# Improved Runtime Analysis of a Multi-Valued Compact Genetic Algorithm on Two Generalized OneMax Problems

Sumit Adak Carsten Witt

DTU Compute Technical University of Denmark Kgs. Lyngby, Denmark {suad, cawi}@dtu.dk

#### Abstract

Recent research in the runtime analysis of estimation of distribution algorithms (EDAs) has focused on univariate EDAs for multi-valued decision variables. In particular, the runtime of the multi-valued cGA (r-cGA) and UMDA on multi-valued functions has been a significant area of study. Adak and Witt (PPSN 2024) and Hamano et al. (ECJ 2024) independently performed a first runtime analysis of the r-cGA on the r-valued OneMax function (r-OneMax). Adak and Witt also introduced a different r-valued OneMax function called G-OneMax. However, for that function, only empirical results were provided so far due to the increased complexity of its runtime analysis, since r-OneMax involves categorical values of two types only, while G-OneMax encompasses all possible values.

In this paper, we present the first theoretical runtime analysis of the r-cGA on the G-OneMax function. We demonstrate that the runtime is  $O(nr^3 \log^2 n \log r)$  with high probability. Additionally, we refine the previously established runtime analysis of the r-cGA on r-OneMax, improving the previous bound to  $O(nr \log n \log r)$ , which improves the state of the art by an asymptotic factor of log n and is tight for the binary case. Moreover, we for the first time include the case of frequency borders.

# 1 Introduction

Estimation of distribution algorithms (EDAs) have gained significant attention in recent years as a powerful class of optimization techniques. In particular, univariate EDAs [3, 10, 12, 15], which focus on multi-valued decision variables [1, 4], have been a key area of study for improving algorithmic efficiency in solving complex problems. These algorithms have demonstrated promise in various domains such as combinatorial optimization, and others. Among these, the multi-valued compact genetic algorithm (r-cGA) [1] and the multi-valued univariate marginal distribution algorithm (r-UMDA) [4] have been explored for their runtime performance on multi-valued functions, providing valuable insights into their capabilities and limitations in different problem settings.

Despite the growing interest in EDAs, the runtime analysis of these algorithms, especially when applied to functions with a large range of possible values, remains an area in need of deeper exploration. One significant contribution in this area is the work by Ben Jedidia et al. [4], who conducted the first theoretical runtime analysis of the r-UMDA on the r-valued LEADINGONES function. Following this, Adak and Witt [1] and, independently, Hamano et al. [9] provided the first theoretical runtime analysis of the r-cGA on the r-valued OneMax function (r-OneMax), interpreted as categorical variables with only two settings. Building upon this, Adak and Witt also introduced the r-valued generalized OneMax function (G-OneMax), which extends the r-OneMax function by considering all possible values for the decision variables. This extension posed a more complex scenario for runtime analysis on G-OneMax was given.

In this work, we address this gap by presenting the first theoretical runtime analysis of the r-cGA on the G-OneMax function. We show that the runtime of the r-cGA on G-OneMax is  $O(nr^3 \log^2 n \log r)$ with high probability (w.h.p.). Additionally, we improve upon the existing runtime analysis of the r-cGA on r-OneMax, refining the previously best bound by Hamano et al. [9] from  $O(nr \log^2(nr))$  to  $O(nr \log n \log r)$ , effectively eliminating a  $\log n$  factor from the original estimate and leading to the tight bound  $O(n \log n)$  in the binary case [16]. Our work not only extends the understanding of the r-cGA's performance on more complex problems but also opens the door for future research on runtime optimization for EDAs in multi-valued settings. Moreover, the analysis on r-OneMax for the first time includes the so-called borders on frequencies that are commonly used in the theoretical literature to guarantee finite expected optimization time; although for a parameter choice that does not lead to tight bounds. Finally, our revised analysis for the first time avoids the so-called well-behaved frequencies assumption, which is generally ruled out in the r-cGA due to its more complex update of the multi-valued frequency model.

The manuscript is structured as follows. Section 2 defines the multi-valued OneMax functions and and the multi-valued cGA. Section 3 describes probabilistic properties of the algorithm. In Section 4, we present the primary technical results, including genetic drift analysis and the runtime analyses of the r-cGA on the r-OneMax and G-OneMax functions. Section 5 explores the empirical runtime for different values of the parameter K, which represents the hypothetical population size of the r-cGA. Finally, the manuscript concludes with a summary.

## 2 Preliminaries

We analyze the r-valued compact genetic algorithm (r-cGA) with the goal of maximizing r-valued functions  $f: \{0, 1, \ldots, r-1\}^n \to \mathbb{R}$  where f(x) denotes the *fitness* of an individual  $x \in \{0, 1, \ldots, r-1\}^n$ . In this setting, the vector  $x = (x_1, x_2, \ldots, x_n)$  represents a candidate solution consisting of n values, each from the set  $\{0, 1, \ldots, r-1\}$ .

This work extends the analysis of the OneMax function by considering multi-valued variants, as independently considered by Adak and Witt [1] and Hamano et al. [9]. Following the notation from the first paper, these generalizations are called the *r*-OneMax and *G*-OneMax functions and accommodate the larger value set  $\{0, 1, \ldots, r-1\}$ , where  $r \in \mathbb{N}_{\geq 2}$  and  $n \in \mathbb{N}_{\geq 1}$ . Specifically, we define *r*-OneMax and *G*-OneMax as follows:

$$r$$
-OneMax $(x) \coloneqq \sum_{i=1}^{n} \mathbb{1}\{x_i = r-1\}$  and  $G$ -OneMax $(x) \coloneqq \sum_{i=1}^{n} x_i$ .

The single maximum in both the r-OneMax and G-OneMax functions is the all-(r-1)s string. The primary distinction between these two functions lies in how they handle the contribution of each position in the string to the overall fitness. In r-OneMax, the values are categorical, which means that only the correct value for a position (especially, r-1) contributes to the fitness. In other words, r-OneMax evaluates each position independently and assigns a fitness signal only if the value at that position matches the optimal value, r-1. This leads to a fitness value of n for the optimal string.

In contrast, G-OneMax employs a finer distance metric between values, where each position contributes a fitness signal toward the optimal value. Specifically, for each position, the contribution to fitness is proportional to how close the value is to the optimal value, r-1. This means that G-OneMax considers all values in the set  $\{0, 1, \ldots, r-1\}$  for each position, with fitness increasing as the value approaches r-1. As a result, the maximum fitness for the G-OneMax function is n(r-1). The function G-OneMax was only defined in [1] but without a concrete runtime analysis.

The compact genetic algorithm (cGA), introduced by Harik et al. [10], is a popular univariate estimation of distribution algorithm that operates with a compact representation of the population. Unlike traditional evolutionary algorithms, which maintain a population of candidate solutions, cGA approximates the distribution of solutions using a probabilistic model. It relies on a single parameter  $K \in \mathbb{R}_{>0}$ , often referred to as the hypothetical population size [6]. This parameter describes the strength of updates to the probabilistic model in an iteration of the algorithm.

An extension of the cGA is the r-cGA, introduced in [4] and independently analyzed in [9] and [1], which supports multi-valued variables instead of only binary ones. See Algorithm 1.

The probabilistic model of the *r*-cGA is defined by an  $n \times r$  frequency matrix, where each row  $i \in \{1, \ldots, n\}$  corresponds to a frequency vector  $p_i := (p_{i,j}^{(t)})_{j \in \{0,\ldots,r-1\}}$  representing the marginal probabilities of each value  $j \in \{0, \ldots, r-1\}$  at position *i* at time *t*. Initially, each element of the matrix is set to 1/r, leading to a uniform probability distribution for the first individuals sampled. After generating the individuals, their fitness values are compared. Depending on which individual has a higher fitness, the frequencies are updated by  $\pm K$ . Specifically, the frequency vector of the better individual (that one with higher fitness) has the corresponding frequency at each position increased by 1/K, while the corresponding frequency for the worse individual is decreased by the same amount.

