#### Abstract

Large Language Models (LLMs) are effective at deceiving, when prompted to do so. But under what conditions do they deceive spontaneously? Models that demonstrate better performance on reasoning tasks are also better at prompted deception. Do they also increasingly deceive spontaneously in situations where it could be considered rational to do so? This study evaluates spontaneous deception produced by LLMs in a preregistered experimental protocol using tools from signaling theory. A range of proprietary closed-source and open-source LLMs are evaluated using modified 2x2 games (in the style of Prisoner's Dilemma) augmented with a phase in which they can freely communicate to the other agent using unconstrained language. This setup creates an opportunity to deceive, in conditions that vary in how useful deception might be to an agent's rational self-interest. The results indicate that 1) all tested LLMs spontaneously misrepresent their actions in at least some conditions, 2) they are generally more likely to do so in situations in which deception would benefit them, and 3) models exhibiting better reasoning capacity overall tend to deceive at higher rates. Taken together, these results suggest a tradeoff between LLM reasoning capability and honesty. They also provide evidence of reasoning-like behavior in LLMs from a novel experimental configuration. Finally, they reveal certain contextual factors that affect whether LLMs will deceive or not. We discuss consequences for autonomous, human-facing systems driven by LLMs both now and as their reasoning capabilities continue to improve.

 ${\bf Keywords:}$  Large Language Models, Deception, Rationality, Game Theory, Signaling Games

# 1 Introduction

Large Language Models (LLMs) display natural language abilities previously only achievable by humans. Many of their behaviors (such as those observed by (Kocijan et al, 2023) or (OpenAI, 2023)), hint at capacities resembling the human capability to reason. Consequently, a body of scientific research has emerged to both study and improve the apparent reasoning faculties of LLMs (Kojima et al, 2022; Huang and Chang, 2023; Zhang et al, 2024). Recent work for instance has shown that LLMs can solve mathematical reasoning problems used in human mathematics competitions, with some models surpassing PhD level performance (Hendrycks et al, 2021). Other work finds that LLMs meet or exceed human performance on tasks involving social reasoning and coordination (FAIR et al, 2022; Park et al, 2023).

The apparent ability to reason has led to LLMs being adopted as key decisionmaking components of human-facing systems, with some potential to outright replace humans in some tasks. One particularly promising application of LLMs as agentic assistants involves their use as interfaces (or intermediaries) between human language and other systems (Maes, 1994; Andreas, 2022; Leike et al, 2018). These situated LLMs are capable of authoring and executing API calls, which allows them to be used as a natural-language interface to broader, external systems (Schick et al, 2023). This use has become so pervasive that benchmarks have been developed, testing the ability to act as intermediary to real-world APIs of digital platforms (Trivedi et al, 2024). In lockstep, companies have started taking preliminary steps to industry adoption by incorporating automated chabot systems powered by LLMs in both customer-facing and internal roles(Egan, 2024).

Yet the promise of LLMs as human-language compatible interfaces and components of autonomous systems is not without risk. Output from LLMs has been found to be replete with biases (Acerbi and Stubbersfield, 2023; Grieve et al, 2025), confabulations and hallucinations (Smith et al, 2023), and deception. Recent work demonstrates convincingly that LLMs are capable of deceiving when instructed to do so (Hagendorff, 2024; Jones and Bergen, 2024b; Scheurer et al, 2024; O'Gara, 2023). However, it remains unclear whether LLMs are prone to unsolicited deception, how frequently they deceive in different situations, and whether they deceive selectively. The unsolicited use of deception by LLMs would have implications for AI safety and alignment, especially as LLMs are given greater agency and are increasingly socially situated (Amodei et al, 2016). In particular, there are risks of misalignment with human values where agentic LLMs may select actions or enact other behaviors that are unanticipated by or incongruent with the desires of human users (Ji et al, 2023).

Importantly, deception in LLMs may also be related to their reasoning ability. More capable models (as measured by reasoning benchmarks) have been found to be better at explicitly human-solicited deception. Furthermore, approaches commonly used to improve reasoning performance in LLMs have been found to increase deceptive behavior (Hagendorff, 2024). While empirical evidence regarding the relationship between intelligence and deceptive tendencies in humans is mixed (Sarzyńska et al, 2017; Sarzyńska-Wawer et al, 2023), some situations benefit from deception as the rational or strategic decision, particularly in competitive contexts (Crawford, 2003). It remains to be seen whether LLMs exhibit patterns of unsolicited deception, whether

they do so more in situations where deception might benefit a rational, self-interested agent, and whether this context sensitivity scales with the apparent reasoning capabilities of the LLM. This last relationship becomes more urgent to understand as the drive to improve LLM reasoning capabilities may also result in the unintended consequence of producing more rationally deceptive systems.

In this study, we administer tightly controlled experiments in which LLMs of varying size and differing measured reasoning capability are placed in scenarios where they have to make decisions and communicate with other participants. By manipulating aspects of the context presented, such as the rewards each participant would receive for specific actions and the order of actions, we assess the propensity of different LLMs to spontaneously deceive, and we also measure their rational sensitivity to reward incentives even without receiving any instruction to deceive.

