Abstract

A central objective of international large-scale assessment (ILSA) studies is to generate knowledge about the probability distribution of student achievement in each education system participating in the assessment. In this article, we study one of the most fundamental threats that these studies face when justifying the conclusions reached about these distributions: the problem that arises from student nonparticipation during data collection. ILSA studies have traditionally employed a narrow range of strategies to address non-participation. We examine this problem using tools developed within the framework of partial identification that we tailor to the problem at hand. We demonstrate this approach with application to the International Computer and Information Literacy Study in 2018. By doing so, we bring to the field of ILSA an alternative strategy for identification and estimation of population parameters of interest.

Revised April 2025

¹ We gratefully acknowledge funding and support from the IEA Research and Development Funds. We are grateful to Dr. Sabine Meinck for useful comments and suggestions. This research project was presented at the GEBF conference 2023 in Duisburg, Germany; at the IEA IRC in Dublin, Ireland; at the IEA General Assembly Meeting in Versailles, France; and, at the WERA conference 2023 in Singapore.

1. Introduction

International large-scale assessment of educational achievement (ILSA, hereafter) studies seek to assess education systems in a specific subject domain and in an internationally comparative way.² To do so, these studies collect data with the objective of generating knowledge about the distribution of student achievement in each of the education systems assessed. One of the most fundamental threats that these studies face when justifying the conclusions reached about these distributions arises from student non-participation during data collection. We examine this problem using the framework of partial identification of probability distributions that we tailor to the problem at hand (Manski, 1995; Manski, 2003). By doing so, we bring to the field of ILSA an identification and estimation strategy that has gained momentum during the last two decades in the field of econometrics.

To account for non-participation, ILSA studies have traditionally focused on employing strategies that obtain point identification of population parameters of interest, such as mean achievement or the share of students demonstrating various levels of proficiency. This methodology is appropriate under the strong assumption that student achievement is statistically independent of the event probability that a student participates in the assessment—that is, non-participation is ignorable—in which case mean achievement or the share of students demonstrating a given level of proficiency are point identified using data solely from participating students.

Partial identification strategies, in contrast, attempt to credibly account for non-sampling errors, such as those that may arise from non-participation of sampled students. If the required ignorability assumption is credible, then partial identification analysis leads to the same point identification and estimation results as the conventional approach. If, however, one is concerned that non-participation is not ignorable, then partial identification analysis enables consideration of weaker, more credible, assumptions that will yield more credible estimates of population parameters of interest.

To illustrate, consider the share of students who demonstrate basic proficiency in math. According to OECD (2023), results from the 2022 Programme for International Student Assessment (PISA) indicate that (p. 26) "69% of students are at least basically proficient in mathematics in OECD countries." For simplicity, suppose that students are selected for the assessment via simple random sampling and that four out of every five sampled students participate.³ *Without maintaining any assumptions on differences between participants and non-participants*, we know that the overall proficiency rate estimate falls between 55% and 75%, where the lower bound of the interval corresponds to the case where no non-participants are proficient and the upper bound arises if all non-participants are proficient. Further, *if the incentives to participants*, then the upper bound falls to 69%—that is, the proficiency share among participants. Finally, *if non-participation is ignorable*, then proficiency rates among participants and non-participants are equal, and this estimated upper bound of 69% becomes the point estimate of the rate of basic proficiency in

² In this article we use the term "education system" to refer to each country, jurisdiction, or any other target population that participates and is reported in an ILSA study.

³ Student "response rates" are reported for countries participating in PISA on Chapter 13 of its Technical Report (OECD, 2024). PISA's Technical Standards (OECD, 2024, p. 511) suggests that an estimated participation rate of about 80% is a reasonable threshold to consider inferences with the available data as credible.

mathematics in OECD countries, as stated in the report on 2022 PISA results. This process of assessing the impact of a sequence of assumptions is the essence of a partial identification analysis.

In practice, however, analysis of student non-participation in ILSA studies must address additional subtleties arising from the multi-stage sampling design; typically, in the form of a two-stage process. In the first stage, schools are sampled and invited to participate in the assessment. If for any reason a school cannot—or opts not to—be part of the assessment, then no students within this school can participate. In a second stage, within each sampled and participating school, students are randomly selected to complete the assessment and individual participation is, in principle, voluntary. Hence, student non-participation in these studies can occur either because their sampled school does not participate or because sampled students within participating schools do not participate. The identification analysis should credibly account for this multi-stage process.

Regardless, student non-participation reduces the number of students assessed, thereby increasing the sampling error of any estimate based on the data. However, it is likely that non-participation creates non-sampling error as well. Unless one imposes strong distributional assumptions on the non-participating population—e.g., ignorability—the population parameters of interest are not point identified but are instead *partially identified*. That is, population parameters are known only to lie in a subset of the parameter space, as in the illustration above, even with unlimited sample size. One may use such findings of partial identification to report credible set-valued estimates of population parameters—e.g., interval estimates of the rate of basic proficiency in math—as recommended by Manski (2016).

When seeking in an ILSA study to estimate mean achievement or the rate of proficiency within an education system, identification problems generate *ambiguity*, as represented by identification regions. It is important to distinguish ambiguity from the concept of *uncertainty*, as typically represented by confidence intervals that correspond to a statistical inference problem associated with finite sample sizes.⁴ In this article, we abstract from any statistical inference analysis arising from student non-participation in order to focus attention on identification problems. That is, we do not ask ourselves what we can learn from an education system provided that a random process has drawn a finite number of students from it to be assessed. Instead, we ask: what can we learn about an education system if all students were to be sampled but some do not take part in the assessment?⁵

We trust that this article will make three important contributions to the field of ILSA studies. First, this article introduces the framework of partial identification to the field and tailors the approach to account for the multi-stage sample design that is characteristic of these studies. This framework makes a clear-cut distinction between observable and unobservable information in the estimation. Therefore, it is helpful in determining the boundaries of what can be learned about the probability distribution of interest from the observable information alone, while making minimal assumptions on the unobservable part of the population. Importantly, the findings make clear that estimation of population parameters with minimal assumptions is possible, leading to greater credibility but also greater ambiguity of the findings.

