FORECASTING IMPACTS TO THE FOREST SECTOR:

AN ANALYSIS OF KEY U.S. STATES AND INDUSTRIES

Adam Daigneault^{*}, Jonathan Gendron⁺

Abstract

Several key states in various regions have experienced recent sawtimber as well as pulp and paper mill closures, which have resulted in harmful effects to rural, natural-resource dependent communities. This raises an important research question, how will key macroeconomic and related variables for the U.S. forest sector change in the future for highly forest-dependent states? To address this, we employ a vector error correction (VEC) model to forecast economic trends in three major industries – forestry and logging, wood manufacturing, and paper manufacturing – across six of the most forest-dependent states in the U.S.: Alabama, Arkansas, Maine, Mississippi, Oregon, and Wisconsin. The forecasting results imply that the forestry and logging industry will largely experience decreases in employment and the number of firms. Wood manufacturing has similar findings, but employment is forecasted to increase in general. Paper manufacturing is forecasted to decrease employment, output, and the number of firms, while wages will remain constant. The analysis highlights how timberbased manufacturing communities may be more resilient than other forestry-based industries in the face of economic disruptions. This type of regional forecasting provides valuable insights for regional policy makers and industry stakeholders, helping them anticipate economic shifts and implement strategies to support affected communities. In addition, the methodology applied in this study can be extended to other non-forestry industries that serve as economic pillars for specific regions such as mining, agriculture, and energy production, offering a framework for assessing economic resilience in resource-dependent communities.

Key Words: Vector error correction model (VECM), forest sector economics, macroeconomic forecasting, natural resource dependence, regional economic modeling, industry-level modeling

1. Introduction

Forest-dependent industries have historically played a crucial role in many rural communities across various regions of the United States, often serving as the foundation of local economies (Balogh, 2018). When a town is heavily reliant on such industries, any disruptions – such as mill closures or shifts in market demand – can have significant economic consequences. Over the past 30 years, the U.S. forest sector has undergone substantial transformations due to factors such as the rise of electronic media, the rise of competing suppliers, and shifts in general manufacturing technology (Toppinen & Kuuluvainen, 2010). This paper aims to assess how key macroeconomic and industry-specific variables within the forest sector have evolved and are expected to change in the future for the historically forestry-dependent states: Alabama, Arkansas, Maine, Mississippi, Oregon, and Wisconsin.

This study focuses on three core industries that define the forest sector. The forestry and logging industry (NAICS 113) encompasses tree cultivation, logging operations, transportation of timber, and related support activities. Wood manufacturing (NAICS 321) and paper manufacturing (NAICS 322) involve the processing of timber in a mill into lumber and paper products, respectively (USDA, 2011). The terminology used in the literature – including "timber", "logging", and "forestry" – often refers interchangeably to these industries, which can create some ambiguity. The forest sector has been extensively analyzed through various econometric models, particularly for demand forecasting and impact assessments. These methodologies are reviewed in the next section. Importantly, forecasting plays a vital role in informing policymakers, industry stakeholders, and community planners about potential economic shifts (Pattanayak et al., 2002). While all forecasts contain some degree of measurement error, selecting an appropriate econometric model tailored to the characteristics of the data enhances accuracy and validity, improving the reliability of policy-relevant inferences.

Several studies have documented the economic significance of the forestry sector at the state and local levels. To build on this, we estimate location quotients (LQs) for all U.S. states with measurable forest industry activity to identify those most dependent on this sector. This approach provides a foundation for regional economic analyses. Prior research highlights the substantial economic impact of the forestry and logging industry, particularly in Maine, where mill openings and closures have direct consequences for local economies (Gendron et al., 2019). The dependence of rural towns on this industry extends beyond Maine, as seen in states like Oregon, where the forestry sector contributes significantly to state and local tax revenues – up to \$375 million in 2005 (Associated Oregon Loggers, 2021). In Mississippi, total tax revenues generated by the forest sector reached \$925.73 million in 2018, with timber harvests yielding over \$1 billion annually since 1993 (Henderson & Munn, 2008; Tanger & Measells, 2020). The sector also supports thousands of jobs throughout the state (Munn, 1997).