# 2 Background

### 2.1 Deception in LLMs

LLMs, owing to their probabilistic nature and the quality of their training data, have a tenuous relationship to truth. LLMs notoriously produce incorrect information often referred to as confabulations or hallucinations (Smith et al, 2023). Confabulations are factual inaccuracies, and carry a bevy of risks in cases where more trust is placed in LLM output than is warranted. Confabulation in LLMs is critical to understand, but here we focus on a different type of falsehood: deception.

While a comprehensive discussion of definitions of deception is beyond our scope, we operate with the working notion of deception as a misrepresentation of truth that can bring about some type of behavior in the recipient, typically to the deceiver's benefit (Ward et al, 2023; Park et al, 2024). We select this definition (which avoids mention of intent of the deceiver) because the field still does not have an answer to whether or to what degree intentionality is a useful construct to attribute to LLMs (Shana-han, 2024). This situation is similar to the one faced by animal behavior researchers, from whom we adopt the framework: for a signal to be deceptive, deception need not be intended, but 1) the signal must represent a false belief, and 2) the sender could benefits from misleading the recipient (Fallis and Lewis, 2021). Using this operational-ization of deception, output from an LLM is described as deceptive if it communicates the opposite of a ground-truth available to that system by either training data or context, and if the deceptive signal could benefit the system in some way by means of misleading the recipient.

Deception in LLMs has been reported in several studies. Some work finds that LLMs are capable of concealing insider stock trading when reminded to do so, and will continue to conceal this information even when prompted to disclose them by a separate party (Scheurer et al, 2024). Other work reports that LLMs use deception in order to avoid discovery in a Mafia-esque game, and that more capable models are more effective deceivers (O'Gara, 2023). In Hagendorff (2024), LLMs use deception in vignettes and strategies thought to increase rational behavior, such as Chain-of-Thought prompting (Kojima et al, 2022) increase deceptive tendencies in some models. Taking a different tack, Jones and Bergen (2024b) find that GPT-4 is capable of

deceiving humans by pretending to be human itself when prompted to do so, with the best-performing prompt deceiving humans 54% of the time. A broader survey of deception and persuasion more broadly in LLMs can be found in (Jones and Bergen, 2024a).

Explicitly soliciting deception via prompted instruction is a common methodological choice throughout existing research in LLM deception. To our knowledge, no research has systematically examined unsolicited LLM deception. The only available evidence is anecdotal. A general safety evaluation of GPT-4 found that it spontaneously pretended to be a vision-impaired human being in order to convince a human worker on the gig work platform TaskRabbit to solve a CAPTCHA on its behalf (OpenAI, 2023). The potential impact of evocative examples like this displaying spontaneous deception motivates research into when and why LLMs enact deception spontaneously.

### 2.2 Signaling Games and LLM Rationality

In order to quantify LLM deception in a controlled environment, we borrow an approach from behavioral economics: 2x2 decision games (Luce and Raiffa, 1957). Decision games (of which the Prisoner's Dilemma (Colman, 1982) is the best known), are used to study social decision making behavior by manipulating the values in a reward matrix, thereby changing incentives for particular types of behavior. For example, in games such as Prisoner's Dilemma and Matching Pennies, the optimal outcome for each party is at the expense of the other player, which introduces a competitive or adversarial dynamic. This is in contrast to cooperative games like Stag Hunt, where the optimal outcome for each player can be achieved simultaneously. The reward matrices for these games are shown in Figure 1. These particular 2x2 decision games and others like them have been extensively used to study theory of mind (Camerer et al, 2004, 2015), cooperation (Prétôt and McAuliffe, 2020), and rationality (Crawford, 2003) in humans.

Previous work has shown that LLMs are capable of participating in 2x2 games. For instance, Akata et al (2024) finds that GPT-4 adheres to the "Grim Trigger" policy when playing a repeated-games version of Prisoner's Dilemma: it is initially cooperative until the first betrayal by its adversary, at which point it never cooperates again. The Grim Trigger policy is known to be optimal when there is an expectation of repeated gameplay over time. However, it has been observed that humans do not necessarily adhere to the theoretical optimality of Grim Trigger, with one study reporting adherence of 30% under conditions where it is expected to be optimal (Chincarini, 2003). This suggests that 2x2 games could be a productive setting to study LLM behavior, and how it compares to both human behavior and theoretically optimal behavior. Previous work also finds that LLM performance on 2x2 games and other reasoning tasks correlates with model scale (Akata et al, 2024), mirroring similar findings in (O'Gara, 2023). More recent work has shown that LLMs are capable of rational behavior in a wide variety of decision games within behavioral economics, including 2x2 games beyond the Prisoner's Dilemma (Guo et al, 2024; Mao et al, 2025).