**Algorithm 1:** *r*-valued Compact Genetic Algorithm (*r*-cGA) for the maximization of  $f : \{0, \ldots, r-1\}^n \to \mathbb{R}$ 

**Initialization:**  $t \leftarrow 0$ ;  $p_{i,j}^{(t)} \leftarrow \frac{1}{r}$ , where  $(i,j) \in \{1,\ldots,n\} \times \{0,\ldots,r-1\}$  $\mathbf{1}$  while termination criterion not met do for  $i \in \{1, 2, \ldots, n\}$  independently do  $\mathbf{2}$  $\begin{bmatrix} x_i \leftarrow j \text{ with probability } p_{i,j}^{(t)} \text{ w.r.t. } j = 0, \dots, r-1 \\ y_i \leftarrow j \text{ with probability } p_{i,j}^{(t)} \text{ w.r.t. } j = 0, \dots, r-1 \end{bmatrix}$ 3 4 if f(x) < f(y) then  $\mathbf{5}$ swap x and y6 for  $i \in \{1, 2, \ldots, n\}$  do 7 for  $j \in \{0, 1, \dots, r-1\}$  do  $p_{i,j}^{(t+1)} \leftarrow p_{i,j}^{(t)} + \frac{1}{K}(\mathbb{1}\{x_i = j\} - \mathbb{1}\{y_i = j\})$ 8 9 if borders are used then  $\begin{bmatrix} p_{i,j}^{(t+1)} \leftarrow \text{restrict } p_{i,j}^{(t+1)} \text{ to } \left[\frac{1}{(r-1)n}, 1 - \frac{1}{n}\right] ([4])$ 10 11  $t \leftarrow t + 1$  $\mathbf{12}$ 

In this work, we for the first time analyze the r-cGA on r-OneMax in the presence of borders on the marginal frequencies, which are commonly used in the theoretical literature [6, 16]. They restrict the frequencies to the interval [1/((r-1)n), 1/n] to avoid frequencies being irreversibly stuck at 0 or 1. On r-valued spaces, this restriction (also called capping) has to be done in a careful way. We follow the original procedure from [4] to cap the frequencies. Note that this may also update frequencies belonging to values in  $\{0, \ldots, r-1\}$  that were not sampled in any of the two individuals. The restriction ensures that there is always a positive probability to sample an individual of optimum value; on the negative side, the more complicated update mechanism for  $r \geq 3$  rules out the so-called well-behaved frequency assumption ([5], discussed in Section 4.2) that has been useful for the binary cGA. In the rest of the paper, we denote 1/((r-1)n) as lower border and 1 - 1/n as upper border.

We are interested in the runtime (also called optimization time) of the algorithm, which refers to the number of function evaluations required to sample a solution with optimal fitness. This runtime is proportional to the value of t in the algorithm, where t denotes the number of iterations or updates the algorithm performs.

### **3** Framework for the Analysis

In optimization, understanding how algorithms navigate solution spaces is crucial. This section explores the r-cGA and its use of probability vector updates. We focus on two types of updates, random-walk steps and biased steps, as already considered in [1, 16], and their role in guiding the algorithm toward optimal solutions. The following analysis details how these updates influence the optimization of the r-cGA on the G-OneMax function.

The change in  $p_{i,j}^{(t)}$  at each step is defined as  $\Delta_{i,j} \coloneqq p_{i,j}^{(t+1)} - p_{i,j}^{(t)}$ . This allows us to express the change at position *i* for value r-1 as  $\Delta_{i,r-1} \coloneqq p_{i,r-1}^{(t+1)} - p_{i,r-1}^{(t)}$ . The update is influenced by whether the value at position *i* affects the decision to update, based on the two strings *x* and *y* sampled at time *t*. Now, we examine the changes in values at all positions except position *i*. To capture this, we define  $D_i := \left(\sum_{j \neq i} x_j - \sum_{j \neq i} y_j\right)$  for the function *G*-OneMax. At this stage, the *r*-cGA can undergo two distinct kinds of updates. One is *random-walk step (rw-step)* and another is *biased step (b-step)*.

A random-walk step in the r-cGA refers to an update where the probability vector experiences small, stochastic fluctuations. These fluctuations occur due to the random nature of the sampled strings xand y, without a strong directional bias toward improving the objective function. In contrast, a biased step refers to an update in which the changes in the probability vector are influenced by directional tendencies, aligning with the optimization objective. Particularly, the update of the probability vector is directional and aligned with the fitness of the sampled solutions. If one solution is better (has higher fitness), the probability vector is adjusted to favor that solution, which drives the algorithm closer to an optimal solution. Together, these steps characterize the behavior of the r-cGA during its optimization process. The analysis that follows, along with the terminology random-walk and biased step, is closely based on the methodology outlined in [1] for the *r*-OneMax function.

**Random-walk steps:** If  $D_i \ge r - 1$ , then position *i* does not influence the decision to update with respect to strings *x* and *y*. When  $\Delta_{i,j} \ne 0$ , it is required that the value at position *i* for *j* is sampled differently. This implies that the value of  $p_{i,j}^{(t)}$  will either increase or decrease by 1/K (unless a border is hit) with equal probability  $p_{i,j}^{(t)}(1-p_{i,j}^{(t)})$ . Otherwise, it holds the same frequency value. This can be represented by introducing a variable  $F_i$ , where

$$F_i \coloneqq \begin{cases} +1/K & \text{with probability } p_{i,j}^{(t)}(1-p_{i,j}^{(t)}), \\ -1/K & \text{with probability } p_{i,j}^{(t)}(1-p_{i,j}^{(t)}), \\ 0 & \text{with the remaining probability.} \end{cases}$$

The above step is called a random-walk step. On the one hand, it is characterized by  $E(\Delta_{i,j} \mid p_{i,j}^{(t)}, D_i \ge r-1) = E(F_i \mid p_{i,j}^{(t)}) = 0$ . On the other hand, when the value of  $D_i < -(r-1)$ , then the strings are swapped; however, the outcome at position *i* doesn't affect the ranking anymore. Consequently, this step becomes a random-walk step, too. Therefore, as before, the same reasoning remains applicable. **Biased steps:** If  $D_i = 0$ , then the strings *x* and *y* are swapped unless the value at position *i* is sampled as  $x_i \ge y_i$ . In this case, both events of sampling position *i* differently increase the  $p_{i,j}^{(t)}$  value. As a result,  $\Delta_{i,j} = 1/K$  occurs with a probability of  $2p_{i,j}^{(t)}(1-p_{i,j}^{(t)})$ . Let us define a random variable  $B_i$  such that:

$$B_i \coloneqq \begin{cases} +1/K & \text{with probability } 2p_{i,j}^{(t)}(1-p_{i,j}^{(t)}), \\ 0 & \text{with the remaining probability.} \end{cases}$$

Therefore, a biased step occurs under the above condition and is represented by the following expression:  $E(\Delta_{i,j} \mid p_{i,j}^{(t)}, D_i = 0) = E(B_i \mid p_{i,j}^{(t)}) = 2p_{i,j}^{(t)}(1 - p_{i,j}^{(t)})/K$ . Furthermore, when  $D_i \in \{-(r-1), \ldots, -1, 1, \ldots, r-2\}$ , the outcome is determined by the values of  $x_i$  and  $y_i$ . Specifically, there are two cases: if  $(y_i - x_i) > D_i$ , a biased step is performed; otherwise, the process proceeds with a random-walk step.

The framework for analyzing the r-cGA on r-OneMax has already been established by Adak and Witt [1], and we follow this here in the revised analysis the r-cGA on the r-OneMax problem.

## 4 Analysis of Runtime

In this section, we explain how to manage genetic drift using the negative drift theorem. We also present the runtime analysis of the r-cGA on G-OneMax, along with an improved runtime analysis of the r-cGA on r-OneMax without borders. Furthermore, we extend this to the case with borders, at the expense of a weaker bound.

### 4.1 Controlling Genetic Drift through Negative Drift

Genetic drift refers to random fluctuations in the frequency of genetic traits, which can lead to optimal solutions in evolutionary algorithms. Controlling this drift is essential for ensuring that the algorithm converges to the desired solution without being disrupted by randomness. Genetic drift in EDAs has been thoroughly explored in various runtime analyses [7, 8, 14, 16, 17, 18]. In previous research [1], *martingale* techniques were used to control genetic drift effectively. However, in this case, the martingale techniques provide weaker results compared to methods that take advantage of the stochastic drift of a frequency toward higher values. In this work, we employ a *negative drift theorem* to bound genetic drift. Note that negative drift was also the preferred tool in [9].

The negative drift theorem is motivated by the need to analyze the behavior of a stochastic process  $(X_t)_{t\geq 0}$  that evolves over time t within a specific interval  $[a, b] \subseteq \mathbb{R}$ . Our goal is to demonstrate, using negative drift, that while a frequency value passes through this interval, it will not drop significantly below its initial value at a. This will ensure that the frequency remains relatively stable within the bounds of the interval, even as it undergoes fluctuations.

The following negative drift theorem, which does not include self-loops, applies to processes with a bounded step size. It has been taken from [9, Theorem 4] and has been trivially modified to reverse the direction of the process and to permit arbitrary drift intervals [a, b] instead of the fixed limit of 0 on one side of the interval.

