeddings. To measure the performance of the learned embedding, we use two common metrics: (i) distortion, defined as the normalised stress $\bar{\sigma}_L(\mathbf{X}) = \binom{N}{2}^{-1} \sigma_L(\mathbf{X})$, where with $L = F^C$ (resp. E) for the canonical Finsler (resp. Euclidean) embedding space, and weights $w_{i,j} = D_{i,j}^{-1}$, and (ii) Mean Average Precision (MAP) score. We embed six digraphs: Cora [89], Citeseer [108], Gr-QC [57], Chameleon [82], Squirrel [82], and Arxiv-Year [47]. For details on these datasets, refer to Appendix D.2. We show the reconstruction performance in Tab. 1. Our results suggest that Finsler embeddings excel in representing digraphs. Indeed, compared to Euclidean representations, the associated distortions are consistently smaller and the accuracy higher, for all digraphs and by a significant margin. Moreover, Finsler embeddings show consistent performance across embedding dimensions m , providing a stable representation even in low dimensions, where they capture the asymmetrical structure effectively. This makes them a practical choice for digraph embedding.

Link Prediction. To assess the generalisation capability of the proposed Finsler embedding, we conduct two link prediction experiments: existence and direction prediction. We compare our method with NERD [51], DiGCN [97], Magnet [112], DiGAE [53], ODIN [109], and DUPLEX [50]. We conduct experiments on the same digraphs as in the embedding task. Here, we split the graph datasets into 80% for training, 15% for testing, and 5% for validation. Performance is assessed by measuring the Area Under the ROC Curve (AUC). We measure the link prediction quality by computing the average performance and standard deviation over 10 random splits. We present in Tab. 2 the link prediction performance of our Finsler embedding and competing baselines. For the link existence prediction task, our method surpasses by a large margin competing methods on all datasets except Squirrel, where our method is competitive with the best one. In the link direction prediction

Table 2. Area Under the ROC Curve (ROC AUC) for the link prediction tasks (the highest in bold and the second highest underlined). For each task, our Finsler embedding largely outperforms existing methods for nearly all datasets, and is on par for the remaining dataset.

task, the Finsler approach achieves the best performance by a significant margin on all datasets except Cora, where it is on par with the best one. For both experiments, our method is either far superior to the baselines by several percentage points, or is comparable to the best baseline within 0.3%. These results demonstrate the superior performance and generalisation of our Finsler method across both tasks.

8. Conclusion

We propose a novel framework for multi-dimensional scaling, called *Finsler MDS*. It extends traditional MDS by embedding data in a Finsler manifold rather than a Riemannian one. By doing so, we naturally accommodate asymmetry in data dissimilarities, which is a notorious blind spot in traditional methods. Inspired by the Euclidean space, we design a simple canonical Finsler space in which to embed asymmetric data, enabling intuitive and computationally efficient representations. Through both theoretical analysis and empirical validation, we demonstrate that Finsler MDS achieves accurate embeddings and preserves essential structures in diverse datasets where asymmetric relationships are critical. We experimentally showcase the ability of Finsler MDS to provide novel insights in a wide range of visualisation applications. We also demonstrate its contribution to the field of graph representation learning providing superior embeddings for node embedding and link prediction, areas where traditional methods fall short. Additionally, we illustrate the flexibility of the Finsler MDS framework by incor-

porating modern tools from both the traditional MDS, and the deep learning communities. We hope that this framework will inspire further research in asymmetric manifold learning and the use of Finsler geometry in computer vision applications, opening pathways for richer data representations and deeper insights into the complex structures underlying high-dimensional asymmetric data, beyond the mainstream Riemannian geometry.

Limitations and Future Work. First, due to asymmetry, providing a closed-form solution of the Finsler MDS embedding is non-trivial. Indeed, the extension of the kernel-based solution for simple cases in Euclidean geometry is not straightforward. Instead, we rely on iterative descent strategies to find a local minimum. Although Finsler MDS extends traditional MDS methods and their Euclidean space by allowing a asymmetric geometrical representation, it similarly leads to increasing distortion the more the data manifold departs from the chosen metric structure. Let us also mention that in the canonical Randers space, all the asymmetry is encoded in a single dimension. However, there might be applications where two independent semantic concepts create asymmetry, and then other Finsler metrics might be preferable to generate disentangled asymmetric embeddings. Finally, let us highlight that the encoding of asymmetry via Finsler geometry extends beyond our dimensionality reduction and embedding applications. Nevertheless, it has been largely understudied for practical applications in computer vision and deserves further attention.

Finsler Multi-Dimensional Scaling: Manifold Learning for Asymmetric Dimensionality Reduction and Embedding

Supplementary Material

This supplemental material is organized as follows:

- **Appendix A** contains the proofs of Theorems 1 and 2 and Propositions 1 and 2 and the details of the derivations for the Finsler stress function (Eq. (7)).
- **Appendices B and C** contain additional theoretical discussions. The former is dedicated to the link between current fields and Randers metrics, while the latter focuses on a generalisation of the Wormhole criterion to Finsler MDS to handle manifolds with missing parts.
- **Appendix D** contains implementation details and additional experiments complementing the visualisation experiments in Sec. 7.1 and the digraph representation learning experiments in Sec. 7.2.

A. Proofs and Derivations

A.1. Proof of Theorem 1

We here provide two proofs of this result. The first uses the Euler-Lagrange equation, a powerful and general tool in the calculus of variations. It can give some insights for generalisation to other metrics. However, given the simplicity of the canonical Randers space, a quick and direct proof is also given.

Euler-Lagrange. In calculus of variations, the Euler-Lagrange equation provides first order optimality necessary conditions on the solution of functionals involving functions $x(t)$ and their derivative $x'(t)$.

Theorem 3 (Euler-Lagrange equation). *If a functional of a smooth scalar function $x(t)$ is given by $\mathcal{L}(x) = \int_0^1 L(t, x(t), x'(t))dt$, where L is a positive smooth function, then the solution minimising the functional \mathcal{L} satisfies the equation*

$$\frac{\partial \mathcal{L}}{\partial x} - \frac{d}{dt} \frac{\partial \mathcal{L}}{\partial x'} = 0.$$

Many generalisations of the Euler-Lagrange equations exist. In our case, when $x(t) = (x_1(t), \dots, x_m(t))^\top \in \mathbb{R}^m$ is multi-dimensional, the Euler-Lagrange equation is duplicated for each output dimension. In other words, the minimum solution satisfies the set of equations

$$\frac{\partial \mathcal{L}}{\partial x_i} - \frac{d}{dt} \frac{\partial \mathcal{L}}{\partial x'_i} = 0 \quad \forall i \in \{1, \dots, m\}. \quad (11)$$