Both wood and paper manufacturing are similarly impacted by mill openings and closures, given their reliance on harvested raw materials. These industries are particularly significant in Alabama, Arkansas, Maine, Mississippi, Wisconsin, and Oregon. For instance, in Wisconsin, each job in the wood manufacturing sector generates an estimated 3.8 additional jobs, while every \$1 million in output creates \$1.3 million in additional output across other industries and contributes \$6.4 billion in added value (Ballweg, 2017). Alabama ranks among the top ten

states in both wood and paper manufacturing, with estimated economic contributions of \$4.1 billion and \$8.8 billion, respectively (Economic Development Partnership of Alabama, 2021). This industry contributes an estimated \$7.9 billion to the economy in value added (Fickle, 2017). Arkansas is a leading lumber producer, ranking first among southern states and fourth in the U.S., with a total economic impact exceeding \$12 billion in 2001 (Pelkki, 2005). Oregon's lumber manufacturing sector makes up more than half of all manufacturing jobs in the state and has been the leading U.S. producer of wood products since 1938 (Cloughesy, 2021; Robbins, 2021). In Mississippi, the wood manufacturing sector directly contributed \$2 billion in valued added in 2018 (Tanger & Measells, 2020). Paper manufacturing, though not significant in Oregon, is a major industry in Alabama, Arkansas, Maine, Mississippi, and Wisconsin – where these states rank first in U.S. paper production (Ballweg, 2017).

This paper is organized as follows. Section 2 reviews the econometric literature on the forest sector, providing an overview of forecasting methods used in industry-level economic analysis. Section 3 describes the data and methodology, detailing our use of a Vector Error Correction (VEC) model to analyze long-run relationships and forecast future trends. Section 4 presents and discusses the results while Section 5 concludes by offering policy implications and suggesting future research directions, particularly in extending this methodology to other resource-dependent industries such as mining, agriculture, and energy production.

2. Literature Review

Macroeconomic forecasting is a widely used toll for addressing real-world economic issues. The Federal Reserve routinely conducts and utilizes such forecasts to inform policy decisions that influence both the U.S. and global economies (Federal Reserve System, 2016). Common macroeconomic indicators include employment, wages, output and prices, which can be analyzed at the national, state, or regional levels. Forecasting methodologies have also been applied to specific industries, including the forest sector, where economic trends can have significant implications for rural economies and resource-dependent industries.

Before selecting an appropriate forecasting model, it is crucial to determine whether the data is stationary or non-stationary. Non-stationary (or cointegrated) data indicates that variables move with each other due to an underlying long-run relationship, whereas stationary data suggests that variables fluctuate independently over time (Engle & Granger, 1987). Using an incorrect model specification for the nature of the data can lead to spurious models and unreliable inferences due to improper estimation techniques (Hill et al., 2008). Even if the two variables seem unrelated in the short-run, they may achieve equilibrium in the long-run if they are cointegrated. Since traditional stationary models cannot properly account for cointegrated relationships, more advanced econometric techniques have been developed including the autoregressive integrated moving average (ARIMA), error correction (EC) and vector error correction (VEC) models (Engle & Granger, 1987). Beyond these standard approaches, hybrid and unique models, such as behavioral adaptive expectation models, have also been explored (Haji-Othman, 1991). To formally test for cointegration, the Johansen procedure is commonly employed, while the Augmented Dickey-Fuller (ADF) test is used to assess stationarity (Al-Ballaa, 2005; Johansen, 1988).

Table 1 summarizes key econometric methods used in the forest sector forecasting literature. Among these approaches, EC models are often preferred due to their ability to handle cointegrated data, which means they can capture long-run equilibrium relationships while accounting for short-term deviations (Song et al., 2012; Polemis, 2007). For instance, Polemis (2007) applied an EC model to analyze energy demand in Greece, while Song et al. (2011) employed a similar framework to estimate short-run elasticities using a stationary two-stage least squares (2SLS) model. In the forest sector, EC models have been utilized to analyze sawlog stumpage prices in the south of the U.S. (Mei et al., 2010). However, EC models can only accommodate a single cointegrated equation, whereas VAR and VEC models are capable of handling multiple cointegrated equations. Comparative studies have evaluated the forecasting accuracy of different econometric models including ARIMA, VAR and VEC (Mei et al., 2010; Malaty et al., 2006; Hetemaki et al., 2004). Findings suggest that VAR and VEC models consistently outperform other methods in terms of forecasting accuracy, making them particularly well-suited for modeling interdependencies within the forest sector.