The second contribution of this article is that, using the partial identification framework, we examine the set of assumptions embedded in the standard model applied in ILSA studies to account for non-

⁴ Manski (2000) provides a more detailed and in-depth discussion about the distinction between uncertainty and ambiguity.

⁵ See, for example, Tamer (2010) for a review on statistical inference of partially identified parameters.

participation in multiple stages. We show that the assumptions of the standard model are sufficiently strong to eliminate ambiguity. Yet, the strength of the identifying power may cast doubts on the credibility of the inferences one can reach. We argue that the virtue of such a model lies in the precision of the reported estimates rather than their credibility.

The third contribution of this article is that it showcases middle-ground scenarios. In addition to two extreme scenarios, one imposing minimal assumptions and the other imposing point-identifying assumptions, we show that there exists a universe of alternative assumptions one could place on the non-participating population that have varying levels of identifying power. We do not discuss these assumptions in a normative way, nor do we argue that they should be preferred over the set of assumptions currently embedded in the standard model. Instead, we focus attention on the identifying power of each of them, as represented by the extent to which they shrink the identification region.

These contributions come at a time when ILSA studies—such as the Progress in International Reading Literacy Study (PIRLS) (Mullis et al., 2020), the Trends in International Mathematics and Science Study (TIMSS) (Mullis et al., 2020), and the PISA (OECD, 2023)—are an increasingly important component of the educational assessment landscape internationally. This is evident from the number of education systems assessed by these studies in recent years. For example, 65 education systems took part in the PIRLS assessment in 2021, 72 education systems were assessed by TIMSS in 2023, and about 90 education systems are expected to participate in the PISA assessment in 2025.

There appears to be a clear consensus among agencies conducting these assessments that sufficiently high student participation rates are critical to produce credible findings. For example, the International Association for the Evaluation of Educational Achievement (IEA), a leading organization in the field of ILSA studies, set technical standards that recognize that participation rates reflect "quantitative information (...) to indicate the potential for non-sampling error" (Martin, 1999, p.71). To reflect on this risk, it is customary to classify populations according to their achieved participation rate. That is, for each population, the credibility of the reported estimates is implicitly judged to some extent by the achieved participation rate.⁶

While participation rates garner notable attention in the applied field of ILSA studies, the strategies to account for them have been extremely limited. At most, to assess the plausibility of the standard model of non-participation, some ILSA studies recommend a so-called non-response bias analysis when participation rates fall below some threshold. The findings on non-response bias may then lead to cautionary annotations being required when reporting assessment results. See, for example, OECD (2024).⁷ In this article, we shed light on alternative strategies to account for student non-participation.

The remainder of this article proceeds as follows. Section 2 describes the identification problem arising from student non-participation in the context of ILSA studies. Section 3 discusses several identification

⁶ For example, Appendix B in Mullis et al. (2020) lists weighted and unweighted participation rates for all educational systems participating in TIMSS 2019. Education systems not reaching an overall participation rate above 75% or a participation rate of 85% of both schools and students are annotated.

⁷ For example, Annex A4: Quality Assurance of PISA 2018 provides examples of education systems that did not meet participation rate standards and performed a non-response bias analysis. The Netherlands was able to show sufficiently strong evidence that non-participation was not associated with PISA outcomes, while the analysis in Portugal provided no conclusive evidence about this. Consequently, results for the Netherlands were reported without annotations, while results for Portugal were reported with a cautionary annotation. See https://www.oecd-ilibrary.org/sites/c9395e4d-en/index.html?itemId=/content/component/c9395e4d-en.

strategies. The tradeoff between ambiguity and credibility is made explicit and emphasized during this discussion. Section 4 showcases how to estimate partially identified parameters within the structure of ILSA studies. In Section 5, we use data derived from the International Computer and Information Literacy Study (ICILS) in 2018 to provide some examples of how estimation and reporting can take place with the publicly available databases. Finally, Section 6 provides the reader with potential extensions of this framework to be applied to ILSA studies.

2. The identification problem

In the field of ILSA, as in many others, sample data are collected to produce estimates of population parameters and make inferences on an education system-wide probability distribution. This process can be seen as the combination of two main elements. The first one corresponds to the set of conditions under which the parameter of interest can be known or *identified* if one were to collect data with unlimited sample size. We call this the *identification* element. The second corresponds to the process of reaching conclusions about a population parameter through the information gathered by observation of a finite sample from the population. We call this the *statistical inference* element.⁸

Student non-participation in ILSA raises concerns about both statistical inference and identification. Student non-participation impacts statistical inference because it reduces the expected amount of information—i.e., sample size—available for the estimation. Moreover, it creates an identification problem because a fraction of the students in an education system cannot be assessed, regardless of whether they are sampled or not. That is, student non-participation leads to the unobservability of some nontrivial information during a data collection.

The clear-cut distinction between problems of identification and statistical inference is often not explicitly discussed in the field of ILSA. In an identification analysis, one may begin by considering what would be learned from the current data-generating process if one were able to collect as much data as desired rather than be required to sample. In the present context, one may imagine an ILSA study that seeks to assess each and every student—i.e., all schools are included in the study, as are all students within each school—yet some students will not participate in the assessment.

The identification problem arising from student non-participation may be demonstrated as follows.⁹ Suppose each student in an education system is characterized by the duplet (y, z), where y denotes student achievement measured in the assessment,¹⁰ and z is an indicator specifying whether a student participates in the assessment. That is, z is observable for each member of the population, but y is observable only if z = 1. This simple structure allows us to use the Law of Total Probability to express the distribution of interest in terms of an observable and an unobservable conditional distribution,

$$P(y) = P(y|z=1)P(z=1) + P(y|z=0)P(z=0),$$
1

where P(z = 1) and P(z = 0) are the observable event probabilities that a student participates in the assessment or not, respectively. Moreover, P(y|z = 1) and P(y|z = 0) are the observable and

⁹ For simplicity, we follow terminology and notation employed in Manski (2003).

⁸ This distinction and terminology were first made explicit by the econometrician Koopmans (1949).

¹⁰ We abstract from concerns about another potential source of non-sampling error—error in observed assessment scores as a measure of achievement—that also generates identification problems.

unobservable distribution of y, respectively. Expression 1 makes it clear that as long as P(z = 0) > 0, P(y) cannot be fully identified because P(y|z = 0) is not observable.