The Euler-Lagrange equations can be used to derive shortest geodesic paths in our canonical Randers space. The length is a functional (Eq. (1)), that can be rewritten from a

Lagrangian perspective as

$$\mathcal{L}_{FC}(\gamma) = \int_0^1 L(t, \gamma(t), \gamma'(t))dt, \quad (12)$$

where

$$L(t, \gamma(t), \gamma'(t)) = F_{\gamma(t)}^C(\gamma'(t)) = \|\gamma'(t)\|_2 + \omega^\top \gamma'(t). \quad (13)$$

Denoting $\gamma = (\gamma_1, \dots, \gamma_m)$ and $\gamma' = (\gamma'_1, \dots, \gamma'_m)$, the Euler-Lagrange equations for this functional are given for all $i \in \{1, \dots, m\}$ by

$$\frac{\partial L}{\partial \gamma_i} - \frac{d}{dt} \frac{\partial L}{\partial \gamma'_i} = 0. \quad (14)$$

Since L does not explicitly depend on γ , but only its derivative, we have that the Euler-Lagrange equations simplify to

$$0 = \frac{d}{dt} \frac{\partial \mathcal{L}}{\partial \gamma'_i} \quad (15)$$

$$= \frac{d}{dt} \left(\frac{\gamma'_i(t)}{\|\gamma'(t)\|_2} + \omega_i \right). \quad (16)$$

In the canonical space, ω is a uniform vector field, as such its coordinates ω_i do not depend on t . Thus, $\frac{d}{dt} \omega_i = 0$. We then have, stacking the Euler-Lagrange equations into vector form, that

$$\frac{d}{dt} \left(\frac{\gamma'(t)}{\|\gamma'(t)\|_2} \right) = 0. \quad (17)$$

Equation (17) is the same as the one we would obtain if $\omega \equiv 0$, i.e. if the metric was Riemannian. It is well-known to describe the equation of a straight line. To see this, if we take $t = s$ to be the Euclidean arclength parametrisation, then $\|\gamma'(s)\|_2 = 1$ and then the Euler-Lagrange equation becomes $\frac{d}{ds} \gamma'(s) = 0$, meaning that $\gamma'(s)$ is constant and thus $\gamma(s)$ is a straight Euclidean line. Shortest paths in the canonical Randers space are thus the straight segments as in the Euclidean space, making it a flat space.

Calculation. To better understand the particular structure of the canonical Randers space, we provide an alternative simple proof. Assume without loss of generality that $\omega = \alpha(0, \dots, 0, 1)^\top$, and denote $\gamma(t) = (x_1(t), \dots, x_m(t))^\top$.

Then

$$\begin{aligned}
\mathcal{L}_{FC}(\gamma) &= \int_0^1 F_{\gamma(t)}(\gamma'(t)) dt \\
&= \int_0^1 (\|\gamma'(t)\|_2 + \omega^\top \gamma'(t)) dt \\
&= \int_0^1 \|\gamma'(t)\|_2 dt + \alpha \int_0^1 x'_m dt \\
&= \int_0^1 \|\gamma'(t)\|_2 dt + \alpha \int_{x_0}^{x_1} dx \\
&= \int_0^1 \|\gamma'(t)\|_2 dt + \alpha(x_1 - x_0). \quad (18)
\end{aligned}$$

The right term is a constant not depending on the curve γ , whereas the left term is the usual functional giving the Euclidean length of the curve γ . Thus, the shortest path in the canonical Randers space is also the shortest path in the Euclidean space, which is given by the Euclidean segment $\gamma(t) = (1-t)x + ty$.

A.2. Proof of Proposition 1

Although the shortest paths are the same in the canonical Randers space and in the Euclidean space, i.e. $\gamma_{x \rightarrow y}^{FC}(t) = (1-t)x + ty$, their lengths are not the same as they depend on the direction of traversal. Since the metric is canonical, it does not depend on the position $\gamma_{x \rightarrow y}^{FC}(t)$. Noticing that $(\gamma_{x \rightarrow y}^{FC})'(t) = y - x$, a direct calculation gives

$$\begin{aligned}
d_{FC}(x, y) &= \mathcal{L}_{FC}(\gamma_{x \rightarrow y}^{FC}) \\
&= \int_0^1 F_{\gamma_{x \rightarrow y}^{FC}}(\gamma_{x \rightarrow y}^{FC})'(t) dt \\
&= \int_0^1 (\|\gamma_{x \rightarrow y}^{FC})'(t)\|_2 + \omega^\top (\gamma_{x \rightarrow y}^{FC})'(t)) dt \\
&= \int_0^1 (\|y - x\|_2 + \omega^\top (y - x)) dt \\
&= \|y - x\|_2 + \omega^\top (y - x). \quad \square \quad (19)
\end{aligned}$$

A.3. Proof of Theorem 2

By assumption, the data can be accurately embedded in the Euclidean space \mathbb{R}^m . Denote $\mathbf{X} \in \mathbb{R}^m$ this solution, with $d(x_i, x_j) = D_{i,j}$ for all pairs (i, j) . Consider now the Finsler MDS problem into the canonical Randers space of dimension \mathbb{R}^{m+1} . Without loss of generality, we can assume that ω is along the last coordinate axis. The embedding $\mathbf{Y} = [\mathbf{X}, 0] \in \mathbb{R}^{N \times (m+1)}$, which is the concatenation of the m -dimensional Euclidean embedding with a last 0 coordinate is the minimal solution. Indeed, since the embedding lies in a hyperplane orthogonal to ω , we have $d_F(x_i, x_j) = d_E(x_i, x_j)$ for all pairs (i, j) . Since the Euclidean embedding is accurate, we have $d_{FC}(x_i, x_j) =$

$D_{i,j}$ for all pairs (i, j) . \square

A.4. Derivation of Eq. (7)

Plugging into the Finsler stress (Eq. (4)) the canonical Randers distances between embedded points (Eq. (6)), we have

$$\begin{aligned}
\sigma^2(\mathbf{X}) &= \sum_{i,j} w_{ij} \|x_j - x_i\|_2^2 \\
&\quad + 2 \sum_{i,j} w_{ij} \|x_j - x_i\|_2 \omega^\top (x_j - x_i)^\top \\
&\quad + \sum_{i,j} w_{ij} (x_j - x_i) \omega \omega^\top (x_j - x_i)^\top \\
&\quad - 2 \sum_{i,j} w_{ij} D_{ij} \|x_j - x_i\|_2 \\
&\quad - 2 \sum_{i,j} w_{ij} D_{ij} \omega^\top (x_j - x_i)^\top + \sum_{i,j} w_{ij} D_{ij}^2. \quad (20)
\end{aligned}$$