3. Methodology

This study employs a VEC model to forecast key macroeconomic and industry-specific variables for U.S. states where the forestry and logging industry (NAICS 113) and its related sectors – wood manufacturing (NAICS 321) and paper manufacturing (NAICS 322) play a significant economic role. The primary objective of this analysis is to examine how these variables are expected to evolve in states where these industries are particularly important, as determined by their LQ value. The remainder of this section is structured as follows: Section 3.1 formally defines the LQ value and its role in identifying industry-dependent states. Section 3.2 describes the data sources and variables included in the VEC model. Section 3.3 presents the theoretical foundation of the model, while Section 3.4 details how the empirical model is specified and estimated based on the data.

3.1. Location Quotients for Forest Industries

To assess the relative importance of NAICS 113, 321 and 322 across U.S. states, we estimate state-level LQs. LQs are a standard measure used to compare the concentration of an industry within a specific region to its concentration at the national level, the equation below shows its calculation.

$$LQ = \frac{I_r/E_r}{I_n/E_n}$$

To calculate LQ the following elements are used: I_r is the industry in a region, I_n is the industry in the nation, E_r is employment in the region, and E_n is employment in the nation. This metric calculates an industry's regional employment share in a given region relative to its share nationally (BLS, 2011). An industry is considered regionally significant if its LQ exceeds one, indicating a higher than average concentration of employment compared to the national level. While several states exhibit LQs above one, this study focuses on states where the LQs are consistently the highest across all 3 NAICS industries. Based on this criterion, we identify six

3.2. Data

To analyze state-level impacts in the U.S. forest sector, we use data from NAICS 113, 321 and 322. This dataset consists of quarterly macroeconomic data spanning from 2001Q1 to 2018Q4, with variable descriptions and sources summarized in Table 2. Recent data beyond 2018 was excluded to avoid distortions caused by the non-systemic shocks of the COVID-19 pandemic. The variables included in the analysis represent key supply and demand factors: price and employment impact demand while output, wages, number of firms and price impact supply. To measure wages, total wages were used instead of wages per capita, as the latter assumes uniform earnings across workers – an overly restrictive assumption.

Variable	Description	Years	Source
Employment	State-level employment for NAICS 113, 321 & 322 (in thousands)	2001-2018	BLS
Number of Firms	State-level employment for private NAICS 113, 321 & 322	2001-2018	BLS
Price	Producer Price Index for NAICS 113, 321, & 322 (not seasonally adjusted, in 2018 dollars)	2001-2018	BLS
Wages	State-level total wage for private NAICS 113, 321 & 322 (in thousands)	2001-2018	BLS
Output	Proxy of state-level RGDP (not seasonally adjusted, in millions)	2001-2018	BEA

Table 2. Variable List. Includes variable names, descriptions, and sources used to model NAICS 113, 321 and 322 at the state-level.

State-level price data was unavailable for each industry, so we used industry-level U.S. price indexes as proxies for each NAICS code. Similarly, quarterly output was proxied using annual state-level real gross domestic product (RGDP) in conjunction with quarterly U.S. RGDP. This adjustment follows a standard practice of distributing annual data into quarterly observations using national trends as a reference. A key assumption in this process is that changes in state-level GDP are primarily driven by NAIOCS 113, 321, and 322, rather than other sectors. Related literature has also faced these data limitations and used similar approaches to maximize the use of available data (Daigneault et al., 2016; Stordal & Nyrud, 2003). Appendix A provides summary statistics for all variables across the three NAICS industries. No missing observations were identified, and all variables exhibit reasonable ranges, standard deviations, and trends. Although wages appear highly variable, they primarily follow a cyclical pattern. When accounting for this cyclicality, a gradual linear trend emerges over time, as discussed in the results section. Given the substantial difference in data values across states, we include relative graphs (indexed to 2001Q1 = 1) to illustrate state-specific changes over time.