**Theorem 1** Consider a stochastic process  $(X_t, \mathcal{F}_t)_{t \in \mathbb{N}_0}$  with  $X_0 \geq b$ . Let  $a \leq b$ . Let T be a stopping time defined as

$$T = \min\{t \in \mathbb{N} : X_t \le a\}$$

Assume that, for all t, there are constants  $0 < \varepsilon < (b-a)/2$  and 0 < c < b-a satisfying

$$\mathbb{E}[X_{t+1} - X_t \mid \mathcal{F}_t] \ge \varepsilon \Pr(X_{t+1} \neq X_t \mid \mathcal{F}_t), \\ |X_{t+1} - X_t| \le c \quad w. p. 1.$$

Then, for all  $t \geq 0$ ,

$$\Pr(T \le t) \le \frac{2(b-a)t}{\varepsilon} \exp\left(-\frac{(b-a)\varepsilon}{4c^2}\right).$$

Now, we apply the negative drift theorem to bound the probability that the frequency falls below a = (k/r) - 1/(2r) when started at b = k/r, in the context of the *r*-cGA applied to the *G*-OneMax problem. In this case, we obtain the following lemma.

**Lemma 2** Consider the r-cGA applied to the G-OneMax problem, and assume that the frequency  $p_{i,r-1}^{(t)}$  has reached a value of at least k/r (k > 0). Then, if  $K \ge cr^2\sqrt{n}\log n$  is chosen where c is a sufficiently large constant and K, r = poly(n), the probability that  $p_{i,r-1}^{(t)}$  drops below (k/r) - 1/(2r) within the next  $T^* = c'Kr\sqrt{n}(\log r + \log n)$  steps is at most  $n^{-c''}$  where  $c'' \ge K/(288r^2\sqrt{n}\ln n)$ .

**Proof.** In the negative drift theorem (Theorem 1), we set a = (k/r) - 1/(2r) and b = k/r, so b - a = 1/(2r). Using Lemma 5 (which is part of the next subsection) and noting that the probability of changing the frequency is  $2p_{i,r-1}^{(t)}(1-p_{i,r-1}^{(t)})$ , we find that  $\varepsilon = \frac{4}{9K(2(r-1)\sqrt{3n+1})} \ge \frac{4}{9K(2r\sqrt{4n})} \ge \frac{1}{9Kr\sqrt{n}}$ , and c = 1/K.

Therefore, the probability that  $p_{i,r-1}^{(t)}$  never drops below a in t steps is

$$\Pr(T \le t) \le \frac{2(b-a)t}{\varepsilon} \exp\left(-\frac{(b-a)\varepsilon}{4c^2}\right) \le t \cdot e^{\ln(9K\sqrt{n}) - \frac{K}{72r^2\sqrt{n}}}.$$

Further, since  $K\sqrt{n} = poly(n)$ , we have  $\ln(K\sqrt{n}) \leq c''' \ln n$  for some large constant c'''. On the other hand, we have  $K/(72r^2\sqrt{n}) \geq c'' \ln n$  for another constant c'' that can be arbitrarily large depending on our choice of c in the assumption  $K \geq cr^2\sqrt{n}\log n$ . Hence, for sufficiently large c that  $K/(72r^2\sqrt{n}) \geq 2\ln(9K\sqrt{n})$ . Therefore, the above exponential term is no larger than  $e^{-K/(144r^2\sqrt{n})}$ . If c' is large enough,  $e^{K/(288r^2\sqrt{n})} \geq T^* = c'Kr\sqrt{n}(\log r + \log n)$ . Then, we can choose  $t \leq e^{K/(288r^2\sqrt{n})}$ . The total failure probability is

$$\Pr(T \le T^*) \le e^{\frac{K}{288r^2\sqrt{n}}} \cdot e^{-\frac{K}{144r^2\sqrt{n}}} \le e^{-\frac{K}{288r^2\sqrt{n}}}.$$

As a result, the negative drift theorem provides a failure probability of  $e^{-\frac{K}{288r^2\sqrt{n}}} \leq n^{-c''}$  where  $c'' \geq K/(288r^2\sqrt{n} \ln n)$ .

Using martingale techniques like in [1] instead of the negative drift method, we would arrive at (asymptotically) the same probability bound when applying these results in the context of the G-OneMax problem. However, for the r-OneMax problem the negative drift method provides a better bound than the martingale approach. We derive the following lemma for r-OneMax using the negative drift method. To prove this lemma, we can apply the same technique used in the proof of Lemma 2.

**Lemma 3** Consider the r-cGA applied to the r-OneMax problem, and assume that the frequency  $p_{i,r-1}^{(t)}$  has reached a value of at least k/r (k > 0). Then, if  $K \ge cr\sqrt{n}\log n$  is chosen where c is a sufficiently large constant, and K, r = poly(n), the probability that  $p_{i,r-1}^{(t)}$  drops below (k/r) - 1/(2r) within the next  $T^* = c'K\sqrt{n}\log r$  steps is at most  $n^{-c''}$  where  $c'' \ge K/(288r\sqrt{n}\ln n)$ .

**Proof.** This proof is similar to the proof of Lemma 2. In the context of the negative drift theorem (Theorem 1), we set a = (k/r) - 1/(2r) and b = k/r, so the b - a = 1/(2r). Using Lemma 8, we find that  $\varepsilon = \frac{4}{9K(2\sqrt{3n}+1)} \ge \frac{4}{9K(2\sqrt{4n})} \ge \frac{1}{9K\sqrt{n}}$  and c = 1/K.

Therefore, the probability that  $p_{i,r-1}^{(t)}$  never drops below a in t steps is

$$\Pr(T \le t) \le \frac{2(b-a)t}{\varepsilon} \exp\left(-\frac{(b-a)\varepsilon}{4c^2}\right)$$
$$\le t \cdot e^{\ln\left(\frac{9K\sqrt{n}}{r}\right) - \frac{K}{72r\sqrt{n}}}$$

Further, since  $K\sqrt{n} = poly(n)$ , we have  $\ln(K\sqrt{n}) \leq c'' \ln n$  for some large constant c'''. On the other hand, we have  $K/(72r\sqrt{n}) \geq c'' \ln n$  for another constant c'' that becomes arbitrarily large depending on our choice of c in the assumption  $K \geq cr\sqrt{n}\log n$ . Hence, we have for sufficiently large c that  $K/(72r\sqrt{n}) \geq 2\ln(9K\sqrt{n}/r)$ . Therefore, the above exponential term is at most  $e^{-K/(144r\sqrt{n})}$ . If c' is large enough,  $e^{K/(288r\sqrt{n})} \geq T^* = c'K\sqrt{n}\log r$ . Then, we can choose  $t \leq e^{K/(288r\sqrt{n})}$ . Then, total failure probability is

$$\Pr(T \le T^*) \le e^{\frac{K}{288r\sqrt{n}}} \cdot e^{-\frac{K}{144r\sqrt{n}}}$$
$$\le e^{-\frac{K}{288r\sqrt{n}}}$$

As a result, the negative drift theorem provides a failure probability of  $e^{-\frac{K}{288r\sqrt{n}}} \leq n^{-c''}$  where  $c'' \geq K/(288r\sqrt{n}\ln n)$ .

#### 4.2 Runtime of the *r*-cGA on *G*-OneMax

To prove the main theorem, we first require the following lemmas.

**Lemma 4** Let  $p_{i,j}^{(t)}$  and  $p_{i,j}^{(t+1)}$  represent the frequency vectors of the current and the next iteration of the *r*-*cGA* on the *G*-OneMax function, where  $(i, j) \in \{1, ..., n\} \times \{0, ..., r-1\}$ . For sufficiently large *n*, the probability that  $D_i = 0$  is bounded below by:

$$P[D_i = 0] \ge \frac{4}{9\left(2(r-1)\sqrt{3n} + 1\right)}$$

where  $D_i \coloneqq \left(\sum_{j \neq i} x_j - \sum_{j \neq i} y_j\right)$ .

**Proof.** Let  $x \in \{0, \ldots, r-1\}^n$  and  $y \in \{0, \ldots, r-1\}^n$  represent two solutions from an iteration of the *r*-cGA. Define  $D_i$  as the difference between the number of entries in all the positions except position *i*. Specifically, let:  $X \coloneqq \sum_{j \neq i} x_j$  and  $Y \coloneqq \sum_{j \neq i} y_j$ , then the difference defined as  $D_i \coloneqq X - Y$ . We aim to estimate the probability that  $D_i = 0$ .