As $w_{ij} = w_{ji}$, the second summation term vanishes

$$\begin{aligned}
\sigma^2(\mathbf{X}) &= \sum_{i,j} w_{ij} \|x_j - x_i\|_2^2 \\
&\quad + \sum_{i,j} w_{ij} (x_j - x_i) \omega \omega^\top (x_j - x_i)^\top \\
&\quad - 2 \sum_{i,j} w_{ij} D_{ij} \|x_j - x_i\|_2 \\
&\quad - 2 \sum_{i,j} w_{ij} D_{ij} \omega^\top (x_j - x_i)^\top + \sum_{i,j} w_{ij} D_{ij}^2. \quad (21)
\end{aligned}$$

The terms $\sum_{i,j} w_{ij} \|x_j - x_i\|_2^2$ and $\sum_{i,j} w_{ij} D_{ij} \|x_j - x_i\|_2$ are the ones we would obtain in the traditional SMA-COF algorithm [44], and can be written, respectively, $\text{tr}(\mathbf{X}^\top V \mathbf{X})$ and $\text{tr}(\mathbf{X}^\top B(\mathbf{X}) \mathbf{X})$, with V and B given by Eq. (8) and Eq. (9).

The terms $\sum_{i,j} w_{ij} (x_j - x_i) \omega \omega^\top (x_j - x_i)^\top$ and $\sum_{i,j} w_{ij} D_{ij} \omega^\top (x_j - x_i)^\top$ are specific to the Randers metric, and can be simply written as $\text{tr}(\mathbf{X}^\top V \mathbf{X} \omega \omega^\top)$ and $\text{tr}((W^\top \odot D^\top - W \odot D) \mathbb{1}_m \omega^\top \mathbf{X}^\top)$.

A.5. Proof of Proposition 2

Our proof is based on the *majorisation* approach [32, 44]. Inspired by the traditional SMACOF algorithm, we aim to find a function $g(\cdot, \cdot)$ that satisfies all the following conditions for any points \mathbf{X} and \mathbf{Y} :

- (i) $\sigma^2(\mathbf{X}) = g(\mathbf{X}, \mathbf{X})$,
- (ii) $\sigma^2(\mathbf{X}) \leq g(\mathbf{X}, \mathbf{Y})$ for any \mathbf{Y} ,
- (iii) $g(\mathbf{X}, \mathbf{Y})$ can be easily minimised with respect to \mathbf{X} for any \mathbf{Y} .

For such a function g , the algorithm

$$\mathbf{X}^{(k+1)} = \underset{\mathbf{X}}{\text{argmin}} g(\mathbf{X}, \mathbf{X}^{(k)}) \quad (22)$$

decreases the stress at each iteration as

$$g(\mathbf{X}^{(k)}, \mathbf{X}^{(k)}) \geq g(\mathbf{X}^{(k+1)}, \mathbf{X}^{(k)}) \geq g(\mathbf{X}^{(k+1)}, \mathbf{X}^{(k+1)}). \quad (23)$$

Since the stress $\sigma^2(\mathbf{X}^{(k)}) = g(\mathbf{X}^{(k)}, \mathbf{X}^{(k)})$ decreases at each iteration, the algorithm converges to a local minimum (sandwich theorem).

We now look for a suitable function g . From the derivation of the stress function in Eq. (21), we have

$$\begin{aligned} \sigma^2(\mathbf{X}) &= \text{tr}(\mathbf{X}^\top V \mathbf{X}) + \text{tr}(\mathbf{X}^\top V \mathbf{X} \omega \omega^\top) \\ &\quad + 2 \text{tr}(C \mathbf{X}^\top) - 2 \text{tr}(\mathbf{X}^\top B(\mathbf{X}) \mathbf{X}), \end{aligned} \quad (24)$$

As in the traditional SMACOF [10], the Cauchy-Schwarz inequality implies that

$$\text{tr}(\mathbf{X}^\top B(\mathbf{X}) \mathbf{X}) \geq \text{tr}(\mathbf{X}^\top B(\mathbf{Y}) \mathbf{Y}) = \mu(\mathbf{X}, \mathbf{Y}). \quad (25)$$

We thus have

$$\sigma^2(\mathbf{X}) \leq g(\mathbf{X}, \mathbf{Y}), \quad (26)$$

where

$$\begin{aligned} g(\mathbf{X}, \mathbf{Y}) &= \text{tr}(\mathbf{X}^\top V \mathbf{X}) + \text{tr}(\mathbf{X}^\top V \mathbf{X} \omega \omega^\top) \\ &\quad + 2 \text{tr}(C \mathbf{X}^\top) - 2\mu(\mathbf{X}, \mathbf{Y}). \end{aligned} \quad (27)$$

To implement the majorisation update rule (Eq. (22)), we need to compute the gradient of $g(\cdot, \mathbf{X}^{(k)})$ (Eq. (27)). We have

$$\begin{aligned} \nabla_{\mathbf{X}} g(\mathbf{X}^{(k+1)}, \mathbf{X}^{(k)}) &= 2V \mathbf{X}^{(k+1)} + 2V \mathbf{X}^{(k+1)} \omega \omega^\top \\ &\quad + 2C - 2B(\mathbf{X}^{(k)}) \mathbf{X}^{(k)}. \end{aligned} \quad (28)$$

Since $\mathbf{X}^{(k+1)}$ minimises g (Eq. (22)), the first-order optimality conditions lead to

$$2V \mathbf{X}^{(k+1)} + 2V \mathbf{X}^{(k+1)} \omega \omega^\top + 2C = 2B(\mathbf{X}^{(k)}) \mathbf{X}^{(k)}. \quad (29)$$

The terms in $\mathbf{X}^{(k+1)}$ are linear, we can thus pseudo-invert this system of equations to get the update rule. Recall how to rewrite a linear system of equations to only have the unknowns to the right of the coefficient matrix.

Lemma 1. *For any matrices A , X , and C , we have*

$$AXB = C \iff (B^\top \otimes A) \text{vec}(X) = \text{vec}(C).$$

Applying this rewrite to the linear system of equations Eq. (29), we get the desired update rule

$$\text{vec}(\mathbf{X}^{(k+1)}) = K^\dagger \text{vec}(B(\mathbf{X}^{(k)}) \mathbf{X}^{(k)} - C), \quad (30)$$

where $K = (I_m + \omega \omega^\top) \otimes V$ is a Kronecker matrix.

B. The Relationship between Current Fields and Randers Metrics

The search of shortest-time trajectories in a medium with time-independent wind is an old problem first studied by Ernst Zermelo [111] and is called the *Zermelo navigation problem*. In fact, it has turned out to be such an important question that it can be used to explain causality in space-time [17]. In the presence of wind $v(x)$, unit balls of the

Finsler metric F_x are offset by $v(x)$. To remain in a Finsler space, where 0 is inside unit balls, the wind must have a small magnitude $F_x(-v(x)) < 1$. Note that in the presence of large winds, the wind implies irreversible displacements, explaining the irreversibility of time and causality in the world. However, the obtained metric in large winds is no longer a Finsler metric.