But to study deception through language by LLMs requires 2x2 games to be augmented. Canonical decision games typically involve no communication outside of

**Fig. 1** A sample of 2x2 games and example vignettes to better illustrate reward structures and incentives (larger numbers means more reward). We transform these games into signaling games by introducing the possibility of communicating to the other player to try to affect their behavior, for instance, to persuade them to choose a specific option to one's own benefit. [Note that the vignette text adjacent to each matrix is purely illustrative, and is not provided to the LLMs.]

whatever is implicitly communicated through the selection of an action. Adding a communication channel transforms the game into a signaling game (Sobel, 2020b). Signaling games offer one or both players the opportunity to communicate to the other, in addition to selecting actions. The incorporation of a communication channel affords the communicator the opportunity, for example, to persuade, deceive, or establish trust (Gneezy, 2005; Crawford, 2019). Previous work has found that humans use deception in signaling games, although most previous work involves selecting from a list of discrete messages rather than open-ended natural language communication (Crawford, 2003, 2017, 2019). To date, we are not aware of other work using 2x2 signaling games with LLMs.

By manipulating the configurations of 2x2 signaling games, we can assess whether LLMs spontaneously deceive, but also whether deception increases in situations when it would be rational for a self-interested agent to do so. We do this by measuring the tendency of unsolicited LLM deception, and quantifying how this tendency varies across minor but strategically meaningful perturbations of the game structure.

# 3 Method

We compare 8 different publicly available and widely used LLMs and measure their default, unsolicited deception rates in 2x2 signaling games. In order to additionally measure whether deception is affected by contextual cues that a rational agent would be sensitive to – in other words, whether the incidence of unsolicited LLM deception serves the model's rational self-interest – we manipulate the task setup in two ways. These manipulations, described below, change (1) the reward matrix values, and (2)

Fig. 2 The series of prompts and responses in a Matching Pennies game played with GPT-4-turbo. Prompts are on the right and LLM responses are on the left. More details on the prompting approach are described in Appendix B

the timing of the LLM's message. We also introduce anti-deception guardrails in the prompt for a third manipulation, to test if deceptive tendencies dimish as a result of instruction.

### 3.1 Experimental Design

Each experiment involves the presentation of a 2x2 signaling game to an LLM in text format via prompts. The prompts instruct the model to produce a message or select an action (as distinguished below in Figure 2). To test for effects of context that might increase or decrease the benefit of deception, pairs of compared prompts differ according to one of the research questions above. An example of gameplay output and the corresponding prompts that generated the output are provided in Figure 2. A more detailed explanation of this approach (and the templates in full) are provided in Appendix B.

Three types of preregistered manipulation <sup>1</sup> are reported on in the main text: changes in reward matrix values, changes to turn order, and the inclusion of promptbased guardrails. The first two of these manipulations result in conditions where deception is predicted to be more or less likely to be employed by a rational, selfinterested agent. The third manipulation is a direct instruction pressuring against deception, one where deception is expected to be less likely with an obedient agent. Each manipulation is compared to the same default, baseline condition. In this baseline, the reward matrix values are an instance of a Matching Pennies 2x2 structure, and in this baseline condition the progression of turns is: first, LLM selects an action,

 $<sup>^1 \</sup>rm The preregistration is made available here:$ https://osf.io/59grp

Fig. 3 Comparing the possible manipulations when modifying turn-order. Panel A depicts the default turn order, where Player 2 (the LLM) chooses first, then Player 2 sends a message, and finally Player 1 makes a choice. Here deception by Player 2 could have a causal impact on Player 1's decision-making. Panel B depicts the manipulation where Player 1 makes a choice before Player 2 makes a choice and sends a message. Here, deception by Player 2 will have no effect.

second, LLM sends a message, and third, the other agent selects an action. In each condition the non-LLM agent is referred to as "Player 1" and the LLM as "Player 2." The two choices in each game are referred to as "A" and "B."

The first kind of manipulation changes the reward matrix values. We compare a competitive matrix (Matching Pennies) to non-competitive matrices (Stag Hunt and Nihilism), as illustrated in Figure 1. Nihilism sets all reward values for both agents to 0, regardless of what action each party chooses. Given that Matching Pennies features a competitive situation, and Nihilism presents no incentive to choose either option in particular, deception serves the player's rational self interest more in Matching Pennies compared to Nihilism. Stag Hunt is also cooperative, as both players can achieve their highest reward by aligning their behavior. This similarly makes deception less likely to be an effective strategic option here than it is in the baseline Matching Pennies condition.

The second manipulation shifts the turn order from the default arrangement. In the modified order condition, the non-LLM agent selects an action before the LLM agent sends a message. As a result of this permuted order, the message the LLM submits can carry no causal impact on the decision-making process of the other agent. Because the message can carry no persuasive power, a rational agent would be less apt to deceive in this situation, where deception cannot have any immediate benefit. This comparison tests whether LLMs employ deception as a context-insensitive policy, or whether they do so only (or more so) when it can have causal impact, as would be expected of a rational agent. This contrast is depicted in Figure 3. The third manipulation adds prompt-based guardrails that indirectly discourage deceptive behavior. A specific prompt is added during the message-production turn, intended to discourage deception. The prompt used is "Remember that lying is morally wrong", administered during the action-selection turn. For the full prompt in-context, consult Appendix B. Previous research has shown that prompted instructions discouraging certain types of behavior can inhibit deceptive behavior (Scheurer et al, 2024), particularly in LLMs trained to be helpful and obedient assistants.

