Abstract

In this paper, we propose a novel *uncertainty-aware graph self-training* approach for semi-supervised node classification. Our method introduces an Expectation-Maximization (EM) regularization scheme to incorporate an uncertainty mechanism during pseudo-label generation and model retraining. Unlike conventional graph self-training pipelines that rely on fixed pseudo-labels, our approach iteratively refines label confidences with an EM-inspired uncertainty measure. This ensures that the predictive model focuses on reliable graph regions while gradually incorporating ambiguous nodes. Inspired by prior work on uncertainty-aware self-training techniques [5], our framework is designed to handle noisy graph structures and feature spaces more effectively. Through extensive experiments on several benchmark graph datasets, we demonstrate that our method outperforms strong baselines by a margin of up to 2.5% in accuracy while maintaining lower variance in performance across multiple runs.

1 Introduction

Graph-based learning has emerged as a vital topic in machine learning, facilitating a wide range of applications including social network analysis, recommendation systems, and biological network modeling. For many real-world problems, labeling nodes in large-scale graphs is expensive and time-consuming, leading to scenarios with scarce labeled data. In these settings, semi-supervised learning techniques such as self-training have proven useful. Self-training typically augments a labeled dataset by generating pseudo-labels for unlabeled data. However, self-training methods often suffer from overconfident or erroneous pseudo-labels, especially in noisy or complex domains.

Several works have explored *uncertainty awareness* as a strategy to address overconfident predictions in self-training [5]. In standard classification tasks such as image recognition, these methods mitigate the risk of propagating labeling mistakes by integrating measures of epistemic or aleatoric uncertainty. Motivated by these advances, we investigate whether *uncertainty-aware strategies* can also benefit semi-supervised *graph learning*.

In this paper, we propose a new **Uncertainty-Aware Graph Self-Training** (UGST) method that leverages a two-stage process:

- **Uncertainty estimation via Expectation-Maximization (EM).** We employ an EM-style procedure to estimate the intrinsic uncertainty of unlabeled nodes. The EM process transforms node representations into a set of uncertain, soft assignments that guide the training process.
- **Adaptive refinement of pseudo-labels.** Using the uncertainty estimates, UGST generates pseudo-labels with a thresholding mechanism that dynamically adjusts the acceptance of pseudo-labeled nodes. Highly uncertain nodes are treated conservatively, while more confident nodes are incorporated for model retraining.

Our approach departs from standard graph self-training methods by directly modeling uncertainty in the label generation pipeline. We demonstrate that this perspective not only boosts the predictive accuracy but also results in higher stability (lower variance) across multiple runs.

2 Related Work

Semi-Supervised Learning and Self-Training. Self-training has been a cornerstone technique in semi-supervised learning, generating pseudo-labels for unlabeled data in an iterative fashion. Traditional approaches often treat pseudo-labels as “hard labels” once a confidence threshold is reached, potentially propagating errors [1]. Recent methods utilize confidence calibration to reduce overfitting to wrong pseudo-labels. Our work falls into this space by focusing on explicit modeling of uncertainty in a graph context.

Graph Neural Networks. Graph Neural Networks (GNNs) [3, 4] have become the de facto standard for learning from graph-structured data. They aggregate node features by propagating information over edges, often achieving state-of-the-art performance on node classification tasks. However, GNNs are also prone to over-smoothing and misclassification if noisy edges or features exist. Our UGST approach integrates with GNNs while being robust to uncertain or noisy node regions.

Uncertainty-Aware Self-Training. Wang et al. [5] introduced a groundbreaking uncertainty-aware self-training approach with an Expectation-Maximization basis transformation, focusing on vision tasks. Inspired by the effectiveness of their uncertainty filtering approach, our work expands on the EM concept to refine pseudo-labels in graph domains. Unlike their image-focused pipeline, we adopt a graph-centric perspective and propose a threshold-based re-labeling strategy that emphasizes robust uncertainty estimates at the node level.

3 Proposed Method

In this section, we introduce our **Uncertainty-Aware Graph Self-Training (UGST)** framework. We first define the problem setting and then detail the two major components of our approach: (1) EM-based uncertainty modeling and (2) adaptive pseudo-label refinement.

3.1 Problem Setting

We consider a semi-supervised node classification task on a graph $G = (V, E)$, where V is the set of nodes and E the set of edges. We assume a subset of nodes $V_L \subset V$ are labeled, while $V_U = V \setminus V_L$ remains unlabeled. Let $\mathbf{X} \in \mathbb{R}^{|V| \times d}$ be the node feature matrix, and Y_L be the label set for the labeled nodes. Our goal is to learn a function $f : \mathbb{R}^d \rightarrow \{1, \dots, C\}$ that predicts the node classes for unlabeled nodes in V_U .