Next, we calculate the variance, which is given by:  $\operatorname{Var}(X) = \sum_{j \neq i} \operatorname{Var}(X_j)$ . We can get  $\operatorname{E}(X_i) = \sum_{j=0}^{r-1} p_{i,j}^{(t)} \cdot j$ . Now, we compute the variance of  $X_i$  as:

$$\operatorname{Var}(X_i) = \operatorname{E}((X_i)^2) - (\operatorname{E}(X_i))^2 = \sum_{j=0}^{r-1} p_{i,j}^{(t)} \cdot j^2 - \left(\sum_{j=0}^{r-1} p_{i,j}^{(t)} \cdot j\right)^2$$
$$\leq \sum_{j=0}^{r-1} p_{i,j}^{(t)} \cdot j^2 \leq (r-1)^2 \sum_{j=0}^{r-1} p_{i,j}^{(t)} = (r-1)^2.$$

Further, we get

$$\operatorname{Var}(X) = \sum_{j \neq i} \operatorname{Var}(X_j) \le (n-1)(r-1)^2$$

Further, by applying Chebyshev's inequality, we can estimate the probability that X deviates from its mean by more than a specified multiple of its standard deviation  $\sigma$ . Let  $\sigma^2 = \text{Var}(X)$ . Then, we obtain the following:

$$\mathbf{P}\left[\left|X-\mu_{\backslash i}\right| \ge \sqrt{3}\sigma\right] \le \frac{1}{3}$$

where  $\mu_{\backslash i} = \sum_{j \neq i} \sum_{k=0}^{r-1} p_{j,k}^{(t)} \cdot k.$ 

Let  $I := [\mu_{\setminus i} - \sqrt{3}\sigma, \mu_{\setminus i} + \sqrt{3}\sigma]$ , and observe that there at most  $2\sqrt{3}\sigma + 1$  integers in the interval I. Assume that  $X \in I$  and  $Y \in I$ , which occurs with a probability of at least  $(1-1/3)^2 = 4/9$ . Additionally, observe that  $D_i = 0$  is equivalent to X = Y, and we compute:

$$\begin{split} \mathbf{P}[X = Y \mid X, Y \in I] &= \sum_{z \in I} \mathbf{P}[X = z \mid X \in I] \cdot \mathbf{P}[Y = z \mid Y \in I] \\ &= \sum_{z \in I} \mathbf{P}[X = z \mid X \in I]^2 \\ &\geq \sum_{z \in I} \left(\frac{1}{|I|}\right)^2 = \frac{1}{|I|} \geq \frac{1}{2\sqrt{3}\sigma + 1}. \end{split}$$

The first inequality holds due to the convexity of the square function, which means that shifting the probability mass to the average value 1/I minimizes the sum of squares. Therefore, the unconditional probability  $P[X = Y] = P[D_i = 0]$  is at least:  $4/(9(2\sqrt{3}\sigma + 1))$ . Substituting for  $\sigma$ , we obtain:

$$P[D_i = 0] \ge \frac{4}{9\left(2\sqrt{3(n-1)(r-1)^2} + 1\right)} \ge \frac{4}{9\left(2(r-1)\sqrt{3n} + 1\right)}$$

if n is large enough.

The proof of the previous lemma is similar to the analysis in [1, Lemma 2]; however, the sampling variance derived here is by an asymptotic factor of  $r^2$  greater than for the case of r-OneMax, which results in the factor (r-1) in the denominator.

The next lemma is an important drift bound for frequencies.

Lemma 5 If 
$$\frac{1}{K} \le p_{i,r-1}^{(t)} \le 1 - \frac{1}{K}$$
 and  $\Delta_{i,r-1} = p_{i,r-1}^{(t+1)} - p_{i,r-1}^{(t)}$ , then  

$$E(\Delta_{i,r-1} \mid p_{i,r-1}^{(t)}) \ge \frac{8\left(p_{i,r-1}^{(t)}(1-p_{i,r-1}^{(t)})\right)}{9K\left(2(r-1)\sqrt{3n}+1\right)}$$

where  $i \in \{1, ..., n\}$ .

**Proof.** From Section 3, we derive the following inequality, which depends on the position i:

$$\Delta_{i,r-1} = F_i \cdot R_i + B_i \cdot \overline{R_i}.$$

where  $R_i$  is an indicator for the event of a random-walk step.

Further, the expected change for a position with a specific value is

$$E(\Delta_{i,r-1} \mid p_{i,r-1}^{(t)}) = E(F_i \mid p_{i,r-1}^{(t)}) \cdot E(R_i) + E(B_i \mid p_{i,r-1}^{(t)}) \cdot E(\overline{R_i}).$$

From the random-walk step, we know that  $E(F_i \mid p_{i,r-1}^{(t)}) = 0$  and from the biased step, we have  $E(B_i \mid p_{i,r-1}^{(t)}) = 2p_{i,r-1}^{(t)}(1-p_{i,r-1}^{(t)})/K$ . Additionally, from Lemma 4, we know that

$$\mathbf{E}(\overline{R_i}) \ge \mathbf{P}[D_i = 0] \ge \frac{4}{9\left(2(r-1)\sqrt{3n} + 1\right)}$$

Multiplying the results together, we derive the following expression:

$$E(\Delta_{i,r-1} \mid p_{i,r-1}^{(t)}) \ge \frac{8\left(p_{i,r-1}^{(t)}(1-p_{i,r-1}^{(t)})\right)}{9K\left(2(r-1)\sqrt{3n}+1\right)}.$$

The previous drift bound from Lemma 5 includes a term of  $\Theta(1/(r\sqrt{n}))$ , which stems from the upper bound  $O(nr^2)$  on the sampling variance, which is used to derive the probability of a biased step. It is not difficult to see that the initial sampling variance indeed is  $\Omega(nr^2)$ ; however, as the probabilistic model of the *r*-cGA becomes more focused over time, the sampling variance will decrease and the probability of a biased step will increase. This effect is ignored in this section. In the following section on *r*-OneMax, we will analyze the reduction of the sampling variance over time. We are now ready to state our first result for G-OneMax. For simplicity, it will consider the r-cGA without borders. This allows us to assume well-behaved frequencies [5] here, which means that the starting frequency 1/r is a multiple of 1/K and hence, every frequency will only take values in  $\{i/K \mid i = 0, \ldots, K\}$ . In the subsequent analysis on r-OneMax, we begin by presenting our results without borders. In Section 4.4, we consider the r-cGA with borders where well-behaved frequencies are ruled out.

**Theorem 6** The runtime of the r-cGA without borders on the G-OneMax problem is  $O(Kr\sqrt{n}(\log r + \log K))$  with high probability, where  $K \ge cr^2\sqrt{n}\log n$  for some sufficiently large constant c > 0 and both K and r are polynomial functions of n. The runtime bound is  $O(nr^3\log^2 n\log r)$  for  $K = r^2\sqrt{n}\log n$ .

**Proof.** The main concept is to estimate the expected optimization time, assuming low genetic drift, by studying the process described by an arbitrary frequency  $p_{i,r-1}^{(t)}$  for value r-1. We employ additive drift analysis over a sequence of phases. This is followed by multiplicative drift analysis. Specifically, additive drift analysis with tail bounds is applied over a sequence of phases from the initial frequency 1/r to 1/2, while multiplicative drift analysis with tail bounds is used from 1/2 to the maximum frequency.

Using the choice of  $K \ge cr^2 \sqrt{n} \ln n$ , we apply Lemma 2 to analyze and control genetic drift. This allows us to demonstrate that after  $T = c' Kr \sqrt{n} (\log r + \log K)$  iterations, no frequency of value r - 1deviates by more than 1/(2r) in the negative direction from a given value it has reached. According to Lemma 2, the probability of a single frequency dropping by 1/(2r) is at most  $n^{-K/(288r^2\sqrt{n}\ln n)} \le n^{-c/288}$ . By choosing  $c \ge 288\kappa$ , the failure probability becomes  $O(1/n^{\kappa})$  for a self-chosen constant  $\kappa$ . Furthermore, by applying the union bound over all frequencies, the probability of any frequency dropping by 1/(2r)remains bounded by  $O(1/n^{\kappa-1})$ .