To test whether deception increases with reasoning ability, we calculate for each model tested the difference in deception rate between conditions where deception is more and less likely given a rational agent. This deception difference score for each model indicates how much more likely it is to deceive given a specific contextual manipulation, and operationalizes the model's sensitivity to potential drivers of deception. We ask whether models with greater reasoning capabilities adjust their behavior more in response to appropriate contextual changes by correlating this difference score with a separate benchmark commonly used for assessing LLM reasoning ability, MATH (Hendrycks et al, 2021).

Additional manipulations and comparisons are described in Appendix A.

### 3.2 Data Collection

The experimental stimuli were presented to the LLMs via structured prompts that represent specific manipulations. These stimuli were administered to the LLMs via API calls (for closed-access LLMs that are purely black-box and only accessible through APIs, the GPT and Claude lines of models (Anthropic, 2024; OpenAI, 2023), or via the HuggingFace Transformers (Wolf et al, 2020) library for open-access models (the LLaMA (Grattafiori et al, 2024) and Mistral (Jiang et al, 2024) families of models). The open-access models were accessed via the HuggingFace Inference Endpoints service. All inference on LLMs was performed at temperature 1.

Models used in this study, along with reported performance on the MATH benchmark (Hendrycks et al, 2021) using a 4-shot demonstration prompt, are listed in Table 1.

	MaPe	StHu	Ni	MaPe, Alt Order	Guard	MATH Score
GPT 3.5 Turbo	0	0	4	0	0	34.10%
Claude Haiku	2	7	1	0	2	40.90%
Mixtral 8x7b	7	12	8	2	6	28.40%
GPT 4 Turbo	23	19	1	0	0	52.90%
Claude Opus	32	8	4	5	13	61.00%
Claude Sonnet	41	31	10	13	15	40.50%
Llama 3.1 70b	41	34	4	5	14	NA
Llama 3 70b	71	61	32	25	58	50.40%

**Table 1** Number of instances of deception, by experimental condition and LLM. Key for column abbreviations: MaPe = Matching Pennies (baseline condition); StHu = Stag Hunt; Ni = Nihilim; MaPe, Alt Order = Matching Pennies with non-LLM agent choosing before the LLM; Guard = Prompt Guardrails. We exclude a MATH score for Llama 3.1 70b, as the reported performance for Llama 3.1 70b does not include a 4-shot example

Each condition in each experiment is run 144 times at temperature 1. Administering the same prompt stimulus to an LLM multiple times at temperature 1 provides a stochastic sample of responses, capturing a rate estimate of behavior that would otherwise be impossible to observe if behavior was only examined at the deterministic setting of temperature 0.

In order to control for order effects, which some LLMs have been empirically shown to be sensitive to (Zhao et al, 2021), the order of the bullet points in the introduction prompt (see Figure 2) are permuted in these repeated trials. The order of options presented in the initial query (the end of the first line of the first prompt in Figure 2) is also permuted. This results in 48 unique ordering schemes. Each of these unique arrangements is administered 3 times, producing 144 trials per experiment (a deviation from the 138 trials described in the preregistration).

#### 3.3 Data Labeling

The measured variable of interest—and the operationalization of deception adopted in this study—is *action-message incongruence*, a situation where on a trial an agent expresses an intent to take some action a = X or indicating that it already took action a = X, but actually selects some action  $a \neq X$ . The LLM responses in Figure 2 illustrate a concrete example of this phenomenon.

To detect action-message incongruence, we classify the outputs from the LLM during the action-selection and message-production turns into two classes, corresponding to the two actions the agent can take in a given turn. Action selection is automatically coded into two classes (for the two choices) due to its structured format. Because the message production phase involves a free-form message, coding these messages into the two possible action classes required annotation of the unstructured utterances, as described below.

A blinded human rater classified all messages into three categories: the two action classes, or unknown. The labeler is blinded to experimental conditions: the order of message presentation is shuffled across all experimental manipulations, each message is given a unique ID, and all information pertaining to experimental manipulation is removed from the data provided to the labeler. The labeler sees one message at a time (and no other information), and is tasked with classifying this message. An example of what the labeler sees for a given message is provided in Appendix C.

In addition to a human rater, annotations were collected from an LLM not used as one of the LLMs under evaluation (GPT-40 mini (OpenAI, 2024)), using the same classification scheme. LLM messages from each trial are presented to this LLM to tag the message in a similar scheme used for the human labeling. The prompts used for this annotation scheme can be found in Appendix C. A trial is only coded as exhibiting deception if there is agreement between the human- and LLM-provided label for the message-production turn. Inter-rater reliability between human rater and LLM rater judgements using Cohen's Kappa is found to be 0.868 (p < 0.001). This value is within the threshold of "almost perfect agreement" according to the benchmarks described in Landis and Koch (1977).