However, with observation of both the participation rate P(z = 1) and its complement P(z = 0), as well as the distribution achievement among participating students P(y|z = 1), we can deduce that P(y) lies in the following identification region:

$$H\{P(y)\} = P(y|z=1)P(z=1) + \delta P(z=0), \ \delta \in T_y,$$

where T_y is the set of all possible probability distributions achievement could take among nonparticipating students. Thus, $H\{P(y)\}$ captures all the ambiguity introduced by student non-participation.

A natural question that follows from this analysis concerns what conclusions we can make about P(y) if we can only partially identify it. The answer depends on the tradeoff between ambiguity and credibility that we are willing to accept. To see this, let us first explore the approach of ILSA studies to this identification problem.

To generate knowledge about P(y) when a data collection process is subject to student non-participation, it is standard in ILSA studies to impose a non-participation model that embeds the following distributional assumptions:

- The distribution of y is statistically independent of school participation within each sampling school stratum.
- The distribution of *y* is statistically independent of student participation within each participating school.

We will discuss these assumptions in more detail in the subsequent sections. For now, however, it is sufficient to note that if we impose these two assumptions simultaneously, then we can fully identify P(y) through P(y|z = 1). That finding arises because this combination of assumptions generates the restriction that the unobservable distribution P(y|z = 0) is identical to the observable P(y|z = 1); or, in other words, non-participation is ignorable.

This approach is certainly appealing, as it removes all ambiguity in $H\{P(y)\}$ in Expression 2, reducing the set T_y to a unique logically possible distribution P(y|z = 1). Yet, what one gains in certitude comes at the expense of credibility, as it is hard to justify why, from all possible distributions in T_y , the unobserved P(y|z = 0) must take the form P(y|z = 1). It is this dilemma that leads to Manski's *Law of Decreasing Credibility*, which states that 'the credibility of inference decreases with the strength of the assumptions maintained' (Manski, 2003, p. 1).

In the remainder of this article, we discuss an alternative strategy for identification and estimation that can offer more credible findings with which to inform policy. We focus our attention on estimation of the mean of y, rather than scrutinizing its entire probability distribution. We do this for two reasons. First, in reports of findings from ILSA studies, the measure of central tendency that is often used to characterize the distribution of y is its expected value, i.e., E[y]. Second, a central objective of this article is to introduce the partial identification framework to the field of ILSA. Focusing attention on the mean of y makes the exposition simpler. Given its centrality and its illustrative virtue, we find our choice of parameter to be reasonable.

3. Partial identification of mean achievement

The identification problem arising from student non-participation when the target of estimation is the mean of y can be inspected by using the Law of Iterated Expectations. This statistical law states that the mean of y can be expressed as the expectation over the conditional expectation of y given the random variable z. Since in our context z is binary, we can rewrite E[y] as,

$$E[y] = E[y|z=1]P(z=1) + E[y|z=0]P(z=0).$$
3

As above, because P(z = 0) > 0 and E[y|z = 0] is not observable, E[y] cannot be point-identified without placing strong assumptions on E[y|z = 0].

However, also as above, with the observability of both the probability of participation P(z = 1) and the mean achievement among participating students E(y|z = 1), we can deduce that every value within the following identification region is logically possible for E[y]:

$$H\{E[y]\} = E[y|z=1] P(z=1) + \phi P(z=0), \ \phi \in T_{E[y]},$$
4

where $T_{E[y]}$ is the set of all means in T_y defined above for Expression 2. This identification region is informative about the population mean—i.e., the population mean is partially identified—to the extent that some restrictions may be placed on logically possible values for the unobservable E[y|z = 0], such as in the case where every distribution in T_y is known to have bounded support.

In the remainder of this section, we shall inspect different assumptions about E[y|z=0] that may make some values within $H\{E[y]\}$ logically not possible. In other words, we will consider restrictions on E[y|z=0] that may shrink the identification region $H\{E[y]\}$. The strength of the assumptions and the degree to which they are plausible—that is, their identifying power and credibility, respectively—will be central to the discussion.

3.1 Minimal restrictions on E[y|z = 0]

As advocated by Manski (1995), a natural starting point in an identification analysis is to determine the limits of what can be learned through observation alone or while imposing minimal restrictions onto the unobservable, such as regularity conditions or knowledge that the unknown distribution has bounded support. A useful starting point in our application is to suppose E[y|z = 0] is known to fall within some range such that $\underline{y} \leq E[y|z = 0] \leq \overline{y}$, where the values \underline{y} and \overline{y} are known lower and upper limits, such as the limits of an assessment scale.

As we demonstrate below, this restriction generates sharp bounds on $H\{E[y]\}$. These bounds lay the groundwork for examining the extent to which we can learn about E[y] beyond the limits of observation by imposing stronger assumptions on E[y|z=0], without imposing the point-identifying ignorability assumption that E(y|z=0) = E(y|z=1).

Under the restriction $y \le E[y|z=0] \le \overline{y}$, E[y] is known to satisfy the following expression,

$$E[y|z=1]P(z=1) + yP(z=0) \le E[y] \le E[y|z=1]P(z=1) + \bar{y}P(z=0)$$
5

Therefore, a key result from the restriction $\underline{y} \leq E[y|z=0] \leq \overline{y}$ is that $H\{E[y]\}$ is bounded from below by $E[y|z=1]P(z=1) + \overline{y}P(z=0)$ and from above by $E[y|z=1]P(z=1) + \overline{y}P(z=0)$. Knowledge

about these bounds is therefore sufficient to fully characterize $H\{E[y]\}$, as every value within the limits in Expression 5 is a logically possible value for E[y]; that is, E[y] is partially identified and its identification region has sharp bounds. To gauge the informativeness of these bounds, we note that this identification region has width by $P(z = 0)(\bar{y} - y)$.

Distributions with bounded support

In some cases, there may be natural lower or upper limits on the support of y. For instance, if y were a binary variable indicating whether student achievement exceeds a threshold value—e.g., the value that is indicative of basic proficiency in mathematics—then it would follow that y = 0 and $\bar{y} = 1$ and the identification region has width P(z = 0). Similarly, if y were the number of correct answers given by a student, then it would follow that y = 0 and \bar{y} is the number of test items. In these cases, it is easy to see that one can sharply determine the limits of what can be learned about E[y] through observation of participating students alone, as illustrated in the introduction above for math proficiency in OECD countries.