To reach the value 1/2 starting from 1/r, we need r/2 phases with an increase of 1/r per phase, starting from phase 1. We consider phase indices k = 1, 2, ..., r/2. Additionally, thanks to our analysis of genetic drift, we assume that throughout phase k, the condition  $p_{i,r-1}^{(t)} \ge k/r - 1/(2r) \ge k/(2r)$  holds for each  $i \in \{1, ..., n\}$ . The aim is to use an additive drift theorem with tail bounds to limit the time  $T_k$  to complete phase k. Since the process involves many idle steps (as already mentioned, the frequency changes with probability at most  $2z_i$ , where  $z_i := p_{i,r-1}^{(t)}(1 - p_{i,r-1}^{(t)})$ ), the simple additive drift theorem with tail bounds [11, Theorem 2] does not give a strong enough result. Instead, we use the stronger Theorem 15 from [11] that applies to processes whose increments are bounded by sub-Gaussian random variables. For notational convenience, let  $X_t = p_{i,r-1}^{(t)}$ . Let  $\varepsilon = \mathbb{E}[X_{t+1} - X_t | \mathcal{F}_t]$  denote the drift, which, according to Lemma 5 satisfies

$$\varepsilon \geq \frac{8z_i}{9K(2(r-1)\sqrt{3n}+1)} \geq \frac{8z_i}{20Kr\sqrt{3n}} \geq \frac{z_i}{3Kr\sqrt{3n}} \eqqcolon \varepsilon'.$$

In the following, we pessimistically assume  $\varepsilon = \varepsilon'$ . To apply the drift theorem, the difference  $X_{t+1} - X_t - \varepsilon$  has to be stochastically bounded. This is done below in Lemma 10, part 1, which shows that the difference is  $(4z_i/K^2 + 2\varepsilon/K, K)$ -sub-Gaussian. Finally, the time bound  $s_k$  for the phase must satisfy  $s_k \geq 2D/\varepsilon$ , where D = 1/r is the distance to be overcome. We choose  $s_k \coloneqq 2D/\varepsilon$ . With these quantities, the drift theorem yields

$$P[T_k \ge s_k] \le \exp\left(-\frac{s_k\varepsilon}{4}\min\left(\delta, \frac{\varepsilon}{2c}\right)\right)$$
$$\le \exp\left(-\frac{D}{2}\min\left(K, \frac{z_i}{3Kr\sqrt{3n}}\frac{1}{8z_i/K^2 + 4\varepsilon/K}\right)\right).$$

Since  $8z_i/K^2 + 4\varepsilon/K = 8z_i/K^2 + 4z_i/(3K^2r\sqrt{3n}) \le 9z_i/K^2$ , the above minimum is taken on the second term and we obtain

$$\mathbf{P}[T_k \ge s_k] \le \exp\left(-\frac{1}{2r}\frac{K}{27r\sqrt{3n}}\right) \le \exp\left(-\frac{c\log n}{54\sqrt{3}}\right)$$

where the last inequality used the assumption  $K \ge cr^2 \sqrt{n} \log n$ . Hence,  $T_k < s_k$  w.h.p.

Now, we apply a union bound over all r/2 phases, ensuring that we still have a high probability of each phase finishing within at most

$$\frac{2D}{\varepsilon} = \frac{2}{r} \cdot \frac{12Kr^2\sqrt{3n}}{k} \le \frac{42Kr\sqrt{n}}{k}$$

steps, where we used our assumption  $p_{i,r-1}^{(t)} \ge k/(2r)$  and  $1 - p_{i,r-1}^{(t)} \ge 1/2$ , so  $z_i \ge k/(4r)$ . Furthermore, by summing up all  $s_k$ , we can bound the total time for all phases  $1, \ldots, r/2$ , which is  $O(Kr\sqrt{n}\log r)$  with probability at least  $1 - \mathcal{O}(rn^{-\kappa})$  for any constant  $\kappa > 0$ .

After the frequency reaches 1/2, we need to analyze the remaining time until  $p_{i,r-1}^{(t)}$  reaches its maximum (which is 1). In this phase, we apply the multiplicative drift with tail bounds as stated in [13, Theorem 2.4.5]. The starting point is  $p_{i,r-1}^{(t)} \ge 1/2$ , and by our analysis of genetic drift, the frequency will not decrease below 1/4 w. h. p. Therefore, we will assume  $p_{i,r-1}^{(t)} \ge 1/4$ . Let  $q_{i,r-1}^{(t)} \coloneqq 1 - p_{i,r-1}^{(t)}$ . Further, we bound  $p_{i,r-1}^{(t)}(1-p_{i,r-1}^{(t)})$  by using  $p_{i,r-1}^{(t)} \ge 1/4$  and let  $q_{i,r-1}^{(t)} \coloneqq 1 - p_{i,r-1}^{(t)}$ . Then, by Lemma 5, we obtain:

$$\mathbb{E}[q_{i,r-1}^{(t)} - q_{i,r-1}^{(t+1)}] \ge \frac{8\left(p_{i,j}^{(t)}(1 - p_{i,j}^{(t)})\right)}{9K\left(2(r-1)\sqrt{3n} + 1\right)} \ge \frac{8 \cdot \frac{1}{4} \cdot q_{i,r-1}^{(t)}}{9K\left(2(r-1)\sqrt{3n} + 1\right)} \\ \ge q_{i,r-1}^{(t)} \cdot \frac{2}{9K\left(2(r-1)\sqrt{3n} + 1\right)}.$$

Assuming a well-behaved frequency, the smallest possible state is 1/K, by applying the multiplicative drift theorem with tail bounds [13, Theorem 2.4.5], with  $s_{\min} = 1/K$  and  $X_t = q_{i,r-1}^{(t)}$ , and using the previously derived value of

$$\delta = \frac{2}{9K\left(2(r-1)\sqrt{3n}+1\right)},$$

it follows that for  $T \coloneqq \min\{t \mid X_t = 0\}$ , the following holds:

$$\mathbf{P}\left[T \le \frac{u + \ln\left(X_0/s_{\min}\right)}{\delta}\right] \le \mathbf{P}\left[T \le \frac{(u + \ln K) \cdot 9K(2(r-1)\sqrt{3n} + 1)}{2}\right] \le e^{-u}.$$

By selecting  $u = c \ln K$ , where c is a constant, we get

$$T \le \frac{(c+1)\ln K}{2} \cdot 9K\left(2(r-1)\sqrt{3n}+1\right)$$

with probability at least  $1 - e^{-c \ln n}$ .

Therefore, the time for the frequency to reach its maximum 1 is  $O(\sqrt{nr}K\log K))$  with high probability. Further, we obtain that the total time until all frequencies for value r-1 have been raised to their maximum is  $O(\sqrt{nr}K(\log r + \log K))$  with high probability by a union bound. At this point, the optimum  $(r-1, \ldots, r-1)$  will be sampled. By selecting  $K \ge cr^2\sqrt{n}\log n$ , which limits genetic drift as mentioned above, the runtime of the *r*-cGA on *G*-OneMax is  $O(nr^3\log^2 n\log r)$  with high probability.

### 4.3 Improved Runtime Analysis of the *r*-cGA on *r*-OneMax

The initial runtime analysis of the r-cGA on r-OneMax was independently provided by Adak and Witt and Hamano et al. [1, 9]. We revisit this problem now and improve the previously best result by a logarithmic factor. This method applies to scenarios without frequency borders. However, unlike the previous analyses, the following Section 4.4 also presents a theorem that studies the above-mentioned borders. To prove our runtime bound, we will employ the negative drift theorem (see Theorem 1) and additive drift analysis with tail bounds. This approach is different from [9], where multiplicative drift on a non-linear potential function of frequencies of the kind  $(1 - p_{i,r-1}^{(t)})/p_{i,r-1}^{(t)}$  was used. Moreover, in contrast to [9], we do not only consider the drift of single frequencies, but the combined drift of frequencies, which allows us to track the sampling variance and to obtain tight bounds for r = O(1)(cf. [16]).

**Theorem 7** The runtime of the r-cGA without borders on the r-OneMax problem is bounded by  $O(K\sqrt{n}\log r)$  with high probability. In this expression, K is at least  $cr\sqrt{n}\log n$ , where c > 0 is a sufficiently large constant, and both K and r are polynomial functions of n. For  $K = cr\sqrt{n}\log n$ , the runtime bound is  $O(nr\log n\log r)$ .

To prove the aforementioned theorem on runtime bounds, we require the following lemmas, which have been taken from [1], with slight modifications to the notation. In the first lemma, we establish a positive drift of an individual frequency. In the second lemma, we capture the combined drift of frequencies within a potential function  $\varphi_t$ .

**Lemma 8** If  $\frac{1}{K} \le p_{i,r-1}^{(t)} \le 1 - \frac{1}{K}$ , then

$$\mathcal{E}(\Delta_{i,r-1} \mid p_{i,r-1}^{(t)}) \ge \frac{8}{9} \cdot \frac{p_{i,r-1}^{(t)}(1-p_{i,r-1}^{(t)})}{K(2\sqrt{3V}+1)},$$

where  $V = \sum_{i=1}^{n} p_{i,r-1}^{(t)} (1 - p_{i,r-1}^{(t)}).$ 

**Lemma 9** For any  $t \ge 0$ , let  $\varphi_t \coloneqq \sum_{i=1}^n (1-p_{i,r-1}^{(t)})$ . If, for any  $t \ge 0$ , it holds that  $p_{i,r-1}^{(t)} \ge 1/4$  for all  $i \in \{1, \ldots, n\}$  and furthermore  $\varphi_t \ge 1/2$ , then

$$\mathbf{E}(\varphi_t - \varphi_{t+1} \mid \varphi_t) \ge \frac{\sqrt{\varphi_t}}{30K}$$

Proof of Theorem 7: We show that, starting with a setting where all frequencies are at least 1/r, after  $O(K\sqrt{n}\log r)$  iterations, w. h. p., the optimum is found, and no frequency has ever dropped below 1/(2r). The key approach involves performing an additive drift analysis with tail bounds in several phases to bound the expected time until all  $p_{i,r-1}^{(t)}$  have been at least 1/2 at least once by  $O(K\sqrt{n}\log r)$  with high probability. This analysis is largely identical to the corresponding part in the proof of Theorem 6. Once we reach a value of 1/2, we perform a different additive drift analysis with tail bounds in several phases, no longer based on individual frequencies but on a potential function involving all frequencies. At this point, our analysis is somewhat similar to a related analysis by Sudholt and Witt [16, Theorem 5] for the binary cGA with borders. At the same time, our analysis is simpler since it avoids the borders and uses additive drift analysis with tail bounds instead of the more involved variable drift with tail bounds carried out in [16].