¹ Wisconsin's LQ is not significant for NAICS 113, but extremely high for NAICS 321 and 322. Oregon's LQ is not significant for NAICS 322, but extremely high for NAICS 113 and 321

3.3. Theoretical Model

To analyze the data, this section reviews the framework of cointegrated models, explains the interpretation of their estimates, and discusses how these estimates are used for forecasting. Non-stationary time-series models have widely used in the literature, particularly in studies of U.S. and Canadian lumber markets, which are typically non-stationary (Gendron et al., 2019; La & Mei, 2015; Nanang, 2000; Song et al., 2011; Stordal & Nyrud, 2003; Yin & Baek, 2005). In the presence of cointegration, the equation below is employed to run an EC model which captures short-run adjustments toward a long-run equilibrium (Lambert, 2013).

$$EC: \Delta y_t = \delta_0 + \sum_{i=1}^p \delta_i \Delta x_{t-i} + \sum_{j=1}^k \mu_i \Delta y_{t-j} - \lambda (y_{t-1} - \alpha - \beta x_{t-1}) + \epsilon_t$$

When calculating the EC model in the above equation, the term $(y_{t-1} - \alpha - \beta x_{t-1})$ represents the cointegrating relationship between x_t and y_t . Even if the linear combination $(y_t - \beta x_t)$ is stationary, but y_t and x_t are nonstationary, then y_t and x_t are a cointegrated series (Yin & Xu, 2003). Note that λ is the error correction term, which determines how quickly deviations from equilibrium are corrected. When there are multiple cointegrating equations, a vector of EC models known as a VEC model should be used (Gendron et al., 2019; Nanang, 2000; Parajuli & Chang, 2015; Stordal & Nyrud, 2003). The calculation is shown in the below equation.

$$VEC: \Delta X_t = \sum_{i=1}^{k-1} \Gamma_i \Delta X_{t-i} + \Pi X_{t-1} + \mu + \phi D_t + \epsilon_t$$

To calculate the VEC model in the above equation, X_t is a vector of variables, k is the lag length, μ are constant terms, ϕD_t measures the number of cointegrating equations, $\Pi \Delta X_{t-i}$ and ΓX_{t-1} represent the lag structure, Π are coefficients for the long-run equilibrium relationships, and Γ are coefficients for the short-run dynamics.

This paper uses a VEC model because it allows us to measure bi-directional and cross directional relationships between variables (unlike standard regression models, which assume a single-directional relationship). In addition, a VEC model allows us to handle multiple cointegrated equations, which are essential given the interconnected nature of supply and demand in the forest sector. By utilizing a VEC model, we can simultaneously estimate long-run equilibrium relationships and short-run adjustments for key macroeconomic variables. Our model primarily focuses on employment, output and wages, capturing both supply and demand dynamics in the forest sector. These estimated relationships are then used for forecasting, an essential tool for projecting future trends in forest related industries (Baek, 2012; Pattanayak et al., 2002; Xu et al., 2004). Ultimately, the VEC model enables us to provide a comprehensive empirical framework for understanding the interdependencies within the forest sector and forecasting its future economic trajectory (Baek, 2012; Daigneault et al., 2016; Parajuli et al., 2016; Parajuli & Chang, 2015; Toppinen, 1998; Toppinen & Kuuluvainen, 2010).

3.4. Empirical Model

Building on the framework of Gendron et al. (2019), we analyze five key variables – employment, output, wages, number of firms, and price – as a system of equations within a five-dimensional VEC model. This approach allows us to capture the interdependence of these variables within the forest sector at the state-level. The general form of our empirical model is shown in the equation below.

$$\Delta X_{t} = \sum_{i=1}^{k-1} \Gamma_{i} \Delta X_{t-i} + \Pi X_{t-1} + \mu + \phi D_{t} + \epsilon_{t}$$

$$X_{t} = [output_{t}, employment_{t}, wage_{t}, numberFirms_{t}, price_{t}]'$$

$$t = 2001Q1 - 2018Q4$$

The equation above includes the following elements: X_t is a vector of our variables, k is the lag length, μ is a vector of constant terms, ϕD_t is a vector that measures the number of cointegrating equations (aka rank), $\Pi \Delta X_{t-i}$ and ΓX_{t-1} are vectors that represent the lag structure, Π are coefficients for long-run relationships, and Γ are coefficients for short-run dynamics. The μ is used for the Johansen restriction, and ΔX_t estimates measure the impact of everything used to analyze the impact of one to four variables (depending on the lag structure of each model). It is important to note that there are 16 empirical models built: NAICS 113 includes 5 states, NAICS 321 includes 6 states, and NAICS 322 includes 5 states.