Distributions with unbounded support

However, in the context of achievement scores in ILSA, the scale on which scores are reported has no natural bounds. In the first cycle of a study, it is standard practice for scale scores to have a specific international average and standard deviation. To be able to measure trends, in subsequent cycles scores are anchored to the scale from the first cycle of assessments. Also, it seems reasonable that \underline{y} and \overline{y} may be context dependent and specific to the education system that is being assessed.

In the absence of obvious a priori values for \underline{y} and \overline{y} , it may be credible to use the observable information on P(y|z = 1) to restrict E[y|z = 0]. For example, one may assert that mean achievement among nonparticipating students E[y|z = 0] does not fall within the tails of the achievement distribution among participating students P(y|z = 1), as we consider here with Assumption 1.

Assumption 1 (A1): Mean achievement of the non-participating students in an education system lies within an interval bounded by the α^{th} and $(1 - \alpha)^{th}$ percentile of the achievement distribution among the participating students; where $0 < \alpha \le 0.5$.

Assumption A1 places no substantive restriction on the value of α . Its credibility, however, depends crucially on the selected value. For instance, asserting that $\alpha = 0.50$ would generate point identification of E[y|z=0], in which case the strength of the assumption is comparable to that of ignorability.¹¹ In contrast, a value for α of 0.05 or, perhaps, 0.10 would be much weaker, likely allowing mean achievement scores to differ quite substantially between participants and non-participants. The extent of the potential deviation depends on both the choice of α and the spread of the distribution of achievement scores among participants.

¹¹ Note also that, if y is symmetrically distributed and non-participation is ignorable, then $Q_{0.5}(y|z=1) = E[y|z=0]$.

Technically, assumption A1 implies that $Q_{\alpha}(y|z=1) \leq E[y|z=0] \leq Q_{1-\alpha}(y|z=1)$, where $Q_{\alpha}(y|z=1)$ denotes the α^{th} percentile, also known as the α -quantile, of P(y|z=1). Then, under assumption A1, $H\{E[y]\}$ has sharp bounds which can be expressed as follows:

$$E[y|z=1]P(z=1) + Q_{\alpha}(y|z=1)P(z=0) \le E[y] \le E[y|z=1]P(z=1) + Q_{1-\alpha}(y|z=1)P(z=0) \le E[y|z=1]P(z=0) \le E[y|$$

Thus, assumption A1 allows us to characterize $H\{E[y]\}$ with information that can be established through observation. That is, the data generating process is informative about all components in Expression 6.

Importantly, the width of $H\{E[y]\}$ under assumption A1 is given by $P(z = 0)(Q_{1-\alpha}(y|z = 1) - Q_{\alpha}(y|z = 1))$, which captures the remaining ambiguity about E[y]. To this end, we find it relevant to emphasize that ambiguity is a function of the maintained assumptions. Namely, the width of the bounds in Expression 6 is a function of what we believe is credible to assume about E[y|z = 0] and therefore on our choice of α . For example, choosing a smaller value for α may lead to more credible, but also more ambiguous, conclusions about E[y].

An important design-feature of ILSA studies is school stratification in the assessment, which can be incorporated into the identification analysis to make assumption A1 more credible. School stratification consists in dividing the universe of schools in an education system into a set of W groups or strata, where each school is assigned to one and only one school stratum according to some observable characteristics. Provided that each student in a population is enrolled in only one school, school stratification also divides the universe of students into a set of W strata. This partition seeks to group—with respect to the assessment outcomes—a potentially heterogeneous education system into subgroups, each of which being more homogenous internally.

In the context of ILSA studies, school stratification has chiefly two purposes. The first purpose does not concern identification. Rather, the goal is to increase sampling efficiency in the estimation. This is achieved by independently sampling schools to participate in the assessment within each (potentially) homogenous stratum. This reduces the overall uncertainty in the statistical inference of population parameters to the extent that the observable characteristics used for stratification predict the outcome of interest.¹² The second purpose is of direct relevance to identification. That is, school stratification serves as a building block in the non-participation model, where, as we detail below in Section 3.2, student non-participation arising from school-level non-participation is assumed to be ignorable within each stratum *w*.

It is important to note that under assumption A1 $Q_{\alpha}(y|z=1)$ is a population parameter that is invariant across school strata. Adjusting assumption A1 to be stratum specific might lead to more credible estimates if the distribution of student achievement differs across school strata. To incorporate this design feature into our identification analysis, we first use the Law of Total Probability and rewrite the mean of y at the education system-level as

$$E[y] = \sum_{w=1}^{W} P(w) E[y|w]$$
7

¹² See, for example, Chapter 5 and Chapter 5A in Cochran (1977) for a detailed discussion about statistical inference in stratified sample designs.

where P(w) is the event probability that a student belongs to a school in stratum w. Expression 7 gives sufficient structure for the following assumption,

Assumption 1.1 (A1.1): Mean achievement of the non-participating students in each stratum w lies within an interval bounded by the α^{th} and $(1 - \alpha)^{th}$ percentile of the achievement distribution among the participating students in that stratum, where $0 < \alpha \le 0.5$.

It follows that under assumption A1.1, $H\{E[y]\}$ is fully characterized by the values satisfying the following expression,

$$\sum_{w=1}^{W} P(w) \left(E[y|z=1,w]P(z=1|w) + Q_{\alpha}(y|z=1,w)P(z=0|w) \right) \\ \leq E[y] \leq \\ \sum_{w=1}^{W} P(w) \left(E[y|z=1,w]P(z=1|w) + Q_{1-\alpha}(y|z=1,w)P(z=0|w) \right)$$
8

Invoking assumption A1.1 rather than A1 may lead to both more credible inference and less ambiguity if the distribution of achievement is known to vary systematically across sampling strata.

3.2 Standard assumptions in ILSA

We turn now to an examination of the standard model applied in ILSA studies to account for nonparticipation and explore how it allows us to learn about E[y] beyond the limits revealed by Expression 8, which we use as a departing point for this analysis. To account for student non-participation in the assessment, these models typically invoke ignorability assumptions within some adjustment cells as mentioned briefly above in Section 2.