Using the choice of  $K \ge cr\sqrt{n} \ln n$ , we use Lemma 3 to analyze and control genetic drift. This method allows us to show that after  $T = c'K\sqrt{n} \log r$  steps, any frequency for value r - 1 will not deviate by more than 1/(2r) in the negative direction with high probability. According to Lemma 2, the probability of a single frequency dropping by 1/(2r) is at most  $n^{-K/(288r\sqrt{n}\ln n)} \le n^{-c/288}$ . By selecting  $c \ge 288\kappa$ , the failure probability is bounded by  $O(1/n^{\kappa})$  for any constant  $\kappa$ . Furthermore, by applying the union bound across all frequencies, the probability of any frequency dropping by 1/(2r) remains bounded by  $O(1/n^{\kappa-1})$ .

The progress of a frequency is analyzed in phases, with each phase increasing the frequency by 1/r. This process continues until the frequency reaches 1/2. The total number of phases required to reach 1/2 from 1/r is r/2, with phases indexed as k = 1, 2, ..., r/2.

Furthermore, thanks to our analysis of genetic drift, we assume that throughout phase k, the condition  $p_{i,r-1}^{(t)} \ge (k/r-1/(2r)) \ge k/(2r)$  holds for position i. The aim is to use an additive drift theorem with tail bounds to limit the time  $T_k$  to complete phase k. The analysis is largely identical to the corresponding part in Theorem 6, with the only exception that here,  $\varepsilon$  and K are different, more precisely by an asymptotic factor r bigger and smaller, respectively. Again, by [11, Theorem 2] and Lemma 10, we obtain

$$\begin{split} \mathbf{P}[T_k \geq s_k] &\leq \exp\left(-\frac{s_k\varepsilon}{4}\min\left(\delta,\frac{\varepsilon}{2c}\right)\right) \\ &\leq \exp\left(-\frac{D}{2}\min\left(K,\frac{z_i}{3K\sqrt{n}}\frac{1}{8z_i/K^2 + 4\varepsilon/K}\right)\right) \end{split}$$

Now, we substitute the present value for  $\varepsilon$  from Lemma 8, which, after straightforward simplifications, gives  $\varepsilon \geq \frac{z_i}{3K\sqrt{n}}$ . We pessimistically assume this drift bound to hold with equality. Thereby, we estimate  $8z_i/K^2 + 4\varepsilon/K = 8z_i/K^2 + 4z_i/(3K^2\sqrt{n}) \leq 9z_i/K^2$ . Hence, the above minimum is again taken on the second term. We obtain

$$P[T_k \ge s_k] \le \exp\left(-\frac{1}{2r}\frac{K}{27\sqrt{n}}\right) \le \exp\left(-\frac{c\log n}{54}\right)$$

where the last inequality used the assumption  $K \ge cr\sqrt{n}\log n$ . Hence,  $T_k < s_k$  w.h.p.

Next, we apply a union bound over all r/2 phases, which ensures that each phase completes with a high probability, with the total time not exceeding:

$$\frac{2D}{\varepsilon} \leq \frac{2}{r} \cdot \frac{9rK(2\sqrt{n}+1)}{2k} \leq \frac{18K\sqrt{n}}{k},$$

where we used our assumption  $p_{i,r-1}^{(t)} \ge k/(2r)$  and  $1 - p_{i,r-1}^{(t)} \ge 1/2$ , so  $z_i \ge k/(4r)$ . By summing over all  $s_k$ , we obtain  $O(K\sqrt{n}\log r)$  on the total time for all phases  $1, \ldots, r/2$ . By a union bound, this bound also holds for all frequencies  $p_{i,r-1}$  together w. h. p.

Once a frequency has reached 1/2, we need to analyze the remaining time until it reaches its maximum value 1. During this stage, we will again employ additive drift analysis with tail bounds in the strong version. Our analysis requires that all frequencies satisfy  $p_{i,r-1}^{(t)} \ge 1/4$ , which holds w. h. p. due to our analysis of genetic drift. Now we consider the potential function  $\varphi_t \coloneqq \sum_{i=1}^n (1-p_{i,r-1}^{(t)})$ , which combines all frequencies into a single value, and then track this potential.

We consider a number of phases such that the potential is consecutively halved. More precisely, phase i starts with a potential of at most  $n/2^{i-1}$  and ends when the potential has become at most  $n/2^i$ . Since the potential is at least  $n/2^i$  in the phase, then according to Lemma 9, the drift in the phase is bounded according to

$$\mathrm{E}(\varphi_t - \varphi_{t+1} \mid \varphi_t) \ge \frac{\sqrt{n/2^i}}{30K}$$

We again apply the additive drift theorem with tail bounds for drift processes with sub-Gaussian increments [11, Theorem 15], this time on the process  $\varphi_t$ . Using Lemma 10, part 2, we have  $\delta = K$ , and  $c = 8\varphi_t/K^2$  and  $s_i = 2D/\varepsilon$  where D is the distance to be bridged and  $\varepsilon = \sqrt{\varphi_t}/(30K)$ . To handle a possible overshooting of the target  $n/2^i$ , we replace it by the most remote state possible, which is 0, and set  $D = (n/2^{i-1} - 0) = n/2^{i-1}$  despite the fact that we are only interested in a distance of  $n/2^{i-1} - n/2^i = n/2^i$ . Applying [11, Theorem 15], we obtain for the time  $T_i$  to complete phase *i* that

$$P[T_i \ge s_i] \le \exp\left(-\frac{D}{2}\min\left(K, \frac{K}{480\sqrt{\varphi_t}}\right)\right).$$

Now, by substituting our assumption that  $K \ge cr\sqrt{n}\log n$  and  $\varphi_t \ge \sqrt{n/2^i}$ , we conclude

$$\mathbf{P}[T_i \ge s_i] \le \exp\left(-\frac{c'nr\log n}{\sqrt{2^i}}\right)$$

where c' is a constant. Hence, the time required to complete the phase *i* is at most

$$\frac{2n}{2^{i-1}} \cdot \frac{30K}{\sqrt{n/2^{i-1}}} \le 60K\sqrt{n/2^{i-1}}$$

w. h. p.

We choose constants in the time bound appropriately to obtain a failure probability of at most  $1/n^{\kappa}$  per phase for any constant  $\kappa > 0$ . We consider at most log *n* phases until the potential has dropped to at most 1/2. The total time spent in these phases is then at most

$$\sum_{i=1}^{\log n} \frac{60K\sqrt{n}}{\sqrt{2^{i-1}}} = \mathcal{O}(K\sqrt{n}),$$

which holds w. h. p. by a union bound over the  $O(\log n)$  phases.

Altogether, with high probability, the potential has reached at most 1/2 within  $O(K\sqrt{n})$  iterations. After this point, the probability of sampling the optimum becomes a constant. If the optimum is not found, the expected next value of the potential is no more than  $1/2 + n/K \leq \sqrt{n}$ , since in each step, the frequency decreases by at most 1/K. With high probability, the time to return to a potential of at most 1/2 is  $O(K\sqrt{\sqrt{n}}) = O(Kn^{1/4})$ , as derived from the previous analysis of the drift of the potential. By repeating this argument  $C \log n$  times, after  $O(K(\log n)n^{1/4})$  additional steps, the optimum will be sampled with probability at least  $1 - e^{\Omega(C \log n)}$ , which ensures that the optimum is found with high probability.

By adding the two stages, the total time becomes  $O(K\sqrt{n}\log r)$  with high probability. Therefore, by choosing  $K = cr\sqrt{n}\log n$ , the runtime of the *r*-cGA on the *r*-OneMax problem is  $O(nr\log n\log r)$  with high probability.

We still have to prove the outstanding claim on the increments analyzed in the two applications of the additive drift theorem with tail bounds. This requires a closer look at the stochastic behavior of a frequency and of the potential function  $\varphi_t = \sum_{i=1}^n (1 - p_{i,r-1}^{(t)})$ , as done in the following lemma.