Consider the traditional case of a Riemannian manifold \mathcal{X} . For notational simplicity, we will drop the explicit dependence on x . The Riemannian metric is written as $R(u) = \|u\|_M$. Consider a wind with small magnitude $\|v\|_{M^{-1}} < 1$. The Zermelo metric F , which provides the Finsler metric measuring the traversal time of agents along curves on \mathcal{X} with wind v is given by the equation [92]

$$R\left(\frac{u}{F(u)} - v\right) = 1. \quad (31)$$

Solving this equation with respect to $F(u)$ yields the Zermelo metric given by

$$F(u) = \|u\|_{M_v} + \omega_v^\top u, \quad (32)$$

where

$$M_v = \frac{1}{(1 - \|u\|_M^2)^2} (M v v^\top M + (1 - \|v\|_M^2) M), \quad (33)$$

$$\omega_v = -\frac{1}{1 - \|v\|_M^2} M v. \quad (34)$$

The Zermelo metric is thus a Randers Finsler metric. In particular, note that for the traditional isotropic Riemannian metric with $M = I$, and a small current $\|v\|_2^2 \ll 1$, then $M_v \approx M$ and the Randers drift component becomes $\omega_v \approx -v$. As we work on synthetic current data with $M = I$, we make the simplifying approximation when computing the Zermelo-Randers metric that it is given by $F(u) = \|u\|_2 - v^\top u$. Thus our Randers linear drift component is given by the opposite of the current field.

C. Wormhole Finsler MDS

Our Finsler MDS formulation allows to use non-uniform weights $w_{i,j}$ in the Finsler stress function, similar to regular MDS approaches. Here, we focus on generalising the recent state-of-the-art method WHCIE [12] for computing theoretically guaranteed consistent pairs of points on manifolds sampled with missing parts. It was originally motivated for improving unsupervised shape matching to handle partial shapes by filtering out inconsistent pairs from the Gromov-Wassertein loss [11]. We first present the existing approaches in Riemannian manifolds and then focus on our generalisation to Finsler manifolds.

Riemannian wormhole criterion. Let $\tilde{\mathcal{X}}$ be a Riemannian data manifold (without missing parts) and $\tilde{\mathcal{Y}} \subset \tilde{\mathcal{X}}$ be a version of the data manifold that is missing some parts $\tilde{\mathcal{Y}} \neq \tilde{\mathcal{X}}$. Let $\tilde{\mathbf{X}}$ be sampled data on $\tilde{\mathcal{Y}}$ (and thus also on $\tilde{\mathcal{X}}$). Data dis-

similarities are computed as shortest path distances. However, depending on whether we are given the full manifold $\tilde{\mathcal{X}}$ or the partial one $\tilde{\mathcal{Y}}$, the computed data dissimilarities $D_{\tilde{\mathcal{X}}}$ and $D_{\tilde{\mathcal{Y}}}$, computed respectively on $\tilde{\mathcal{X}}$ and $\tilde{\mathcal{Y}}$, might differ. This is due to the fact that geodesic trajectories in the full manifold $\tilde{\mathcal{X}}$ might pass through missing parts of $\tilde{\mathcal{Y}}$ making shortest paths on $\tilde{\mathcal{Y}}$ longer for some pairs of points. As the data dissimilarities differ, optimising the stress function with each of them and using the same uniform weight scheme $w_{i,j} = 1$ for all pairs will lead to different embeddings $\mathbf{X} \neq \mathbf{Y}$. The objective here is to design a different strategy on the weights $w_{i,j}$ such that the resulting embeddings are as close as possible $\mathbf{X} \approx \mathbf{Y}$, meaning that the scheme is robust to missing parts.

Pairs of points x_i and x_j are said to be consistent if their shortest path distances $(D_{\tilde{\mathcal{X}}})_{i,j} = (D_{\tilde{\mathcal{Y}}})_{i,j}$ are consistent on the full $\tilde{\mathcal{X}}$ and partial $\tilde{\mathcal{Y}}$ shapes. In practice, a majority of pairs is consistent [12], but a significant amount of pairs are inconsistent, leading to incorrect geodesic dissimilarity estimates in the partial case affecting the embedding. To mitigate this effect, a natural approach is to filter out inconsistent pairs by masking out their contribution to the stress function. This translates to choosing a weight scheme $w_{i,j} \in \{0, 1\}$, with $w_{i,j} = 1$ only for consistent pairs. One way of proceeding is to use heuristics for short distance computations and focus only on local pairs [87]. More recently, another paradigm has shown impressive results [12, 79]. Rather than focusing on local pairs, the idea is to design a criterion that can guarantee whether a pair is consistent. Guaranteeing means that there is theoretically no false alarm possible by the criterion: only consistent pairs are found. More general criteria find more consistent pairs, allowing the method to use more non-perturbed information to find the embedding.

A common misconception is to believe that shortest paths not intersecting the boundary $\tilde{\mathcal{B}} = \delta\tilde{\mathcal{Y}}$ provide consistent pairs, as was debunked in [12]. Rather than focusing on the intersection with the boundary of the partial manifold, the distances to the boundary were used to define the criteria. Let $\tilde{x}_{i_{\tilde{\mathcal{B}}}}$ and $\tilde{x}_{j_{\tilde{\mathcal{B}}}}$ be the closest boundary points to \tilde{x}_i and \tilde{x}_j on the partial shape $\tilde{\mathcal{Y}}$,

$$\tilde{x}_{i_{\tilde{\mathcal{B}}}} = \operatorname{argmin}_{\tilde{x}_b \in \tilde{\mathcal{B}}} (D_{\tilde{\mathcal{Y}}})_{i,b} \quad \text{and} \quad \tilde{x}_{j_{\tilde{\mathcal{B}}}} = \operatorname{argmin}_{\tilde{x}_b \in \tilde{\mathcal{B}}} (D_{\tilde{\mathcal{Y}}})_{j,b}. \quad (35)$$