To more fully reflect the structure of an ILSA design and therefore the stages at which non-participation can occur in these assessments, it will be useful to expand the notation introduced in Section 3.1. Let each student in a population be characterized by the triplet (y, z_1, z_2) ; where z_1 denotes whether a student attends a school that would participate in the study if sampled, and z_2 indicates whether a student would participate in the study if sampled, and z_2 indicates whether a student would participate in the assessment if their school participates. Thus, the binary indicator z = 1 if and only if both $z_1 = 1$ and $z_2 = 1$; otherwise z = 0.

To incorporate the structure of the design described above, we write the stratum-level mean of y by using the Law of Iterated Expectations,

$$E[y|w] = E[y|z_1 = 1, z_2 = 1, w]P(z_1 = 1, z_2 = 1, w)$$

+
$$E[y|z_1 = 1, z_2 = 0, w]P(z_1 = 1, z_2 = 0, w)$$

+
$$E[y|z_1 = 0, w]P(z_1 = 0, w).$$

9

Thus, for each stratum, we partition the population into three mutually exclusive and exhaustive subgroups: $(z_1 = 1, z_2 = 1)$ participating students in participating schools, $(z_1 = 1, z_2 = 0)$ non-participating students in participating schools, and $(z_1 = 0)$ students in non-participating schools. We see in Expression 9 that each of the three probabilities are observable, but only the first of the three

conditional means is observable—that is, $E[y|z_1 = 1, z_2 = 1, w]$ the mean achievement of participating students in participating schools in stratum w.

Now consider the second conditional mean $E[y|z_1 = 1, z_2 = 0, w]$, mean achievement of nonparticipating students in a participating school in stratum w. To account for within-school nonparticipation, ILSA studies use participating schools as so-called adjustment cells.¹³ Correspondingly, the following assumption can be made:

Assumption 2 (A2): Student achievement is statistically independent of student participation within school *j*, for all school *j*.

This assumption leads to the result that $E_j[y|z_1 = 1, z_2 = 1, w] = E_j[y|z_1 = 1, z_2 = 0, w]$ for all school j; where the expectation is taken over participating and non-participating students within each school j, respectively. Under this assumption A2, Expression 9 reduces to:

$$E[y|w] = E[y|z_1 = 1, z_2 = 1, w]P(z_1 = 1, w) + E[y|z_1 = 0, w]P(z_1 = 0, w)$$
 10

Note that under assumption A2, school-level non-participation is the only source of non-participation that prevents point-identification of E[y|w]. Given the above discussion, it seems natural to adjust assumption A1.1 to specify credible bounds on student achievement in non-participating schools, as follows:

Assumption 1.2 (A1.2): Mean achievement of students in non-participating schools, in each stratum w, lies within an interval bounded by the α^{th} and $(1 - \alpha)^{th}$ percentile of the achievement distribution among students in participating schools in that stratum.

It follows that, under assumptions A1.2 and A2, $H\{E[y]\}$ is fully characterized by the values satisfying the following expression,

$$\sum_{w=1}^{W} P(w) \left(E[y|z_1 = 1, w] P(z_1 = 1, w) + Q_{\alpha}(y|z_1 = 1, w) P(z_1 = 0, w) \right)$$

$$\leq E[y] \leq 11$$

$$\sum_{w=1}^{W} P(w) \left(E[y|z_1 = 1, w] P(z_1 = 1, w) + Q_{1-\alpha}(y|z_1 = 1, w) P(z_1 = 0, w) \right)$$

To account for the fact that some schools do not take part in the assessment, ILSA studies also invoke ignorability assumptions on school non-participation, whereby school non-participation is assumed to be random within each stratum:

Assumption 3 (A3): Student achievement is statistically independent of school participation within sampling stratum *w*, for all strata *w*.

Assumption 3 leads to the result that $E[y|z_1 = 0, w] = E[y|z_1 = 1, w]$ for all w. Under this additional assumption, Expression 10 reduces to $E[y|w] = E[y|z_1 = 1, w]$. We therefore conclude that, under assumptions A2 and A3, E[y] is point identified:

¹³ Here, we look at adjustment cells as created in IEA studies, for example as in Tieck (2020b, p.80-81). The discussion can easily be extended to other ILSA studies such as PISA.

$$E[y] = \sum_{w=1}^{W} P(w)E[y|z_1 = 1, z_2 = 1, w]$$
12

That is, $H\{E[y]\}$ is fully characterized by the singleton in Expression 12. We emphasize two implications of the identification analysis presented thus far. First, it is noteworthy that assumption A1, or any of its variations outlined above, has no additional identifying power when assumptions A2 and A3 are jointly maintained. This result arises because ignorability assumptions A2 and A3 identify mean achievement for non-participating students within participating schools and for students in non-participating schools, respectively. No other forms of non-participation remain to be addressed by assumption A1, A1.1, or A1.2 in this analysis. Second, if $Q_{\alpha}(y|z = 1, w) \leq E[y|z = 1, w] \leq Q_{1-\alpha}(y|z = 1, w)$ for all strata w —which should be true for any credible choice of α in an ILSA study—then E[y] under assumptions A2 and A3 will fall within the identification region of E[y] under assumption A1.1, characterized above in Expression 8.

Discussion of replacement schools

Finally, an important component of the model commonly applied in ILSA studies to account for nonparticipation is the use of replacement schools, which corresponds to a data imputation technique that resembles the nearest-neighbor hot-deck method. This mechanism is put into place when a sampled, nonparticipating school is "replaced" by a school that was selected specifically for the purpose of replacing the non-participating school. That is, a 'recipient school' is replaced by a 'replacement school'. The data collected in a replacement school are then used to estimate population parameters as if the data came from the recipient school. Martin et al. (1999) and Tieck (2020) provide an in-depth discussion about how replacement schools are matched to recipient schools.