**Lemma 10** For any  $i \in \{1, ..., n\}$ , let  $X_t \coloneqq p_{i,r-1}^{(t)}$  and let  $\varepsilon_i = \mathbb{E}[X_{t+1} - X_t | \mathcal{F}_t]$ , where  $\mathcal{F}_t$  is a filtration with respect to the underlying stochastic process. Then the random variable  $X_{t+1} - X_t - \varepsilon_i$  is  $(4X_t(1 - X_t)/K^2 + 2\varepsilon_i/K, K)$ -sub-Gaussian in the sense of [11].

Let  $\varepsilon_t \geq \sqrt{\varphi_t}/(30K)$  as derived in Lemma 9. Then the random variable  $\varphi_t - \varphi_{t+1} - \varepsilon_t$  is  $(8\varphi_t/K^2, K)$ -sub-Gaussian.

**Proof.** We start with the first claim. We abbreviate  $p_i \coloneqq p_{i,r-1}^{(t)}$ ,  $z_i \coloneqq p_i(1-p_i)$  and  $\delta_i \coloneqq p_{i,r-1}^{(t+1)} - p_{i,r-1}^{(t)}$ . We re-use the characterization of the  $\delta_i$  from Section 3, which says that the frequency  $p_i$  changes with probability  $2z_i$  by either +1/K or -1/K, and, thanks to the b-steps, has a slight drift towards increasing values:

$$\delta_i = \begin{cases} +1/K & \text{with prob. } z_i(1+K\varepsilon_i/(2z_i)), \\ -1/K & \text{with prob. } z_i(1-K\varepsilon_i/(2z_i)), \\ 0 & \text{with the remaining probability,} \end{cases}$$

which gives  $E[\delta_i] = \varepsilon_i$ .

The aim is to bound the moment-generating function (mgf.) of the differences  $\delta_i - \varepsilon_i$ . Since  $\varepsilon_i$  is a scalar, we first bound the mgf. of  $\delta_i$ . We have for  $\lambda \ge 0$  that

$$\begin{split} \mathbf{E}[e^{\lambda\delta_i}] \\ &= z_i(1+K\varepsilon_i/(2z_i))e^{\lambda/K} + z_i(1-K\varepsilon_i/(2z_i))e^{-\lambda/K} + (1-2z_i)e^{\lambda 0} \\ &= 2z_i\cosh(\lambda/K) + K\varepsilon_i\sinh(\lambda/K) + (1-2z_i). \end{split}$$

We use the following Taylor expansions for the hyperbolic functions:  $\cosh(x) = 1 + x^2/2! + x^4/4! + \dots$ and  $\sinh(x) = x + x^3/3! + x^5/5! + \dots$  Thereby, we obtain for  $\lambda/K \leq 1$  that

$$\mathbb{E}[e^{\lambda \delta_i}] \leq 2z_i (1 + (\lambda/K)^2) + K\varepsilon_i (\lambda/K + (\lambda/K)^3) + 1 - 2z_i$$
  
$$< e^{2z_i (\lambda/K)^2 + \lambda \varepsilon_i + (\lambda/K)^2 \lambda \varepsilon_i}.$$

 $\mathbf{SO}$ 

$$\mathbf{E}[e^{\lambda\delta_i - \lambda\varepsilon_i}] \le e^{\frac{\lambda^2}{2}\frac{(4z_i + 2\lambda\varepsilon_i)}{K^2}} \le e^{\frac{\lambda^2}{2}(\frac{4z_i}{K^2} + \frac{2\varepsilon_i}{K})},$$

using  $\lambda \leq K$ , meaning that the random variable  $\delta_i - \varepsilon_i$  is  $(4z_i/K^2 + 2\varepsilon_i/K, K)$ -sub-Gaussian in the sense of [11].

For the second statement, we decompose  $\Delta_t = \varphi_t - \varphi_{t+1}$  into the sum of independent increments  $\delta_i$  already analyzed above, i. e.,  $\Delta_t = \sum_{i=1}^n \delta_i$ . Note also that  $\varepsilon_t = \sum_{i=1}^n \varepsilon_i$ . To analyze the mgf. of  $\Delta_t - \varepsilon_t$ , we sum over the *n* differences in the exponent of the mgf. Trivially bounding  $z_i \leq 1 - p_i$ , we have

$$\mathbf{E}[e^{\lambda(\Delta_t - \varepsilon_t)}] = \mathbf{E}[e^{\lambda \sum_{i=1}^n (\delta_i - \varepsilon_i)}] \le e^{\frac{\lambda^2}{2}(4\varphi_t/K^2 + 2\varepsilon_t/K)}$$

With our bound  $\varepsilon_t \ge \sqrt{\varphi_t}/(30K)$  and bounding  $\sqrt{\varphi_t} \le \varphi_t$ , we have that the difference is  $(8\varphi_t/K^2, K)$ -sub-Gaussian.

### 4.4 Analysis in the Presence of Borders

The r-cGA with borders is harder to analyze than without borders since frequencies that have reached the upper border 1 - 1/n may decrease again in subsequent steps. Previous work on the binary cGA (e.g. [16]) addresses this by bounding the number of frequencies that leave the upper border again via a non-trivial drift analysis. Moreover, the previous analyses are crucially based on the well-behaved frequencies assumption: in particular, this assumption is used to avoid uneven step sizes when taking the last step towards the maximum frequency. If, e.g., the second-largest frequency value was strictly in between 1 - 1/n - 1/K and 1 - 1/n, then the possible decrease would be 1/K but the increase strictly less. In this situation, Lemma 9 would not hold and the frequency could exhibit a drift away from its maximum. The well-behaved frequency assumption (used in [6, 16] and other works) postulates that Kis chosen so that it evenly divides the interval of allowed frequencies. Unfortunately, the r-cGA for  $r \ge 3$  includes a non-trivial procedure for frequency capping that may result in step sizes different from 1/K even for frequencies that are far away from a border. More precisely, if, for some position *i*, the two values sampled are *a* and *b*, where  $a, b \in \{0, ..., r-1\}$ ,  $a \ne b$ and at least one of  $p_{i,a}$ ,  $p_{i,b}$  is at the lower border, then probability may be taken also from frequencies  $p_{i,c}$  for  $c \notin \{a, b\}$  to normalize the vector. See [4] for details. The amount by which the other frequencies is reduced cannot necessarily be expressed in units (or fixed subunits) of 1/K. However, as already observed in [2], the update is reduced by no more than 1/((r-1)n), which is the value of the lower frequency border. In other words, any positive frequency update is at least 1/K - 1/((r-1)n) unless it is capped at the upper frequency border.

The paper [2] was the first to analyze the r-cGA in the presence of frequency borders. Since their study is on the LEADINGONES function, the optimal value of K is different from the present paper, more precisely, they choose  $K = \Omega(n \log n)$ , while the results above use  $K = \Omega(\sqrt{n} \log n)$ . The larger value of  $K = \Omega(n \log n)$  comes in handy, since a frequency value of 1 - 1/n - 1/K, which still allows a full update of 1/K towards the upper border, is essentially as good as the value 1 - 1/n self; note that 1 - 1/n - 1/K = 1 - 1/n - o(1/n) for this choice of K. We can use the same insights to analyze the r-cGA with borders on r-OneMax for  $K = \Omega(n \log n)$ , see Theorem 11 below; however, this does not give the best possible runtime result.

**Theorem 11** Let  $K \ge cnr \log n$  for a sufficiently large constant c > 0 and assume that  $K = o(n^2)$ and r = poly(n). Then the runtime of the r-cGA with borders on the r-OneMax problem is bounded by  $O(K\sqrt{n}\log r)$  with high probability. For  $K = cnr \log n$ , the runtime bound is  $O(n^{3/2}r \log n \log r)$ .

**Proof.** The proof follows largely the structure of the proof of the case without borders in Theorem 7. The first stage is completely identical since it studies the time until all frequencies for value r - 1 have risen to at least 1/2, and this process cannot be negatively affected by the lower borders on frequencies. Hence, with high probability all frequencies will have reached 1/2 at least once after  $O(K\sqrt{n} \log r)$  steps. Also with high probability by the negative drift theorem, they will not drop below 1/4 in the next  $c_1 K\sqrt{n}$  steps, where  $c_1$  is an arbitrary constant.