In [14, 79], a first criterion $\mathcal{C}_{\mathcal{T}} : \tilde{\mathcal{Y}} \times \tilde{\mathcal{Y}} \rightarrow \{0, 1\}$ was proposed

$$\mathcal{C}_{\mathcal{T}}(\tilde{x}_i, \tilde{x}_j) = \mathbb{1}_{(D_{\tilde{\mathcal{Y}}})_{i,j} \leq (D_{\tilde{\mathcal{Y}}})_{i,i_{\tilde{\mathcal{B}}}} + (D_{\tilde{\mathcal{Y}}})_{j,j_{\tilde{\mathcal{B}}}}}, \quad (36)$$

where $\mathbb{1}$ is the indicator function. The idea behind this criterion is that if geodesic paths on the full manifold $\tilde{\mathcal{X}}$ between points \tilde{x}_i and \tilde{x}_j should pass through missing parts in $\tilde{\mathcal{Y}}$, then their length is at least the sum of the distances to the boundary $\tilde{\mathcal{B}}$. However, this intrinsic criterion is particularly

conservative as it discards the length of this trajectory between boundary points, since information on the manifold is lost inside missing parts. Recently, [12] lifted extrinsic information to provide a worst case bound on the length of paths between boundary points. If the Riemannian metric on the manifold is the standard one given by the identity matrix, then trajectories between boundary points on the manifold are at least longer than the length of the straight segment in the original Euclidean embedding space \mathbb{R}^n

$$(D_{\tilde{\mathcal{X}}})_{b_1, b_2} \geq d_E(\tilde{x}_{b_1}, \tilde{x}_{b_2}) \quad (37)$$

for any boundary points \tilde{x}_{b_1} and \tilde{x}_{b_2} . From this simple observation, [12] generalised the $\mathcal{C}_{\mathcal{T}}$ criterion to the *wormhole criterion* $\mathcal{C}_{\mathcal{W}} : \tilde{\mathcal{Y}} \times \tilde{\mathcal{Y}} \rightarrow \{0, 1\}$ defined as

$$\mathcal{C}_{\mathcal{W}}(\tilde{x}_i, \tilde{x}_j) = \mathbb{1}_{(D_{\tilde{\mathcal{Y}}})_{i,j} \leq \mathbf{K}_{i,j}^E}, \quad (38)$$

where the threshold matrix $\mathbf{K}_{i,j}^E$ is computed as

$$\mathbf{K}_{i,j}^E = \min_{\tilde{x}_{b_1}, \tilde{x}_{b_2} \in B} (D_{\tilde{\mathcal{Y}}})_{i,b_1} + (D_{\tilde{\mathcal{Y}}})_{j,b_2} + d_E(\tilde{x}_{b_1}, \tilde{x}_{b_2}). \quad (39)$$

For more general Riemannian metrics on the manifold, [12] showed how to generalise the wormhole criterion. The idea is to provide a worst case bound on the distance of each infinitesimally small Euclidean arclength step along the straight Euclidean segment between boundary points. Denote $\lambda_{\tilde{M}} > 0$ to be the minimum eigenvalue of the Riemannian metric \tilde{M} over the full manifold $\tilde{\mathcal{X}}$, and can be assumed to be given. By bounding the Riemannian length of Euclidean arclength steps along curves, Eq. (37) becomes

$$(D_{\tilde{\mathcal{X}}})_{b_1, b_2} \geq \sqrt{\lambda_{\tilde{M}}} d_E(\tilde{x}_{b_1}, \tilde{x}_{b_2}) \quad (40)$$

for any boundary points $\tilde{x}_{b_1}, \tilde{x}_{b_2} \in \tilde{\mathcal{B}}$. The wormhole criterion then becomes

$$\mathcal{C}_{\mathcal{W}}(\tilde{x}_i, \tilde{x}_j) = \mathbb{1}_{(D_{\tilde{\mathcal{Y}}})_{i,j} \leq \mathbf{K}_{i,j}^R} \quad (41)$$

where the generalised Riemannian threshold matrix \mathbf{K}^R is now

$$\mathbf{K}_{i,j}^R = \min_{\tilde{x}_{b_1}, \tilde{x}_{b_2} \in B} (D_{\tilde{\mathcal{Y}}})_{i,b_1} + (D_{\tilde{\mathcal{Y}}})_{j,b_2} + \sqrt{\lambda_{\tilde{M}}} d_E(\tilde{x}_{b_1}, \tilde{x}_{b_2}). \quad (42)$$

The criteria $\mathcal{C}_{\mathcal{T}}(x_i, x_j)$ and $\mathcal{C}_{\mathcal{W}}(x_i, x_j)$ are chosen to be the weights $w_{i,j}$ for the TCIE [79] and WHCIE [12] methods respectively. In particular, WHCIE demonstrates impressive robustness and forms the current state-of-the-art in finding consistent pairs on Riemannian manifolds.

The core idea behind the wormhole criterion is in Eqs. (37) and (40), that find how to lower bound the manifold's metric length of Euclidean arclength infinitesimal steps. We propose to take this idea and apply it to Finsler manifolds.

Finsler wormhole criterion. Assume now that the data manifold $\tilde{\mathcal{X}}$ is equipped with a Finsler metric \tilde{F} and that there exists $C_{\tilde{F}} > 0$ such that the Finsler length of infinitesimal Euclidean arclength steps $d\tilde{s}$ is bounded by

$\tilde{F}_{\tilde{x}}(d\tilde{s}) \geq C_{\tilde{F}} \|d\tilde{s}\|_2$. Then the Finsler length of curves between boundary points can be lower bounded using the Euclidean embedding distance.

Proposition 3. *The Finsler distance on the Finsler manifold $\tilde{\mathcal{X}}$ between any points x_i and x_j is lower bounded by*

$$(\mathbf{D}_{\tilde{\mathcal{X}}})_{i,j} \geq C_{\tilde{F}} d_E(\tilde{x}_i, \tilde{x}_j)$$

Proof. The proof is an immediate generalisation of the arguments in the Riemannian case. By integrating the lower bound on Euclidean arclength steps $\tilde{F}_{\tilde{x}}(d\tilde{s}) \geq C_{\tilde{F}} \|d\tilde{s}\|_2$, and since the euclidean length of any curve between x_i and x_j is at least that of the Euclidean straight segment between them, we get the desired lower bound. \square

Denote \mathbf{K}^F the generalised Finsler threshold matrix

$$\mathbf{K}_{i,j}^F = \min_{\tilde{x}_{b_1}, \tilde{x}_{b_2} \in B} (\mathbf{D}_{\tilde{\mathcal{Y}}})_{i,b_1} + (\mathbf{D}_{\tilde{\mathcal{Y}}})_{b_2,j} + C_{\tilde{F}} d_E(\tilde{x}_{b_1}, \tilde{x}_{b_2}). \quad (43)$$

We can then define the Finsler wormhole criterion $\mathcal{C}_{\mathcal{W}_{\mathcal{F}}}$.

Definition 4 (Finsler wormhole criterion). *The Finsler wormhole criterion $\mathcal{C}_{\mathcal{W}_{\mathcal{F}}}$ is defined as*

$$\mathcal{C}_{\mathcal{W}_{\mathcal{F}}}(\tilde{x}_i, \tilde{x}_j) = \mathbb{1}_{(\mathbf{D}_{\tilde{\mathcal{Y}}})_{i,j} \leq \mathbf{K}_{i,j}^F}.$$

By construction, the Finsler wormhole criterion only finds consistent pairs.