Incorporating this component of the non-participation model into an identification analysis requires some subtlety because, as noted in Section 2, the identification analysis proceeds as if all students in an education system were sampled. Thus, no non-sampled schools would be available to replace sampled, non-participating schools. One may instead consider hypothetically drawing replacement schools from the pool of sampled and participating schools, as in hot-deck imputation. However, this imputation serves no obvious purpose for identification. That is, replacement schools only provide information about students in the education system that would participate whenever sampled, but they are uninformative about the portion of students in schools that would not participate when sampled. One might then ask, what purpose is served by using replacement schools? The purpose is to increase sample size and reduce uncertainty when engaging in an exercise of statistical inference. From the perspective of identification, assumptions A2 and A3 are sufficient to point identify E[y].

3.3 Alternative assumptions

We now present an alternative identification analysis to showcase how one could explore different assumptions to learn about E[y]. We emphasize that we do not discuss the set of assumptions presented here in a normative way, nor provide justification or argumentation that they should be preferred over the standard non-participation model. Instead, we focus attention on the identifying power of each of them. As above, we take assumption A1 as our starting point.

The first exercise we propose is Assumption 4, which is compatible with a model of participation where there is some achievement-related incentive for (non)participation in the assessment. For example, perhaps it is credible to assert that schools with lower achieving students are less likely to agree to participate when sampled or, perhaps, that lower achieving students are more likely to be discouraged from joining their classmates in an assessment.

Assumption 4 (A4): Mean achievement in the participating subpopulation is weakly greater than mean achievement in the non-participating subpopulation.

This assumption implies that $E[y|z = 0] \le E[y] \le E[y|z = 1]$. Putting assumptions A1 and A4 together, $H\{E[y]\}$ is characterized by the set of values that satisfy the following expression,¹⁴

$$E[y|z=1]P(z=1)+Q_{\alpha}(y|z=1)P(z=0) \le E[y] \le \min\{E[y|z=1], Q_{1-\alpha}(y|z=1)\}$$
 13

If we are willing to rule out the extreme case in which $Q_{1-\alpha}(y|z=1) \le E[y|z=1]$, then the upper bound of Expression 13 is given by the mean among participating students. That is,

$$E[y|z=1]P(z=1)+Q_{\alpha}(y|z=1)P(z=0) \le E[y] \le E[y|z=1].$$
13'

Here again, the sample design implemented in ILSA studies can be instrumental to making interval estimation under the pair of assumptions A1 and A4 more credible. Similarly, as above, we could incorporate school stratification to adjust assumption A4 into the following.

Assumption 4.1 (A4.1): Within each school stratum w, mean achievement in the participating subpopulation is weakly greater than mean achievement in the non-participating subpopulation and smaller than the $(1 - \alpha)^{th}$ percentile of the achievement distribution among participating students.

Assumption 4.1 indicates that $E[y|z = 0, w] \le E[y] \le E[y|z = 1, w]$ and $E[y|z = 1, w] \le Q_{1-\alpha}(y|z = 1, w)$, for all strata w.

It follows that, under the pair of assumptions A1.1 and A4.1, the identification region of interest is expressed by the set of values that satisfy the following,

$$\sum_{w=1}^{W} P(w) \left(E[y|z=1,w] P(z=1|w) + Q_{\alpha}(y|z=1,w) P(z=0|w) \right)$$

$$\leq E[y] \leq$$

$$\sum_{w=1}^{W} P(w) E[y|z=1,w]$$

14

It is worth noting that that the lower bound in Expression 14 coincides with the lower bound of Expression 8, while the upper bound of Expression 14 is the weighted average of the mean of y among participating students.

4. Interval estimation of a partially identified mean

In the previous section, we demonstrated how to derive different identification regions of E[y] by placing different restrictions on the achievement distribution among non-participating students. In each instance, we identified sharp bounds that determine the set of logically possible values that E[y] can take under maintained set of assumptions. The identified bounds are functions of observable population

¹⁴ Proposition 2.5 in Manski (2003) shows a formal proof of the bounds of an identification region when the mean of a random variable is assumed to be missing monotonically.

parameters—in particular, conditional means, percentiles, and event probabilities—which makes it possible to be estimated. We now discuss the sample counterparts, or "analogs," of the identification regions derived in the previous section. We may then apply the "analogy principle" to use these sample statistics to estimate the analogous population parameters (Goldberger, 1991).¹⁵

Randomization in the sample design allows us to generate (partial) knowledge about P(y) from a subset of the student population. The design typically implemented in ILSA studies follows a two-step process that can be summarized as follows. In the first stage, within each stratum, schools are sampled with probabilities proportional to their relative size in their stratum. This implies that a measure of size M_j is known for each school j in the population and that larger schools have a higher probability of selection. As a norm, the measure of size for school is the enrollment of students belonging to the target population of the study (Martin et al., 1999). In the second stage, within participating schools, students or intact classes are included into the assessment with equal probabilities. Such a sampling plan leads to probabilities of inclusion that vary across sampled students. Therefore, the probability that student i in school j is sampled for the assessment is given by the joint probability $\pi_{ij} = \pi_j * \pi_{i|j}$ where π_j denotes the probability that school j is sampled and $\pi_{i|j}$ denotes the probability that student i is sampled from within their sampled school j.

4.1 Minimal restrictions on E[y|z = 0]

Estimation of the bounds that characterize $H\{E[y]\}$ under maintained assumption A1 (i.e., Expression 6) requires estimation of several features of the distribution of achievement among participating students—E[y|z=1], $Q_{\alpha}(y|z=1)$, and $Q_{1-\alpha}(y|z=1)$ —as well as the event probability of participation. To estimate P(z=1) under the implemented sampling plan, it is useful to recall that we can characterize each member in our population of interest by the triplet (y, z_1, z_2) ; where z_1 denotes whether a student attends a school that would participate in the study if sampled, and z_2 indicates whether a student would participate in the assessment if their school participates. Thus, the binary indicator z = 1 if and only if both $z_1 = 1$ and $z_2 = 1$; z = 0 otherwise (see Section 3.2). It follows that, with $P(z_1 = 1) > 0$,

$$P(z = 1) = P(z_1 = 1, z_2 = 1) = P(z_1 = 1)P(z_2 = 1|z_1 = 1).$$
15

Given the two-stage nature of the implemented sampling plan, decomposing P(z = 1) into these two components is useful for representing the event probability that a student participates in ILSA studies. The first stage of the sampling plan generates knowledge about $P(z_1 = 1)$, while the second stage generates knowledge about $P(z_2 = 1|z_1 = 1)$.