Also the analysis of the second stage, consisting of  $O(K\sqrt{n})$  iterations, is largely identical, except that we apply Lemma 13 instead of Lemma 9 and stop the iterated additive drift analysis at the first point where  $\varphi_t < 10000$ . As argued in [16, Proof of Theorem 2], the probability of sampling the optimum at this point is  $\Omega(1)$  since it is minimized if as many frequencies as possible take the extreme values 1 - 1/n - 1/K and 1/4, using arguments related to majorization and Schur-convexity. After reaching potential at most 10000, we consider the a phase consisting of the next  $T_2 := c_2 \log n$  iterations for an arbitrary constant  $c_2$ . By our assumption on  $K \ge cnr \log n$ , each iteration decreases a frequency by  $O(1/(n \log n))$ , so throughout the phase of  $T_2$  steps all frequencies that were at least 1 - 1/n - 1/K at the beginning of the phase will still be 1 - O(1/n). Therefore, the probability of sampling the optimum is  $\Omega(1)$  in every of the  $T_2$  steps, and the probability of not sampling it in the phase is at most  $e^{-\Omega(c_2 \log n)}$ . Hence, altogether the optimum is sampled in  $O(K\sqrt{n} \log r)$  iterations with high probability.

To study the progress of the frequency vectors, we define a potential function similar to the one used above in the proof of Theorem 7 and in previous works [1, 6, 16]. However, we already consider all frequencies above 1 - 1/n - 1/K as optimal.

**Definition 12** Given the frequency vector  $(p_{1,r-1}^{(t)}, \ldots, p_{n,r-1}^{(t)})$  for value r-1 in the r-cGA at time t, hereinafter abbreviated as  $(p_1, \ldots, p_n)$ , we define

$$q_i = \begin{cases} 0 & \text{if } p_i \ge 1 - 1/n - 1/K \\ 1 - 1/n - 1/K - p_i & \text{otherwise} \end{cases}$$

for  $i \in \{1, \ldots, n\}$  and let  $\varphi_t = \sum_{i=1}^n q_i$ .

Also, similarly to the previous Lemma 9, the drift of this potential function is proportional to its square root.

**Lemma 13** Let  $K = \Omega(nr \log n)$  and  $K = o(n^2)$ . If for all  $i \in \{1, ..., n\}$  it holds that  $p_{i,r-1}^{(t)} \ge 1/4$  and furthermore  $\varphi_t \ge 10000$ , then for n large enough it holds that

$$\mathrm{E}(\varphi_t - \varphi_{t+1} \mid \varphi_t) \geq \frac{\sqrt{\varphi_t}}{66K}.$$

**Proof.** We look into the current frequency vector  $(p_1, \ldots, p_n)$  for value r-1 and distinguish between the ones above 1 - 1/n - 1/K (i. e., essentially at the upper border) and the remaining ones. Without loss of generality, for some  $s \in \mathbf{N}_0$ , the frequencies  $p_1, \ldots, p_s$  are all at least 1 - 1/n - 1/K. Each of these s frequencies changes its value with probability at most 2/n since it is necessary to sample a value different from r-1 at the position in at least one offspring. The maximum change of the underlying  $q_i$  as defined above is 2/K (using  $K = \omega(n)$ ), so the expected increase of the potential due to the first s frequencies is at most  $\frac{4s}{nK} \leq \frac{4}{K}$ . More formally,  $\sum_{i=1}^{s} (p_{i,r-1}^{(t)} - p_{i,r-1}^{(t+1)}) \leq 4/K$ . Each of the other frequencies can both decrease and increase by 1/K. Fix an arbitrary i > s and

Each of the other frequencies can both decrease and increase by 1/K. Fix an arbitrary i > s and assume that  $p_i \leq 1 - 1/n - 1/K$ . For the moment, we assume that the positive update is exactly 1/K, which happens if no frequency  $p_{i,j}$  for j < r - 1 is capped at the lower border. Following the proof of Lemma 5 with  $\Delta_i = p_{i,r-1}^{(t)} - p_{i,r-1}^{(t+1)}$  we have for that

$$\operatorname{E}[\Delta_i \mid p_i] \ge \frac{8p_i(1-p_i)}{9K(2\sqrt{V}+1)},$$

where  $V = \sum_{j=1}^{n} p_j (1-p_j)$ . By definition, we have  $1-p_i \leq q_i + 1/n + 1/K \leq q_i + 2/n$  by our assumption on K. Hence,  $V \leq \sum_{j=1}^{n} q_j + 2 = \varphi_t + 2$ , and, since  $\varphi_t \geq 10000$ , we estimate  $2\sqrt{V} + 2 \leq 4\varphi_t$ . Along with  $p_i \geq 1/4$ , we arrive at the bound

$$\mathbf{E}[\Delta_i \mid p_i] \ge \frac{1 - p_i}{18K\sqrt{\varphi_t}},$$

Now, since  $1 - p_i \ge q_i$  and  $\varphi_t = \sum_{i=s+1}^n q_i$  (since the first s positions do not contribute to  $\varphi_t$ ), we have

$$E[\varphi_t - \varphi_{t+1} \mid \varphi_t] \ge \sum_{i=s+1}^n \frac{q_i}{18K\sqrt{\varphi_t}} - \sum_{i=1}^s (p_{i,r-1}^{(t)} - p_{i,r-1}^{(t+1)})$$
$$= \frac{\sqrt{\varphi_t}}{18K} - \frac{4}{K} \ge \frac{\sqrt{\varphi_t}}{65K},$$

where the last inequality used  $\varphi_t \geq 10000$ .

Finally, we correct the previous drift bound by the effect of  $p_i$  being decreased since frequencies for other values than r-1 are capped at the lower border. This happens only with probability at most  $2(r-1)(\frac{1}{(r-1)n} + \frac{1}{K}) \leq 2/n + O(1/(n \log n)) \leq 3/n$  since the largest frequency value whose update may be capped at the lower border is  $\frac{1}{(r-1)n} + \frac{1}{K}$ , two offspring are sampled and r-1 different values are considered; note also that  $K = \Omega(nr \log n)$ . Together with the fact that the frequency in such a case is reduced by at most 1/((r-1)n), the drift bound is still at least

$$\frac{\sqrt{\varphi_t}}{65K} - \frac{3}{(r-1)n^2} \ge \frac{\sqrt{\varphi_t}}{66K}$$

for *n* large enough since  $K = o(n^2)$ .

We believe that the statement of Theorem 11 also holds for the choice  $K \ge cnr \log n$  taken in Theorem 7. Proving or disproving this conjecture is an open problem.

## 5 Analysis through Experimentation

In this section, we present the results of experiments conducted to evaluate performance of the proposed algorithm without border restriction. The algorithm is implemented using the C programming language, with the WELL1024a random number generator. In the experiments, we ran the r-cGA on r-OneMax and G-OneMax for different n and K. We compare the results for different values of  $n \in \{100, \ldots, 400\}$  and present the average number of iterations for a range of hypothetical population sizes  $K \in \{200, \ldots, 1000\}$ . Various plots for  $r \in \{3, 4, 5\}$  are shown in Fig. 1 for both r-OneMax and G-OneMax.

The empirical runtime initially starts at a high value, decreases to a minimum, and then increases again as K continues to grow. Analyzing the results, this empirical study clearly demonstrates how runtime is influenced by the value of r in both functions.

Additionally, we conducted an experiment to represent the frequencies of a specific position across some values of r. Fig. 2 illustrates how the frequency evolves from its initial value until the optimal

Figure 1: Empirical runtime of the r-cGA on r-OneMax and G-OneMax; with the top side showing results for r-OneMax at r = 3 (left), r = 4 (middle), and r = 5 (right), and the bottom side for G-OneMax at r = 3 (left), r = 4 (middle), and r = 5 (right);  $n \in \{200, \ldots, 400\}$ ,  $K \in \{100, \ldots, 1000\}$  and averaged over 100 runs.

Figure 2: The analysis of frequency evolution for the *r*-cGA on both *r*-OneMax and *G*-OneMax; with the left side displaying results for *r*-OneMax and the right side for *G*-OneMax; n = 400 and K = 600;  $r \in \{0, ..., 7\}$ , for a particular position.

solution is attained for both r-OneMax and G-OneMax problems. The frequency values are colorcoded, transitioning from blue (indicating low values) to red (indicating high values) as the iterations progress. This color gradient visually captures the dynamics of how the algorithm converges over time. Furthermore, it is evident how the frequency for r - 1 ultimately reaches its maximum.

# 6 Conclusion

This work provides the first runtime analysis of the multi-valued r-cGA on the generalized G-OneMax function, deriving a high probability bound on its runtime. Furthermore, we have refined the runtime analysis of the r-cGA on the r-OneMax function, improving previous estimates and eliminating a logarithmic factor. In addition, for the first time, we include the analysis of frequency borders. These results contribute to a deeper understanding of EDAs' performance on multi-valued functions and open avenues for further research, particularly in analyzing the r-cGA on more complex problems and exploring potential runtime improvements. Additionally, based on our experiments, we believe that there is potential to further improve the runtime bounds on G-OneMax.