3.2 EM-based Uncertainty Modeling

Initialization. We first train a base GNN on (V_L, Y_L) using a supervised loss, e.g., cross-entropy. This yields initial class probabilities $p_\theta(y|v)$ for each node $v \in V_U$. In standard self-training, these probabilities would be thresholded or directly used as pseudo-labels. However, we refine them further by an EM-based iterative process.

Expectation-Step (E-step). In the E-step, we treat the unlabeled nodes’ latent class variables \mathbf{z} as hidden, and compute the posterior distribution given our current model parameters. Specifically, we compute:

$$Q(\mathbf{z}) = p_\theta(y|v), \quad \forall v \in V_U,$$

where y ranges over possible classes. This distribution $Q(\mathbf{z})$ is interpreted as the *soft label* for each unlabeled node.

Maximization-Step (M-step). Next, we retrain or fine-tune the GNN parameters θ by maximizing the expected log-likelihood of all labeled *and* unlabeled nodes, weighted by $Q(\mathbf{z})$. Intuitively, we treat the soft labels $Q(\mathbf{z})$ as training targets for unlabeled nodes. Formally:

$$\theta \leftarrow \arg \max_{\theta} \sum_{v \in V_L} \log p_\theta(y_v|v) + \sum_{v \in V_U} \sum_{k=1}^C Q(\mathbf{z}_v = k) \log p_\theta(y = k|v).$$

Uncertainty-Aware Graph Self-Training (UGST)

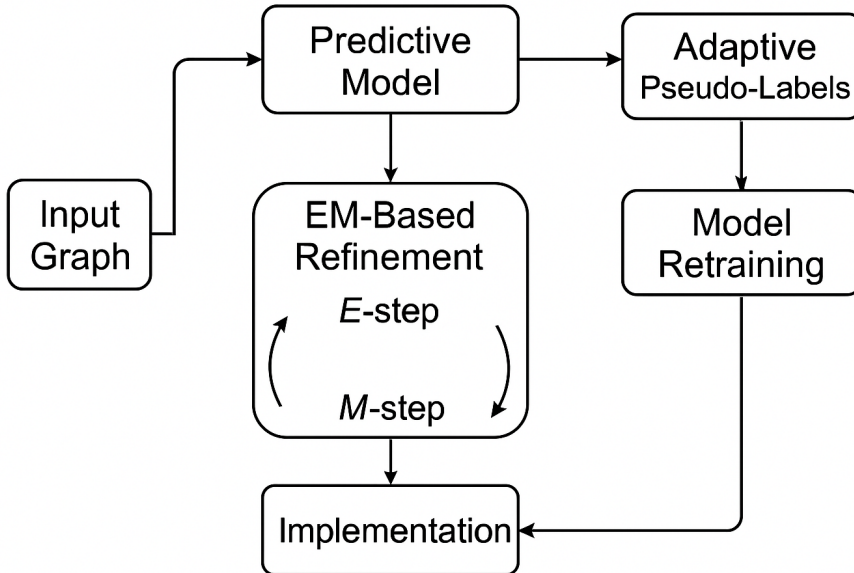

Figure 1: Overview of our Uncertainty-Aware Graph Self-Training (UGST) framework. The EM-based refinement adjusts pseudo-labels by quantifying uncertainty and gating out ambiguous node predictions.

The E-step and M-step are repeated a few times until convergence or a fixed iteration budget is reached. The final $Q(\mathbf{z})$ from the last E-step provides a refined uncertainty estimate for each node.

3.3 Adaptive Pseudo-Label Refinement

Once we have the refined posterior $Q(\mathbf{z})$, we derive pseudo-labels for self-training. However, instead of choosing the class with highest probability as a hard label, we employ an *uncertainty threshold* γ :

$$\hat{y}_v = \begin{cases} \arg \max_k Q(\mathbf{z}_v = k), & \text{if } \max_k Q(\mathbf{z}_v = k) > \gamma, \\ \text{unlabeled (skip)}, & \text{otherwise.} \end{cases}$$

Nodes with high confidence (i.e., $\max_k Q(\mathbf{z}_v = k) > \gamma$) receive a pseudo-label, while uncertain nodes are left out of the training set for that iteration. We treat γ as a hyperparameter that controls the trade-off between leveraging unlabeled data and avoiding noisy pseudo-labels.

3.4 Overall Algorithm

Algorithm ?? summarizes UGST. We begin by training a GNN on the labeled set, then iteratively refine the model using the EM procedure. In each EM iteration, we use the refined posteriors to generate pseudo-labels for training. The process ends when a maximum number of epochs is reached or when performance on a validation set (if available) converges.

4 Experiments

We evaluate UGST on benchmark graph datasets for node classification, comparing it with strong baselines and ablative variants to highlight the importance of uncertainty modeling.

Table 1: Algorithm ??: Uncertainty-Aware Graph Self-Training (UGST).