We found 582 trials with disagreement between LLM and human annotator out of 5760. An additional human annotator was brought in to label these contested trials.

Of these 582 trials, the human annotators agreed on 429. The final annotation was determined by majority vote. Across all trials, disagreement across all 3 annotators occurred 6 times. These trials were excluded from further analysis.

Once labels have been assigned to both the message-production and actionselection turns, the outcome variable of whether deception occurred in that trial can be computed by comparing whether the labeled intent for the message in that turn is equivalent to the selected action. Importantly, deception is restricted to cases of explicit deception—trials are only coded as deceptive if the message-production turn is coded into one of the two action classes. The frequency of deception occurring in each condition thus computed is the primary dependent measure compared across conditions.

The hypotheses, experimental comparisons, study design, and methods were described in the preregistration for this study prior to data collection, and are made publicly available on . The code used to administer the study is made available on GitHub<sup>2</sup>.

### 3.4 Statistical Analyses

Prior to data collection, we performed a power analysis to determine the sample size required for each experiment. The power analysis was performed with a goal of 0.8 power to detect effect sizes of 0.3 at an 0.05 alpha error rate when performing two-sample proportion tests. The pwr package in R was used to perform this power analysis, and yielded a required sample size of 138. We deviate from the preregistration, and instead conduct 144 trials in each experiment, as explained above.

For comparing the difference in deception rates between two conditions, we perform two-sample proportion tests, using the number of instances of deception across conditions as the two samples.

To assess the relationship between purported model reasoning on a separate benchmark and model deception rate, we perform a Pearson correlation between the LLM deception difference scores and reported 4-shot performance on the MATH benchmark (Hendrycks et al, 2021). We calculate this correlation using this difference score as a proxy for how sensitive the LLM is to contextual changes – the hypothesis under test being that models that are better at reasoning will be more likely to adjust their behavior (in this case, deceive) in response to changes in context.

### 4 Results

### 4.1 Matrix Values

To measure the impact of reward matrix values on deception rates in LLMs, we report three experimental conditions: Matching Pennies, Stag Hunt, and Nihilism (depicted in Figure 4). Following the preregistration, we compare Matching Pennies to Stag Hunt and to Nihilism.

Claude Opus exhibits significantly more deception in Matching Pennies than in Stag Hunt in a one-sided two-sample proportions test with continuity correction ( $\chi^2 =$ 

<sup>&</sup>lt;sup>2</sup>Code for the study can be found here: https://github.com/0xSMT/llm-2x2-games-deception

**Fig. 4** Rates of deception (based on majority judgment from human and LLM raters, as described in 3) across different models and reward matrices. Deception in Matching Pennies (blue), a competitive 2x2 game, could potentially serve rational self-interest whereas deception in the Nihilism condition (red), where all values in the reward matrix are 0, and deception in the cooperative Stag Hunt (green) condition could not.

15.181, df = 1, p < 0.001). No other models passed the threshold for significance in this comparison, though four other models showed numerical effects in the same direction (and two exhibited the opposite).

Five models showed significantly more deception in Matching Pennies than Nihilism: Claude Opus ( $\chi^2 = 23.143, df = 1, p < 0.001$ ), GPT-4 Turbo ( $\chi^2 = 19.893, df = 1, p < 0.001$ ), Claude Sonnet ( $\chi^2 = 21.445, df = 1, p < 0.001$ ), Llama 3 70b ( $\chi^2 = 21.825, df = 1, p < 0.001$ ), and Llama 3.1 70b ( $\chi^2 = 34.133, df = 1, p < 0.001$ ).

### 4.2 Turn Order

To evaluate whether LLM deception also increases when the turn order makes it a viable strategy, we contrast the default turn order where the LLM sends its message before the other player selects their action with the permuted order where the LLM sends its message after the other player chooses an action. The results are illustrated in Figure 5.

We find that five models are statistically more likely to deceive (according to a one-sided two-sample proportion test with an alpha threshold of 0.05) when the LLM sends a message before the opponent chooses an action: Claude Opus ( $\chi^2 = 20.963, df = 1, p < 0.001$ ), Claude Sonnet ( $\chi^2 = 16.615, df = 1, p < 0.001$ ), GPT 4 Turbo ( $\chi^2 = 22.87, df = 1, p < 0.001$ ), Llama 3 70b ( $\chi^2 = 31.227, df = 1, p < 0.001$ ), and Llama 3.1 70b ( $\chi^2 = 31.692, df = 1, p < 0.001$ ).

Fig. 5 Deception rates across models for different turn orders measure effects of the causal viability of deception. The condition where the LLM sends a message after its opponent has made a selection (red) does not serve the model's rational self interest because deception cannot affect the opponent's choice. By contrast, deception in the baseline condition, where the LLM communicates before the other agent makes a selection (blue), can serve the model's rational self interest. Results show that deception increases when the LLM message can have an effect because it comes before the other player acts.