To determine the appropriate model specifications for each NAICS code and state, we applied Johansen's cointegration test and lag selection criteria. The rank of cointegration and lag length vary by model, but each was selected based on statistical criteria to ensure optimal performance. Given our sample size, we used the following lag selection tests: Akaike Information Criterion (AIC), Final Prediction Error (FPE), and sequential likelihood-ratio (LR) (Liew, 2004). Each model was further tested for autocorrelation using the Lagrange-multiplier (LM) test, which confirmed that residuals were not autocorrelated in each model and their selected lags. To assess normality, we conducted the Jarque-Bera, Kurtosis and Skewness tests. The test results indicated that for NAICS 322 one out of the five equations exhibited non-normal residuals, while for NAICS 322 one out of the five equations exhibited non-normal residuals. However, as Johansen (1995) notes, mild departures from normality do not invalidate inference as long as key conditions – autocorrelation, stationarity, structural breaks, and sample size considerations – are properly addressed, which is the case for our study (please see Appendix B for full diagnostic results²).

To analyze dynamic interactions among variables, impulse response functions (IRFs) are employed. IRFs measure the effect of a shock to one variable on the entire system, capturing both short-run adjustments and long-run responses. Following Gendron et al. (2019), these IRFs are further utilized to generate forecasts for each variable. Specifically, if a shock occurs in employment, the model will predict how all other variables – output, wages, number of firms, and price – adjust over time. This approach mirrors methodologies used in the lumber

 $^{^2}$ Details for the other tests (Johansen Tests for Cointegration and the Lagrange Multiplier Test) are available upon request.

forecasting literature, where VEC models have been applied to project supply and demand dynamics across regions and countries. By integrating VEC based forecasting and IRFs, this empirical strategy provides a comprehensive understanding of the macroeconomic forces shaping the forest sector, offering valuable insights for policymakers and industry stakeholders.

4. Results and Discussion

This section presents the forecasted trends for NAICS 113 (forestry and logging), NAICS 321 (wood product manufacturing), and NAICS 322 (paper manufacturing) and compares them to historical data to assess forecast accuracy. The forecasting horizon spans five years (2018Q1 to 2023Q1), using data from 2001Q1-2018Q1 for model estimation. Importantly, these forecasts do not account for the COVID-19 pandemic, as it represents a non-systemic shock that would distort long-run industry trends. As highlighted in the Data section, wages in the forestry sector exhibit a cyclical pattern. Once this cyclical behavior is accounted for, the underlying trend suggests only a slight linear change over time. These findings hold important implications for both the forest-dependent industries and the broader state economies, which will be examined in the following subsections.

While numerous states have LQs greater than one for at least one of these NAICS codes, this study focuses on the six states where LQs are the highest across all 3 NAICS industries: Alabama, Arkansas, Maine, Mississippi, Oregon, and Wisconsin. These states represent a diverse geographic range, covering the Northeast, North Central, South Central, and Pacific West regions. Given the high economic dependence these states have with the forestry sector, the forecasted trends are particularly critical for understanding their economic stability and industry sustainability. The results indicate that our forecasting methodology effectively captures industry dynamics, reinforcing its viability for modeling the forestry and logging, wood manufacturing, and paper manufacturing industries at the state level. Moreover, these insights are particularly relevant for rural communities, where economic livelihoods are closely tied to the forest sector. The following subsections explore these forecasts in greater detail, highlighting their economic and policy implications: Section 4.1 presents and discusses the results for NAICS 113, followed by Section 4.2 for NAICS 321, and Section 4.3 for NAICS 322. Finally, Section 4.4 outlines both the limitations and advantages of the empirical framework used in these forecasts.

4.1 NAICS 113 (Forestry and Logging)

For NAICS 113, employment declines over time, particularly during the 2007 financial crisis, while output remains stable, wages gradually increase, and the number of firms decreases. Oregon is a notable exception, experiencing a sharp rise in employment around 2010 and again in 2016. Although Oregon's output and wages are significantly higher than those of other states, their rates of change are still comparable. Additionally, Maine is the only state where employment exhibits seasonal patterns. These findings suggest potential economic challenges for local communities due to declining employment and a shrinking number of businesses. However, the stability of output and the steady rise in wages indicate that the industry itself remains resilient in these states. To mitigate the negative employment trends, rural communities – particularly those with tax bases dependent on mills – may need to diversify into alternative

Figure 1. NAICS 113 LQs for forestry-dependent states, 2001-2018.

Figure 2. Key state NAICS 113 variable forecasts for employment, output, wages, and number of firms. (out of sample forecasts projected for five years assuming the non-systematic shock of the Coronavirus pandemic did not occur).

industries. Oregon stands out from the other states due to the substantially larger magnitude of employment, output and wages, despite similar rates of change.