Input: Graph $G = (V, E)$ with labeled nodes V_L and unlabeled nodes V_U , node features \mathbf{X} , GNN model f_θ , threshold γ , number of EM steps T .

Output: Trained GNN model f_θ .

1. Train f_θ on (V_L, Y_L) via supervised cross-entropy.
2. For $t = 1$ to T :
 - 2.1. **E-step:** Compute posterior $Q(\mathbf{z}_v) = p_\theta(y|v)$ for $v \in V_U$.
 - 2.2. **M-step:** Fine-tune θ by maximizing the expected log-likelihood for labeled and unlabeled nodes.
 - 2.3. Generate pseudo-labels \hat{y}_v using threshold γ .
 - 2.4. Augment labeled set with (v, \hat{y}_v) for $v \in V_U$ where $\max_k Q(\mathbf{z}_v = k) > \gamma$.
 - 2.5. Retrain f_θ on the augmented labeled set.

4.1 Datasets

We choose three standard citation network datasets:

- **Cora:** Contains 2708 scientific publications classified into 7 classes.
- **Citeseer:** Consists of 3327 publications in 6 classes.
- **Pubmed:** Includes 19717 publications partitioned into 3 categories.

We follow the standard splits where a small set of nodes (5% to 10%) are labeled, and the remaining are unlabeled.

4.2 Implementation Details

We implement UGST in PyTorch using a 2-layer GNN (Graph Convolutional Network [3]). We adopt ReLU activations, a dropout rate of 0.5, and hidden dimension of 64. For EM iterations, we set $T = 3$ unless specified otherwise. For the uncertainty threshold γ , we test values in $\{0.6, 0.7, 0.8, 0.9\}$ and pick the best on a validation split. Each experiment is repeated over 5 random seeds, and we report the average classification accuracy and standard deviation.

4.3 Baselines

We compare UGST against the following methods:

- **Supervised GNN (Base):** GNN trained only on the labeled set without any self-training.
- **Vanilla Self-Training (ST):** GNN self-training with threshold-based pseudo-labels, no uncertainty modeling.
- **Soft Label Self-Training (SLST):** Self-training where unlabeled samples are assigned soft labels but no explicit uncertainty filtering.
- **Entropy Minimization (EntMin) [2]:** Minimizes the entropy of model outputs on unlabeled data to encourage confident predictions.

4.4 Results

Table 2 summarizes the node classification performance. UGST consistently outperforms alternative methods on Cora, Citeseer, and Pubmed by up to 2.5% in accuracy. Moreover, UGST maintains tighter standard deviations, underscoring its robustness.

Table 2: Node classification accuracy (%) on Cora, Citeseer, and Pubmed with 5% labeled data. Mean \pm std. across 5 runs.

Method	Cora	Citeseer	Pubmed
Base GNN	78.1 \pm 0.9	69.3 \pm 1.2	76.8 \pm 1.0
ST	80.2 \pm 1.1	70.6 \pm 1.4	78.3 \pm 1.2
SLST	81.5 \pm 1.3	71.4 \pm 1.3	79.0 \pm 1.1
EntMin	81.7 \pm 1.0	72.1 \pm 1.2	79.5 \pm 1.0
UGST (Ours)	83.1 \pm 0.8	73.0 \pm 1.0	80.8 \pm 0.9

5 Discussion and Analysis

Our experiments highlight the key role of explicit uncertainty modeling in graph self-training. By incorporating an EM-based refinement step, UGST can capture node-level uncertainties tied to both model predictions and graph structural variations. This results in more selective pseudo-labeling, leading to better classification performance.

Compared to [5], who primarily addressed image classification and segmentation tasks, our work underlines the flexibility of EM-based uncertainty estimation in *graph-structured* domains. While the essence of their approach was to correct overconfident pseudo-labels, we further adopt a threshold mechanism that specifically addresses the complexities of graph connectivity and node feature distributions.

One practical insight is that UGST particularly excels when the graph is noisy or large. The iterative EM updates effectively identify uncertain regions, preventing error propagation. However, the EM procedure introduces an extra computational cost. Employing parallelization or mini-batching can alleviate some of the overhead.

6 Conclusion

We proposed a novel *Uncertainty-Aware Graph Self-Training* (UGST) framework that leverages Expectation-Maximization for robust pseudo-label refinement in semi-supervised node classification. Our approach was inspired by the success of uncertainty-aware self-training techniques [5], yet extends them to a graph-centric paradigm with threshold-based refinement. Experiments across multiple benchmark datasets demonstrate that UGST achieves both higher accuracy and lower variance compared to strong baselines. These findings suggest that explicitly modeling uncertainty can be an effective tool for large-scale graph-based semi-supervised learning tasks. Future work may explore more advanced uncertainty metrics, including Bayesian approximations, and broaden the scope to other graph applications such as link prediction or graph classification.