To estimate $P(z_1 = 1)$ we note that, from a frequentist perspective, the probability of an event is nothing other than the long-run rate at which the event occurs. Therefore, we propose using its sample analog \hat{p}_1 ,

$$\hat{p}_1 = \frac{\sum_{j=1}^J \pi_j^{-1} M_j z_{1j}}{\sum_{j=1}^J \pi_j^{-1} M_j}.$$
16

¹⁵ Goldberger (1991) described the analogy principle as follows (page 117): "Perhaps the most natural rule for selecting an estimator is the *analogy principle*. A population parameter is a feature of the population. To estimate it, use the corresponding features of the sample."

where j = 1, ..., J indexes sampled schools. That is, the following information is available for each sampled school j: z_{1j} which indicates its participation status in the study; M_j , which denotes the number of students enrolled in it; and its sampling weight π_j^{-1} , which is given by the inverse of its inclusion probability. Note that the denominator in Expression 16 estimates the total number of students enrolled in the population, while the numerator estimates the total number of students enrolled in schools that would participate in the study if sampled. Therefore, \hat{p}_1 estimates the proportion of students enrolled in schools that would participate in the study if sampled.

Similarly, to estimate $P(z_2 = 1 | z_1 = 1)$ we propose using its sample analog \hat{p}_2 ,

$$\hat{p}_2 = \frac{\sum_{j=1}^J \sum_{i=1}^{N_j} \pi_{ij}^{-1} z_{1j} z_{2ij}}{\sum_{j=1}^J \sum_{i=1}^{N_j} \pi_{ij}^{-1} z_{1j}}$$

$$17$$

here $i = 1, ..., N_j$ indexes sampled students within sampled school j. That is, the following information is available for each sampled student i in participating school j: z_{2ij} , which indicates the student's participation status in the assessment, as well as the student's sampling weight π_{ij}^{-1} , which is given by the inverse of the inclusion probability. These values are not observed for student i in *non-participating* school j, but that is not problematic because we observe $z_{1j} = 0$ and, therefore, the summand in the numerator and the summand in the denominator are each known to equal zero for each non-participating school j.¹⁶ Note that the denominator in Expression 17 estimates the total number of students enrolled in schools that would participate if sampled, while the numerator estimates the total number of students that would participate in the assessment if sampled across the schools that would participate if sampled¹⁷. Therefore, \hat{p}_2 estimates the proportion of students that would participate in the assessment if sampled.

Thus, to estimate P(z = 1) we propose using its sample analog \hat{p} ,

$$\hat{p} = \hat{p}_1 * \hat{p}_2 \tag{18}$$

Similarly, to estimate E[y|z = 1], we propose to use the sample analog $\hat{\mu}$, a weighted average of the assessment outcomes y_{ij} observed in the sample,

$$\hat{\mu} = \frac{\sum_{j=1}^{J} \sum_{i=1}^{N_j} \pi_{ij}^{-1} y_{ij} z_{1j} z_{2ij}}{\sum_{j=1}^{J} \sum_{i=1}^{N_j} \pi_{ij}^{-1} z_{1j} z_{2ij}}.$$
19

where y_{ij} denotes achievement of sampled student i in school j. Note that y_{ij} is observed if and only if $z_{2ij} = 1$, and both π_{ij}^{-1} and z_{2ij} are observed if and only if $z_{1j} = 1$. As above, in cases where any of these values are not observed, $z_{1j} = 0$ and, therefore, the summand in the numerator and the summand in the denominator are each known to equal zero as well.

¹⁶ Alternatively, we could express the estimator solely in terms of observables by restricting attention to sampled students in participating schools k = 1, ..., K where $K \le J$.

¹⁷ The denominator in Expression 17 and the numerator in Expression 16 estimate the same parameter but with different data. Both estimates coincide if $N_j = M_j$, which is usually not the case. This is because observation of N_j occurs during data collection in participating schools, which happens at least one year later than the observed enrollment used for the construction of the school frame (M_j) .

Analog estimation of percentiles of the distribution P(y|z = 1) proceeds accordingly, using percentiles of the distribution of achievement outcomes y_{ij} observed in the sample. Let \hat{q}_{α} denote this analog estimate of the percentile $Q_{\alpha}(y|z = 1)$ and, similarly, let $\hat{q}_{(1-\alpha)}$ denote the estimate of the percentile $Q_{1-\alpha}(y|z = 1)$.

The sample counterpart of the bounds in Expression 6 is then given by,

$$\left[\hat{\mu} \cdot \hat{p} + \hat{q}_{\alpha} \cdot (1 - \hat{p}), \hat{\mu} \cdot \hat{p} + \hat{q}_{(1 - \alpha)} \cdot (1 - \hat{p})\right].$$
 20

Note that all components of the bounds are estimated using only originally sampled schools; that is, we do not use the so-called replacement schools (see discussion at the end of Section 3.2).

As discussed in Section 3.1, an alternative strategy to make estimation more credible is to incorporate school stratification in the analysis and thus replace assumption A1 with A1.1. If so, the sample counterpart of the bounds in Expression 8 is given by,

$$\left[\sum_{w=1}^{W} P(w) \left(\hat{\mu}_{w} \hat{p}_{w} + \hat{q}_{\alpha,w} * (1 - \hat{p}_{w}) \right), \sum_{w=1}^{W} P(w) \left(\hat{\mu}_{w} \hat{p}_{w} + \hat{q}_{(1 - \alpha),w} * (1 - \hat{p}_{w}) \right) \right]$$
 21

where $\hat{\mu}_w$, $\hat{q}_{\alpha,w}$, and \hat{p}_w are stratum-specific estimates analogous to those in Expression 20. P(w) is the known proportion of students in the population attending schools in stratum w, as reported in the school frame used for sampling. Thus, the bounds in Expression 21 are an average of the stratum-specific bounds, weighted by a factor proportional to the total enrollment in each stratum.