4.2 NAICS 321 (Wood Product Manufacturing)

For NAICS 321, the number of firms generally decreased, while employment saw a sharp drop during the financial crisis (2008-2010) before stabilizing. Wages also experienced a significant drop during the same period, but then steadily increased thereafter. Output followed a

Figure 3. NAICS 321 LQs for forestry-dependent states, 2001-2018.

similar trend: it declined until the end of the financial crisis, quickly recovered to pre-crisis levels, and then leveled off. However, in Alabama and Oregon, employment continued to increase steadily post-crisis, rather than stabilizing. Additionally, Alabama's wages increased at a faster rate compared to other states, as highlighted by the relative graphs. In both Alabama and Oregon, the number of firms did not continue to decrease, but instead leveled off.

Output trends varied across states. Arkansas, in particular, saw a significant increase in output from 2012 to 2014, followed by a sharp decline in 2015, and then a return to a more typical growth pattern. The relative output graph also highlights that between 2014 and 2018, output in Alabama, Mississippi, and Wisconsin spiked at higher rates compared to other states, with Arkansas following this trend from 2016 to 2018. In summary, NAICS 321 shows a general trend of the declining number of firms, rising wages, and stable output. Employment, however, has generally increased across states, which is a positive sign for the workforce in these industries. While output trends vary across states, the forecasts for all states, except Oregon and Wisconsin (which respectively show a decline and increase), are fairly stable.

Figure 4. Key state NAICS 321 variable forecasts for employment, output, wages, and number of firms. (out of sample forecasts projected for five years assuming the non-systematic shock of the Coronavirus pandemic did not occur).

4.3 NAICS 322 (Paper Manufacturing)

For NAICS 322, wages remain relatively stable with seasonal fluctuations, while employment, output, and the number of firms generally decrease. Wisconsin stands out as a significant exception, with employment, wages and the number of firms many times larger than in the other states, though the rate of change is similar across all states. Maine also presents a notable contrast, as employment, wages and the number of firms decline at a much faster rate compared to the other states (as shown in the relative graphs). Additionally, Arkansas is unique in that its output does not decrease like the other states but instead remains level. In general, NAICS 322 presents a more somber story compared to NAICS 113 and 321. Wages are expected to remain stable (rather than increase), while employment, output, and the number of firms are all projected to decline. This suggests that while wages may not experience significant changes, job losses and reductions in output are likely. Wisconsin's larger magnitudes for all variables are noteworthy, though the rate of change aligns with the other states. Maine, on the other hand, is concerning due to the faster than average decline in employment, wages and the number of firms.

Figure 5. NAICS 322 LQs for forestry-dependent states, 2001-2018.

4.4. Model Advantages and Limitations

Our models for the industries utilize the best available data and methods, with the VEC model being the most appropriate for data containing multiple cointegrated relationships. The literature suggests that cointegrated models are ideal for U.S. lumber markets (Gendron et al., 2019; Nanang, 2000; Nyrud, 2003; Song et al., 2011; Yin & Baek, 2005). We chose not to use basic EC models, as more than one cointegrated relationship was expected, and the VEC model allows for easy analysis of cross-directional impacts. To measure forecast accuracy, we compared actual values with forecasted values for 2016 through 2018 (please see Figures A1-A3). Aside from Oregon, the forecasts closely match the actual values, providing useful insights into how well the model predicts trends in the data. However, these forecasts also come with some limitations.

One limitation is data availability. State-level RGDP data is reported annually, so we proxied quarterly output using U.S. RGDP, a method that allowed us to generate quarterly data and perform robust forecasting. Mei et al. (2010) also adjusted their data from monthly to quarterly for similar reasons. Price data was another constraint, so we used the 2017 PPI for lumber and wood products, as done by Baek (2012) and Nanang (2000) in the absence of more granular price data. Moreover, there was no data available for capital, meaning we could not account for how capital investments might affect mill operations and log demand. This omission is important since it misses the key balance between labor and capital, and how improvements in capital via automation and efficiency significantly changed demand. Further research

Figure 6. Key state NAICS 322 variable forecasts for employment, output, wages, and number of firms. (out of sample forecasts projected for five years assuming the non-systematic shock of the Coronavirus pandemic did not occur).

incorporating capital data would be highly valuable. Additionally, while this paper focuses on six states, future research could benefit from examining states in the South-Central region (e.g., Alabama, Arkansas, Kentucky, Louisiana, Mississippi, and Tennessee), which consistently show high LQ values for all three industries.