Theorem 4 ($\mathcal{C}_{\mathcal{W}_{\mathcal{F}}}$ guarantees consistent pairs). *The Finsler wormhole criterion guarantees found pairs to be consistent.*

Proof. The proof follows the exact same arguments as in the Riemannian case, where now Eqs. (37) and (40) are replaced with Proposition 3. \square

We thus propose the weight scheme $w_{i,j} = \mathcal{C}_{\mathcal{W}_{\mathcal{F}}}(\tilde{x}_i, \tilde{x}_j)$ for Finsler MDS to provide robust embeddings to missing components. For optimisation algorithms requiring a symmetric weight scheme, such as our Finsler Smacof algorithm, we symmetrise it by taking the intersection $w_{i,j} = \sqrt{\mathcal{C}_{\mathcal{W}_{\mathcal{F}}}(\tilde{x}_i, \tilde{x}_j) \mathcal{C}_{\mathcal{W}_{\mathcal{F}}}(\tilde{x}_j, \tilde{x}_i)}$. Note that the square root is superfluous for binary criteria, but is not so when considering soft masks. In [12], the criterion is sometimes softened by considering the ratio between the computed shortest path lengths and the criterion matrix, and cutting it off to 1. This allows to take into account almost consistent pairs where there is only a small perturbation of the true geodesic distance, providing a reasonable compromise between accuracy and amount of data to rely on. We can soften our criterion in the same fashion by taking: $\min \left\{ \frac{\mathbf{K}_{i,j}^F}{\mathbf{D}_{i,j}}, 1 \right\}$.

We now show in a useful example how to derive the Finsler constant $C_{\tilde{F}}$ when the Finsler metric is a Randers metric with isotropic uniform Riemannian component $\tilde{F}_{\tilde{x}}(u) = \|u\|_2 + \tilde{\omega}(\tilde{x})^\top u$. Taking $u = d\tilde{s}$ to be an infinitesimal Euclidean arclength tangent vector, its Finsler

length becomes minimal when $d\tilde{s}$ is oppositely aligned with the Randers drift component $\tilde{\omega}(\tilde{x})$. This leads to $\tilde{F}_{\tilde{x}}(d\tilde{s}) \geq (1 - \|\tilde{\omega}(\tilde{x})\|_2) \|d\tilde{s}\|_2$. Assuming the knowledge of $\tilde{\alpha}_{\max} = \max_{\tilde{x}} \|\tilde{\omega}(\tilde{x})\|_2 < 1$, for instance if we are provided with the maximum possible norm of the current on the manifold, we get $\tilde{F}_{\tilde{x}}(d\tilde{s}) \geq (1 - \tilde{\alpha}_{\max}) \|d\tilde{s}\|_2$, meaning that $C_{\tilde{F}} = 1 - \tilde{\alpha}_{\max}$.

D. Implementation Details and Additional Experiments

D.1. Data Visualisation Experiments

We describe the implementation details in Appendix D.1.1 of experiments in Sec. 7.1 and present additional visualisation results in Sec. 7.1. These simple experiments do not require any advanced hardware, e.g. a commercial CPU suffices.

D.1.1 Implementation Considerations

In the visualisation experiments, we embed data with Finsler MDS into the canonical Randers space $\mathcal{X} = \mathbb{R}^m$, with $m \in \{2, 3\}$. The canonical Randers metric is chosen to have the fixed asymmetry level $\alpha = 0.5$. All Finsler MDS embeddings for visualisation are computed with the Finsler SMACOF algorithm. Unless specified otherwise, they use uniform weights $w_{i,j}$. Recall that the traditional SMACOF algorithm is well-known to be sensitive to initialisation. To avoid getting stuck in bad local minima, it is considered standard practice to initialise it with the Isomap [88, 96] embedding, even if the weights $w_{i,j}$ are not uniform. Following this idea, we initialise the SMACOF algorithm with the Isomap embedding to \mathbb{R}^m applied to the symmetrised dissimilarity matrix $\mathbf{D}^S = \frac{\mathbf{D} + \mathbf{D}^\top}{2}$.

In practice, we found that pseudo-inverting the K matrix for the Finsler SMACOF update (see Proposition 2) was slow and unstable when there are many data points. To overcome this issue, we first multiplied Eq. (29) by V^\top leading to a more stable update rule requiring the pseudo-inversion of a symmetric matrix

$$\text{vec}(\mathbf{X}^{k+1}) = (\mathbf{K}')^\dagger \text{vec}(\mathbf{B}'(\mathbf{X}^k) \mathbf{X}^k - \mathbf{C}'), \quad (44)$$

where the matrices \mathbf{K}' , $\mathbf{B}'(\mathbf{X}^k)$, and \mathbf{C}' are the modified matrices $\mathbf{K}' = (\mathbf{I}_m + \omega\omega^\top) \otimes (\mathbf{V}^\top \mathbf{V})$, $\mathbf{B}'(\mathbf{X}^k) = \mathbf{V}^\top \mathbf{B}(\mathbf{X}^k)$, and $\mathbf{C}' = \mathbf{V}^\top \mathbf{C}$. In addition, we resorted to the Generalized Minimal Residual method (GMRES) [83], which is a fast alternative solver of linear systems, bypassing the need to compute the Moore-Penrose pseudo-inverse of the large matrix $(\mathbf{K}')^\dagger$ when the number of points N is large. We share the seeded code to reproduce our data and results.

Asymmetric Manifold Flattening. In this experiment from

the main paper and the additional one in the supplementary, we sample $N = 3000$ i.i.d. random vertices from the Swiss roll. The unit Euclidean vector $\tilde{\omega}$, giving the direction of the Randers metric equipping the Swiss roll, is chosen to be intrinsically uniform along the length of the Swiss roll. Note that although they are intrinsically uniform in the tangent planes $\mathcal{T}_{\tilde{x}}\tilde{\mathcal{X}} = \mathbb{R}^2$, they are not uniform extrinsically when rotating these planes to be tangent to the original embedding of the Swiss roll, as shown for instance in Fig. 2. Denote $\hat{\omega}(\tilde{x}) \in \mathbb{R}^3$ the extrinsic embedding of $\tilde{\omega}$ in the original embedding space \mathbb{R}^3 of the Swiss roll manifold $\tilde{\mathcal{X}}$. To compute the asymmetric geodesic distances, we compute the symmetric k-Nearest Neighbour (kNN) graph, with $k = 10$, based on the Euclidean distances in \mathbb{R}^3 . Once the logical graph is computed, we compute the distances on these edges using a first order approximation. If points \tilde{x}_i and \tilde{x}_j are neighbours, we approximate $d_{\tilde{F}^{\tilde{\alpha}}}(x_i, x_j) \approx \|x_j - x_i\|_2 + \tilde{\alpha}\hat{\omega}(x_i)^\top(x_j - x_i)$, and assign this distance to the directed edge from node i to node j , and vice versa for the directed edge from node j to node i . This procedure, which generalises the standard Isomap [88, 96] approach, constructs an asymmetric weighted kNN directed graph. We can now apply Dijkstra’s algorithm [34] to compute the approximate geodesic distances between all pairs of points. The results form the dissimilarity matrix D , which is the input for the embedding algorithm. The result in Fig. 2 corresponds to $\tilde{\alpha} = 0.3$.