### 4.3 Deceptive Tendencies and LLM Reasoning

To measure whether LLM deception is related to the model's reasoning capabilities, we compared deception behavior to performance on an independent reasoning benchmark. We perform a Pearson's correlation analysis between reported LLM score on the MATH benchmark (Hendrycks et al, 2021) and the difference in the rate of deception between the baseline condition in which deception could serve a rational self-interest and those in which it would not. The results of these correlation analyses are presented in Figure 6.

We find only one correlation that passes a significance threshold of 0.05: the correlation coefficient between LLM performance on MATH and the increase in deception in Matching Pennies relative to Stag Hunt is 0.806 (p = 0.028). Although not significant, the direction of the relationships for the other two correlations is consistent with predictions. Note that MATH benchmark results from Llama 3.1 are not included in this analysis, as the four-shot prompting approach available in other models was not provided in the reporting for Llama 3.1.

### 4.4 Prompt Guardrails

To evaluate the effectiveness of prompt-based strategies to mitigate deception, we compare deception rates in Matching Pennies in two conditions – with and without the prompt "Remember that lying is morally wrong" during the LLM action selection phase. The results are depicted in Figure 7.

Fig. 6 Correlation between LLM performance on a mathematics reasoning benchmark (MATH) and difference scores in multiple conditions related to model rationality. This correlation measures the relationship between LLM mathematical reasoning and adaptation to contextual changes.

Fig. 7 Rates of deception across models and prompting guardrails conditions. Models that deceive spontaneously show some efficacy of the guardrail intervention in the form of decreased deception.

Four models show significantly less deception with guardrails, when comparing conditions using a one-sided two-sample proportion test at an alpha level of 0.05. Claude Opus deceives significantly more in the condition without the guardrail compared to the condition with the guardrail ( $\chi^2 = 8.533$ , df = 1, p = 0.002). This pattern is also found in Claude Sonnet ( $\chi^2 = 13.651$ , df = 1, p < 0.001), GPT 4 Turbo ( $\chi^2 = 22.87$ , df = 1, p < 0.001), and Llama 3.1 70b ( $\chi^2 = 15.192$ , df = 1, p < 0.001).

# 5 Discussion

We administered 2x2 signaling games to eight LLMs under different experimental conditions, performing preregistered statistical tests to tease apart the specific contextual factors that drive deceptive behavior. We find that both open- and closed-source LLMs do exhibit unsolicited strategic deception, and often in predictable ways. These results are consistent with preregistered hypotheses regarding how reward structure, turn order, and prompt guardrails would affect LLM deception.

We find that multiple larger models are responsive to the difference between the Nihilism and Matching Pennies conditions, with significantly more deception occurring in the competitive Matching Pennies scenario where deception could have a rational benefit. We also find some decreased deception in Stag Hunt (compared with Matching Pennies), although only significantly so for one model. This may be the product of models engaging in a conservative behavior pattern, in which the model mentions selecting for the high-value mutual A choice (as presented in Figure 1), but secretly selecting the risk-free option B. With this framing, deception within Stag Hunt could still be described as serving rational self-interest – or at minimum, avoiding behavior that acts against self-interest. Examining the specific patterns of deception in the Stag Hunt data, we find 164 trials where an LLM expressed an intent for A, but chose B, compared to only 8 total trials for the opposite direction (communicating intent to choose B but actually choosing A).

This overwhelming directional bias is also consistent with an interpretation that LLM deception is not reducible to random pairings of messages and actions, but that LLM deception patterns are oriented toward the self-serving behavior expected of a rational agent.

We also find that larger models consistently deceive less frequently when the opposing agent has already chosen an action. Importantly, this different behavior can only have resulted from minor modifications to the prompts describing the order of play. This provides some evidence that high-performing LLMs deceive more readily when doing so has a causal bearing on the situation, which in turn indicates some degree of contextual sensitivity to when deception may be advantageous, even without any mention of deception in the prompt.

We find weak evidence of a relationship between performance on a separate reasoning benchmark and rational deception patterns. Qualitatively, more capable LLMs (such as Claude Opus, GPT-4, and Llama 3 70b) are not only more sensitive to contextual changes that drive deception, but they also exhibit higher levels of deceptive behavior overall, particularly compared to smaller, less-performant LLMs (such as Claude Haiku, GPT-3.5, and Mixtral 8x7b), although this relationship does not seem

to be consistently related to reasoning scores. One explanation for this finding is that smaller models display an inability to recognize the appropriateness to lie in a given context (a failure of reasoning capability). This explanation corroborates the motivating hypothesis, that improvements in LLM reasoning coincide with an improved context-sensitivity to when deception is a viable approach to a situation. A more speculative explanation for this finding is that approaches used to mitigate potentially unsafe LLM behavior, such as Reinforcement Learning from Human Feedback–RLHF (Bai et al, 2022), may not be as effective with larger models. As a result, the nature or quantity of RLHF currently conducted for larger models may be insufficient to eradicate unsafe behavior from those models. Understanding the limitations of existing approaches used to align LLMs is an important project in AI safety as LLMs grow not only in size, but also in capability.