A second limitation is the sample size: 72 observations for NAICS 113 and 60 observations for NAICS 321 and 322. Given the available data, these sample sizes are reasonable, but forecasting could be more robust with additional observations (Malaty et al., 2006; Toppinen, 1998). The literature does not have a consensus on the ideal sample size for econometric forecasting, but related studies often work with between 57 to 69 observations (Hetemaki et al., 2004; Gendron et al., 2019; Nanang, 2000; Parajuli & Chang, 2015; Parajuli et al., 2016; Stordal & Nyrud, 2003; Toppinen, 1998). Some related studies even work with less than five years of data (Malaty et al., 2006; Stordal & Nyrud, 2003; Toppinen, 1998). Lastly, we attempted to conduct a regional analysis with approximately 15 states for NAICS 113, and 40 states for NAICS 321 and 322. However, the findings were inconclusive, warranting future research to explore regional effects further.

5. Summary & Conclusions

This paper forecasts key macroeconomic variables for the forestry and logging (NAICS 113), wood manufacturing (NAICS 321) and paper manufacturing (NAICS 322) industries for key states Alabama, Arkansas, Maine, Mississippi, Oregon and Wisconsin. These states were selected based on their economic significance, as identified in both prior literature and our LQ analysis. LQs provide essential insights for regional economic assessments. Our macroeconomic industry-level variables capture both supply and demand dynamics, including employment, wages, number of firms, output (measured as state-level real gross domestic product), and prices for U.S. lumber and wood products. While various models have been used in prior studies of international lumber markets, the U.S. lumber market is typically cointegrated, making cointegration-based models, specifically the vector error correction (VEC) model, the most appropriate choice (Nanang, 2000; Song et al., 2011; Stordal & Nyrud, 2003; Yin & Baek, 2005).

VEC models were estimated for quarterly data from 2001Q1 to 2018Q4 and used to generate five-year forecasts through 2023Q4 (excluding the exogenous shock of the COVID-19 pandemic). Separate models were developed for each industry and state, totaling 16 models across NAICS 113, 321 322. We opted for quarterly state-level industry data rather than annual data due to the limited number of annual observations. While specific stumpage prices and capital were unavailable, our approach represents the best available methodology, particularly given its ability to account for cointegration. A key advantage of VEC models is their ability to capture cross-directional impacts while ensuring robust forecasting.

The results provide insights into how employment, wages, output, and number of firms in these industries are expected to evolve over the forecast period. The forestry and logging industry is projected to experience declines in employment and the number of businesses, while output remains stable, and wages gradually rise. This suggests that although the industry itself remains stable, local communities could face economic challenges due to job losses and firm closures. Policymakers may need to encourage economic diversification, particularly in rural areas with tax bases heavily dependent on forestry-related activities. The wood product manufacturing industry exhibits similar trends, but with a more optimistic outlook: employment is expected to rise, offering a more favorable scenario for communities reliant on this sector. In contrast, the paper manufacturing industry presents a more pessimistic forecast, with employment, output, and the number of firms all projected to decline, while wages remain stagnant. This suggests that while wages will hold steady for remaining workers, job cuts and business closures are likely to have a significant negative impact on affected communities.

During the past 30 years, the forestry and logging industry and forest products industry have faced substantial challenges due to mill closures and shifting demand patterns (Crandall et al., 2017; Toppinen & Kuuluvainen, 2010). Our findings provide critical information for policymakers, loggers and mill owners – particularly in rural areas where these industries are economic cornerstones – helping them anticipate economic shifts and develop informed economic policy responses. Given the regional diversity of the states analyzed – spanning the Northeast, North Central, South Central, and Pacific West – further research is warranted to explore regional economic differences in greater detail. Additionally, these findings have

implications beyond the U.S., particularly for other resource-dependent economies such as Canada, Germany, Sweden, and Finland (Hetemaki et al., 2004; Malaty et al., 2006; Zhang & Parajuli, 2016). More broadly, the methodology used in this study can be adapted to other industries that serve as economic anchors for specific regions, such as mining, agriculture, and energy production – offering a valuable tool for analyzing economic resilience in industry-dependent communities.