Robustness to Holes. In this experiment, 2000 i.i.d. points are sampled on the full Swiss roll, but points falling within a rectangular region encoding the hole are removed. The Randers metric equipping the manifold $\tilde{\mathcal{X}}$ is the same as in the *Asymmetric Manifold Flattening* experiments on the Swiss roll with $\tilde{\alpha} = 0.5$. We apply the same algorithm to compute the Randers distance between points, with $k = 15$ in the kNN graph construction. To create an embedding that is robust to the missing part, the weights are given by the binary Finsler wormhole criterion, logically symmetrised: $w_{i,j} = \sqrt{\mathcal{C}_{\mathcal{W}_{\mathcal{F}}}(\tilde{x}_i, \tilde{x}_j)\mathcal{C}_{\mathcal{W}_{\mathcal{F}}}(\tilde{x}_j, \tilde{x}_i)}$ (see Appendix C). To compute the wormhole criterion, we assume that the metric is behaved in the missing parts similarly to the rest of the data, leading to a choice of $\tilde{\alpha}_{\max} = \tilde{\alpha}$ to compute the constant $C_{\tilde{F}}$ in Proposition 3.

Unflattening Current Maps. In this experiment from the main paper and the additional one in the supplementary (corresponding to Fig. 8), we sample N i.i.d. random points in a rectangular region $\tilde{\Omega}$ of the plane \mathbb{R}^2 . Given an unconstrained current $\check{v}(\tilde{x}_i) \in \mathbb{R}^2$ at any point $\tilde{x}_i \in \tilde{\Omega}$, the current is then chosen to be $\tilde{v}(\tilde{x}_i) = \tilde{\alpha} \frac{\check{v}(\tilde{x}_i)}{\max_j \|\check{v}(\tilde{x}_j)\|_2}$. The Randers metric at the sampled point \tilde{x}_i is then chosen to be $\tilde{F}(\tilde{x}_i) = \|u\|_2 - \tilde{v}(\tilde{x}_i)^\top u$ (see Appendix B). We then apply the same algorithm as in the *Asymmetric Manifold*

Flattening experiment on the Swiss roll to compute Randers geodesic distances, using a kNN graph with $k = 10$ neighbours. Note that since the original space and its tangent space coincide $\tilde{\mathcal{X}} = \mathcal{T}_{\tilde{x}}\tilde{\mathcal{X}}$ at all points \tilde{x} , the extrinsic embedding of the drift component $\tilde{\omega}(\tilde{x}) = -\tilde{v}(\tilde{x})$ is the same as its intrinsic version $\hat{\omega}(\tilde{x}) = \tilde{\omega}(\tilde{x})$.

For the experiment in the main paper, we sample $N = 2000$ points from the domain $\tilde{\Omega} = [0, 10]^2$. At any point $\tilde{x}_i = (\tilde{x}_i^{(1)}, \tilde{x}_i^{(2)})^\top \in \tilde{\Omega}$, we define the unconstrained current field $\check{v}(\tilde{x}_i) = (\sin(\nu\tilde{x}_i^{(1)}) + \cos(\nu\tilde{x}_i^{(2)}), \cos(\nu\tilde{x}_i^{(1)}) - \sin(\nu\tilde{x}_i^{(2)}))^\top$, with $\nu = 2$. The current field is constructed with $\tilde{\alpha} = 0.5$. For the river experiment in the supplementary, we sample $N = 1000$ points from the domain $\tilde{\Omega} = [0, 10] \times [0, 1]$. The unconstrained current at point \tilde{x}_i is given by $\check{v}(\tilde{x}_i) = (1 - |2\tilde{x}_i^{(2)} - 1|, 0)^\top$. The current is then constructed with $\tilde{\alpha} = 0.2$.

Revealing Graph Hierarchies In this experiment, we construct a full and complete binary tree of depth $h = 7$, having thus $N = 2^{h+1} - 1 = 255$ nodes. The edge from a parent to its child is given the weight of 0.5, whereas the edge from a child to its parent has a weight of 1.5. Additionally, we add undirected edges between all nodes at the same height, with a weight of 0.1. Given two nodes connected by an edge, their distances is given by the edge weight. Asymmetric geodesic distances between any two nodes are then computed using Dijkstra’s algorithm, which constitute the dissimilarity matrix D .

D.1.2 Additional Results

Figure 6. Flattening the Swiss roll equipped with a Randers metric $\tilde{F}^{\tilde{\alpha}}$ with various asymmetry levels $\tilde{\alpha}$ given by $\tilde{F}^{\tilde{\alpha}}(u) = \|u\|_2 + \tilde{\alpha}\tilde{\omega}^\top u$ and $\|\tilde{\omega}\|_2 = 1$. We superimpose on the right the resulting Finsler MDS embeddings in the 3D canonical Randers space with fixed asymmetry $\alpha = \|\omega\|_2$.

Asymmetric Manifold Flattening. By changing the value of $\tilde{\alpha}$, we vary the amount of asymmetry on the Swiss roll. However, in this experiment, we do not change the asymmetry measure of the canonical Randers space of the embed-

dings: α is fixed. We superimpose in Fig. 6 the resulting Finsler MDS embeddings for various asymmetry levels of the data $\tilde{\alpha} \in \{0, 0.1, 0.3, 0.5, 0.6\}$. In all cases, the embedded Swiss roll resembles a flat 2D band in 3D, albeit with varying vertical orientation. As expected, the higher the value of $\tilde{\alpha}$, the more the embedded Swiss roll becomes vertical along the axis \tilde{z} of asymmetry. When the data is (close to) symmetric, i.e. $\tilde{\alpha}$ is (close to) 0, the embedding is (close to) aligned with the xy plane. Finsler MDS thus not only provides embeddings preserving the manifold structure, but its verticality also provides an intuitive visual cue encoding the asymmetry of the data.

Figure 7. Flattening the original symmetric Swiss roll. The embedding is either into the Euclidean space \mathbb{R}^3 with Isomap or into the canonical Randers space \mathbb{R}^3 with our Finsler MDS. Finsler MDS provides robust embeddings that generalises traditional symmetric embedding methods on symmetric data while revealing the additional information that the data is symmetric.