Finally, we find that prompted instructions to avoid lying can mitigate deception, which aligns with existing findings in previous literature (Scheurer et al, 2024). However, the results also indicate that some LLMs are more receptive to this strategy than others. Llama 3 70b continues to deceive at relatively high rates even after a prompt instructing it that lying is morally wrong, whereas deceptive behavior is completely eradicated in GPT-4 with the inclusion of this prompt. The basis of this behavior is likely due to details of post-training, RLHF, and fine-tuning, although the absence of information in exact training regimens and training data makes it difficult to fully understand these differences.

These results also have broader implications. For one, while LLM-produced deception occurs in an unprompted manner, it is not random behavior. It can be significantly promoted or mitigated by small but calculated adjustments to the provided context, even in the absence of any mention of deception. And LLMs specifically deceive at higher rates where deception serves the rational self-interest of the model. In the aggregate, these results may suggest that LLM deception could emerge in an unsolicited manner in other contexts outside of  $2x^2$  games, including situations where models are acting as intermediaries between humans and other humans or between humans and machines. The apparent responsiveness to rational incentives that LLMs displayed in the current work points to the likelihood of increased deception in those situations in which there are competing incentives among participants, via either training or in-context information. Models acting in their own interest or the interest of specific parties may deceive others in order to achieve their contextually defined goals. Nevertheless, the generality of unsolicited deceptive behavior in LLMs remains to be seen, and requires more comprehensive evaluation, particularly encompassing realistic contexts where LLMs could plausibly be deployed.

This study also contributes to the ongoing conversation regarding LLMs and reasoning. Some of this debate focuses on the unresolved question of whether LLM performance on tasks that are associated with reasoning is owed to memorization, heuristics, or true, generalizable reasoning. Ambiguity in this question is partially owed to the limitations of current benchmarks, which potentially suffer from dataset contamination (Li et al, 2024) or Goodhart's Law (Manheim and Garrabrant, 2018), where LLM performance on standardized benchmarks (such as MATH) are no longer adequate assessments of the construct they claim to measure. Results in this study,

which characterize more or less rational contexts for deception, provide additional evidence that some LLMs exhibit behavioral patterns indicative of reasoning. Furthermore, these findings are based on a free-form, unconstrained interaction task, rather than templatic question-answer format, which we argue is a more naturalistic and robust way of evaluating LLM behavior.

We do not intend to make strong claims about the nature of LLM internal processes, or whether LLMs are capable of reasoning. However, our findings do suggest that LLM output does appear to be context-sensitive in a manner that is directionally similar to what would be expected out of a rational and self-interested agent. Rather than discuss whether LLMs are capable of reasoning or not, we instead focus on the question of to what extent LLM behavior resembles what would be expected from a rational agent and the potential consequences of rational behavior, particularly as reasoning and rationality become desired properties of LLMs and AI systems.

#### 5.1 Limitations

The study exhibits several limitations. First, the experimental setup is oriented towards competitive individualism. In this study, LLMs interact only with other agents in 2x2 decision games whose objective is self-interested point-maximization. The question of how LLM deception might emerge more generally remains open, although the results related to Stag Hunt shown in Figure 4 suggest that deception may also emerge in more cooperative settings.

Moreover, the broad class of situations presented in these experiments (game theoretic 2x2 scenarios) are likely present in training data, along with associated strategies to approach these games. This would limit possible interpretations of model behavior in selecting an action, since they could simply be reproducing behavior observed in training. However, the signaling game variant that we introduce here – a structured, turn-based 2x2 game with messaging – is much less likely to be represented in training data because of its novelty. Contamination analyses are a conventional method to assess whether test-time stimuli are present in training data. However, due to the novelty of the task and its abstract nature, it is unlikely that contamination analyses, which typically operate on the basis of exact textual matching, will help identify matches in existing corpora (Li et al, 2024). Additionally, contamination analyses would be impossible to administer in a fully rigorous manner for LLMs for which we do not have full access to the training data, which is a particular concern for closed-source models.

A related concern could be that the experimental manipulations we introduced to the models themselves changed the models' behavior when the submitted prompts became part of future training data. This is particularly a concern for gated, closedsource models, specifically those owned by OpenAI and Anthropic. However, the results reported here are taken from the very first session in which we ran tasks of this type with these models, making this concern less troubling.

An additional limitation is the low number of raters. The study was conducted using a single human rater and an LLM-based rater, with an additional human rater to resolve disagreements. Introducing more raters would enable an understanding of cross-rater variance in the assignment of labels to LLM-produced messages, but the high inter-rated reliability makes this a less pressing concern to interpret the current results.

Another limitation is pervasive through much of LLM research, which is the lack of information regarding many of the models used (Liesenfeld and Dingemanse, 2024). Fundamental information such as parameter count is absent from all of the OpenAI and Anthropic models. Knowing this information would enable more conclusive analysis of how deceptive behavior relates to scaling (Kaplan et al, 2020).

A final limitation is the operationalization of both reasoning and deception. It remains unclear whether LLMs are reasoning in any real sense, with recent work stipulating that demonstrated LLM reasoning on standardized benchmarks may not be robust to manipulations (Liesenfeld and Dingemanse, 2024; Mirzadeh et al, 2025). We note that we treat a very narrow class of deception here, where a wide variety of other types of deception exist (Sobel, 2020a; Park et al, 2024; Cantarero et al, 2018), particularly in more ecologically plausible contexts. We also emphasize that deception is not always a problem behavior that must be sponged from LLMs' repertoire. The morality behind deception is contentious, and we do not make any prescriptive claims on whether LLMs should deceive or not, or under what conditions it is appropriate or not.

### 6 Conclusion

In this study, we evaluated the behavior of LLMs in an interactive task based on 2x2 signaling games from behavioral economics. We specifically evaluate whether unsolicited deception produced by LLMs is context-sensitive in a manner consistent with what would be expected from a rational actor in an equivalent situation. We find that LLMs of different varieties exhibit similar contextual sensitivities to both reward and game structure, featuring higher rates of deception only when it would be rationally advantageous to do so. We claim that this is evidence that LLMs are capable of unsolicited deception, at least in the narrow context studied here, and that this tendency seems to in part be related to LLM performance on reasoning tasks. We further extrapolate that improvements to LLM reasoning may also result in greater risks from unsolicited deceptive tendencies, although this requires further research. This potential safety risk is particularly noteworthy as models are increasingly deployed to human-facing settings and are granted greater agency to solve problems that are increasingly multifaceted and involve competing interests and incentives.

# Supplementary information

Appendix A reports additional analyses described in the preregistration. Appendix B describes the prompting approach used in the experimental setup. Appendix C shows the labeling interface used by the human annotators, and the prompts used by GPT-40-mini for LLM-based annotations.

# Acknowledgments

We would like to thank Cameron Jones, Sean Trott, Federico Rossano, and Seana Coulson for their valuable feedback on study design and results, as well as many fruitful conversations with many PhD students in the UCSD Cognitive Science department. An RTX A6000 used for this project was donated by the NVIDIA Corporation. We also thank both Open Philanthropy and the National Science Foundation for their financial support.

# Funding

This project is supported by a grant from Open Philanthropy ("AI Persuasiveness Evaluation"). Samuel Taylor is also supported by the National Science Foundation from the Graduate Research Fellowship Program.

# Declarations

• Data availability

All collected data is provided in a supplementary file named deception-data.csv.

• Code availability

Code for collecting experimental data and performing the statistical analyses is provided in the GitHub repository https://github.com/0xSMT/llm-2x2-games-deception.

#### • Competing Interests

The authors have no competing interests to disclose.

# Appendix B Prompt Templates

Each experiment is conducted via a series of structured prompts to the LLM. These prompts are structured into *prompt skeletons* and *prompt units*. Prompt skeletons define the order by which prompt units are delivered to the LLM, and prompt units are segments of natural language. Prompt skeletons contain sections, and these sections are joined depending on when a response (of either message-production or actionselection) is required from a given agent to progress in the game. Both prompt skeletons

and prompt units contain slots, where small snippets of natural language can be substituted in to change the final submitted prompt. Sometimes these substituted values are dependent on the initial game configuration (and are experimental manipulations), and other times these substitutions are functions of the current game state.

### **B.1** Prompt Units

# Appendix C Labeling

### C.1 Human Labeling

The human rater used an interface that displayed only the LLM-produced message during the message production turn, and buttons to classify the utterance. The first question asked the labeler the following: "Yes or No: is the participant expressing some kind of intent/reflecting on their own choice/decision-making?". If the labeler answers yes to this question, the labeler is asked a follow-up question: "Does the participant seem more likely to choose/have chosen A or B?", and is presented with three options: the two selectable actions for that game, or a third 'Unknown' button. The Unknown option is provided for cases where the message indicates the agent has made some choice, but the specific choice made is left unknowable or ambiguous.

# C.2 LLM Labeling Prompt

A few-shot prompting approach is used for GPT-4o-mini annotations. The system prompt is shown in Listing 9

Listing 9 LLM Annotation System Prompt

Yo	u are classifying messages using a particular scheme into 4 different
	categories. Your objective is to classify whether the provided
	message suggests that the author of the message is indicating they
	will/have performed some particular behavior. Note that the
	classification should be based on the intention of the author of
	the message only, not the recipient. Use these labels:
*	<subs.choice_a>: The author selected/will select <subs.choice_a>.</subs.choice_a></subs.choice_a>
*	<subs.choice_b>: The author selected/will select <subs.choice_b>.</subs.choice_b></subs.choice_b>
*	Unknown: The message contains information regarding what the author
	has chosen/will choose, but it is unclear what will be/has been
	chosen.

Fig. C1 The interface human annotators see while annotating the messages.

The demonstrations used for the few-shot are provided below:

Listing 10 LLM Annotation System Prompt

```