Symmetric Manifold Flattening. We focus on the embedding of the vanilla symmetric Swiss roll, i.e. $\tilde{\alpha} = 0$, to \mathbb{R}^3 using either the traditional MDS, with Isomap, or Finsler MDS, with our Finsler SMACOF algorithm. These results are presented without other values of $\tilde{\alpha}$ in Fig. 7. For the Isomap embedding to \mathbb{R}^3 , the Swiss roll is not perfectly flattened in the xy hyperplane. This incorrectly suggests that the Swiss roll is not a flat Riemannian structure, i.e. with effectively 0 Gaussian curvature. This error is due to small noise in the estimate of the distance matrix D as Dijkstra’s algorithm only provides an approximation to geodesic distances as geodesic paths are constrained to live on the neighbourhood graph constructed from the data. To avoid this issue, the Swiss roll is usually embedded to \mathbb{R}^2 , yielding the desired 2D flattened Swiss roll rectangle. In contrast, our Finsler MDS embedding to the canonical Randers space \mathbb{R}^3 is flattened to the xy plane and is similar to the ideal 2D Isomap embedding, as predicted by Theorem 2. Additionally, our embedding also provides the information that the original Swiss roll is a symmetric structure as all embedded points have the same height. As such, Finsler MDS not only robustly provides superior embeddings for symmetric data that generalise the traditional methods, it also yields additional information compared to them.

Dataset	Cora	Citeseer	Gr-QC	Chameleon	Squirrel	Arxiv-Year
$ \mathcal{V} $	2,708	3,327	5,242	2,277	5,201	169,343
$ \mathcal{E} $	5,429	4,552	14,496	31,371	198,353	1,166,243

Table 3. Summary of dataset statistics for link prediction tasks. We note $|\mathcal{V}|$ and $|\mathcal{E}|$ the numbers of nodes and edges, respectively.

Unflattening Current Maps. In addition to the unflattening of the current map in Fig. 4, we also embed using Finsler MDS the classic river manifold in Fig. 8. As explained in Appendix B, from a timewise perspective, we equip the river with a Randers field with $\tilde{\omega} = -\tilde{v}$, where \tilde{v} is the current field. The Finsler MDS embedding of the river leads to an intuitive embedding clearly revealing the existence of asymmetry between points upstream and downstream. This contrasts with the original current map, even when enriched with arrows to artificially break the Euclidean symmetry, as they can be difficult to discern when numerous or with low magnitude.

D.2. Digraph Embedding and Link Prediction Experiments Implementation Details

We describe the setups and additional details of our experiments in Sec. 7.2. The experiments are performed on a NVIDIA DGX A100 GPU.

Datasets. For both the digraph embedding and link prediction tasks, we evaluate on six publicly available directed graph datasets: the citation networks Cora [89] and Citeseer [108], the arXiv collaboration network in general relativity and quantum cosmology (Gr-QC) [57], and three heterophilic graphs: Chameleon, Squirrel [82], and Arxiv-Year [47]. The detailed statistics of these benchmarks are summarized in Tab. 3.

Digraph Embedding Baseline. To utilize the directional property for learning efficient representations, we propose computing embeddings in Finsler space instead of Euclidean space. We note that while [60] explores a Finsler-Riemannian framework for graph embedding, their approach is not applicable to directed graphs. Therefore, we do not include comparisons between their framework and our Finsler representation for digraph embedding.

Link Prediction Baseline. For link prediction tasks, we compare our method with NERD [51], DiGCN [97], MagNet [112], DiGAE [53], ODIN [109], and DUPLEX [50]. NERD is a shallow method that uses node semantics based on a random walk strategy to sample node neighbourhoods from a directed graph. DiGCN introduces a spectral Graph Neural Network (GNN) model built on digraph convolution, utilizing Personalized PageRank as its foundation. MagNet

Figure 8. Embedding of the river map with a fixed current profile \tilde{v} . The associated Randers drift component $\tilde{\omega}$ is in the opposite direction. Plotting arrows on the map might lead to cluttered visualisations that make the asymmetry difficult to read even in this simple toy example. In contrast the Finsler MDS embedding clearly reveals the asymmetric nature of the river while preserving its spatial straight property.

proposes the magnetic Laplacian to define graph convolutions. Both DiGCN and MagNet are spectral-based methods. DiGAE is a digraph autoencoder model that employs a directed GCN as its encoder. ODIN is a recent shallow method that learns multiple embeddings per node to model directed edge formation factors while disentangling interest factors from in-degree and out-degree biases. DUPLEX employs dual graph attention network encoders that operate on a Hermitian adjacency matrix.

Digraph Embedding Setup. To assess the capacity of the Euclidean and Finsler representations, we embed the full data with a Multi-Layer Perceptron (MLP) and compute the pairwise distances in the embedding space. We implement our proposed method using PyTorch [72]. We train the Euclidean embedding with Euclidean stochastic gradient descent. Riemannian stochastic gradient descent [8] generalises classical stochastic gradient descent to optimization on Riemannian manifolds by replacing Euclidean updates with retractions that map stochastic gradients from tangent spaces back onto the manifold. For the Finsler embedding, we train the embedding by adapting the Riemannian stochastic gradient descent from the Riemannian metric with the canonical Randers metric defined in Sec. 5. We consider the embedding space \mathbb{R}^m of various dimensions $m \in \{2, 5, 10, 50\}$. For each dimension m , we use the Optuna [2] hyperparameter optimiser to choose the learning rate, the number of hidden layers, the hidden dimension, and the dropout probability within candidate sets. These candidate sets are $\{5e^{-1}, 3e^{-1}, 2e^{-1}, 1e^{-1}, 5e^{-2}, 1e^{-2}, 5e^{-3}, 1e^{-3}\}$ for the learning rate, $\{1, 2, 3, \dots, 10\}$ for the number of hidden layers, $\{64, 128, 256, 512\}$ for the hidden dimension, and $\{0, 0.1, 0.2, \dots, 0.9\}$ for the dropout probability.

Link Prediction Setup. We evaluate on two types of link prediction tasks. The first task involves predicting the direction of edges between vertex pairs u and v , where it is known that there exists an edge between the two vertices but not its direction: $(u, v) \in \mathcal{E}$ or $(v, u) \in \mathcal{E}$. The sec-

ond task focuses on existence prediction, where the goal is to determine whether $(u, v) \in \mathcal{E}$, considering vertex pairs (u, v) . For link prediction tasks, we divide the graph datasets, by partitioning the edges randomly while preserving the graph connectivity, into 80% (of edges) for training, 15% (of edges) for testing, and 5% (of edges) for validation, following the work [112]. Performance is assessed by measuring the Area Under the ROC Curve (AUC). The link prediction quality is computed by the average performance and standard deviation over 10 random splits. We utilize the source code released by the authors for the baseline algorithms and optimize their hyperparameters using Optuna [2].