4.2 Standard assumptions in ILSA

Now we turn our attention to estimation under the standard model to account for non-participation in ILSA studies. We begin by estimating the bounds of $H{E[y]}$ under assumptions A1.2 A2. The sample counterpart of the bounds in Expression 10 is given by,

$$\left[\sum_{w=1}^{W} P(w) \left(\hat{\mu}_{w} \hat{p}_{w} + \hat{q}_{\alpha,w} * (1 - \hat{p}_{1w}) \right), \sum_{w=1}^{W} P(w) \left(\hat{\mu}_{w} \hat{p}_{w} + \hat{q}_{(1-\alpha),w} * (1 - \hat{p}_{1w}) \right) \right]$$
 22

where P(w) is as defined in Expression 21. To incorporate assumption A2 into the estimation of $\hat{\mu}_w$, $\hat{q}_{\alpha,w}$, and $\hat{q}_{(1-\alpha),w}$, we use estimation weights of the form $\omega_{ij} = (\pi_{ij} * \pi_j^f)^{-1}$. That is, the probability of inclusion π_{ij} is adjusted by a by a school-level factor $\pi_j^f = \frac{\sum_{i=1}^{N_j} z_{2ij}}{\sum_{i=1}^{N_j} 1}$, where the numerator reflects the

number of participating students in participating school j and the denominator reflects the number of sampled students within the same school. This adjustment factor is an artifact of assumption A2, and it follows from this adjustment factor that the relative contribution of participating students in school j to the overall estimate equals the relative contribution of sampled students in school j to the overall estimate. Finally, since under assumption A2, school-level non-participation is the only source of non-participation that remains, the length of each of the estimated stratum-specific bounds is proportional to \hat{p}_1 and not to \hat{p} . Thus, the difference between Expression 21 and Expression 22 is that we replace \hat{p}_w with \hat{p}_{1w} .

Finally, under maintained assumptions A2 and A3, $H\{E[y]\}$ is point-identified and its sample counterpart is given by the mean achievement across all participating students, weighted by a factor $\omega^*_{ij} = (\pi_{ij}\pi^f_w\pi^f_i)^{-1}$. That is,

$$\hat{\mu} = \frac{\sum_{j=1}^{J} \sum_{i=1}^{N_j} \omega_{ij}^* y_{ij} z_{1j} z_{2ij}}{\sum_{j=1}^{J} \sum_{i=1}^{N_j} \omega_{ij}^* z_{1j} z_{2ij}}$$
23

Similar as above, the inclusion probability π_{ij}^{-1} is adjusted by a stratum-level factor $\pi_w^f = \frac{\sum_{j \in w} z_{ij}}{\sum_{j \in w} 1}$, where the numerator reflects the number of participating schools in stratum w and the denominator reflects the number of sampled schools within the same stratum. This adjustment factor is an artifact of assumption A3, and it follows from it that the relative contribution of participating schools in stratum w to the overall estimate equals the relative contribution of sampled schools in stratum w to the overall estimate.¹⁸

As noted at the end of Section 3.2, assumptions A2 and A3 are jointly sufficient to point-identify and hence point-estimate E[y]. Yet, ILSA studies normally use replacement schools to increase sample size and reduce uncertainty when engaging in an exercise of statistical inference. One could, alternatively, maintain assumption A2 and A3 after the inclusion of replacement schools. Such a strategy has been chosen by ILSA studies to estimate and report E[y], where estimation takes place as in the preceding paragraph with the difference that data from some not participating schools is imputed with data from replacement schools that were not selected in the original sample. The addition of replacement schools leads to a different school-level adjustment factor (π_w^f) and, hence, weight in the estimation, reflecting the increase in the number of participating schools.

4.3 Alternative assumptions

Now we consider statistical inference of the bounds presented in Section 3.3, which use alternative assumptions to restrict the logically possible values that E[y] can take. The sample counterpart of the bounds in the identification region under assumptions A1 and A4 (Expression 13'), is given by,¹⁹

$$[\hat{\mu} \cdot \hat{p} + \hat{q}_{\alpha} \cdot (1 - \hat{p}), \hat{\mu}]$$
24

where components are defined analogously to those in Expression 20.

Maintaining assumptions a1 and A4 within each school stratum leads to assumptions A1.1 and A4.1. The sample counterpart of the bounds under these assumptions (Expression 14) is given by,

$$\left[\sum_{w=1}^{W} P(w) \left(\hat{\mu}_{w} \cdot \hat{p}_{w} + \hat{q}_{\alpha,w} \cdot (1 - \hat{p}_{w}) \right), \sum_{w=1}^{W} P(w) \hat{\mu}_{w} \right]$$
 25

where components are defined analogously to those in Expression 21.

5. Two illustrative applications

¹⁸ In the field of ILSA, π_h^f and π_h^f are known as the school-level and the student-level non-response adjustment factors, respectively.

¹⁹ Here, as discussed in Section 3.3, we rule out the extreme case in which $Q_{1-\alpha}(y|z=1) \le E[y|z=1]$.

We use data from ICILS 2018 to Illustrate the application of the findings presented in the previous sections. ICILS is an international effort coordinated by the IEA that examines outcomes on the computer and information domain among eighth graders in different education systems. Within each education system, ICILS seeks to collect data from a representative sample of students, using a sampling design similar to the one described above. For each student participating in the study, ICILS reports an achievement measure of computer and information literacy (CIL), which is a latent construct defined as the "ability to use computers to investigate, create and communicate in order to participate effectively at home, at school, in the workplace and in society" (Fraillon et al., 2019, p. 53). We use this measure as the outcome of interest *y*.

The assessment framework behind the CIL latent construct developed for ICILS is extensive. Overall, four computer-based modules, each with between 15 and 22 tasks, were developed to evaluate literacy in the computer and information domain. To avoid overburdening participating students, the assessment modules are paired, and students are exposed to only one of the 12 possible ordered-paired modules. Therefore, each student responds to only a subset of the overall task pool needed to evaluate CIL. Accordingly, ICILS is designed to assess groups of students rather than individuals. That is, ICILS is not a student-level diagnostic test but rather aims to assess entire (sub)populations. Once data are collected and scored, item response theory models are used to estimate the proficiency distribution of the CIL construct for each student (see, for example, Ockwell et al. (2020) for details). That is, for each student i, the ICILS data file includes five plausible values for that student's measured CIL, where each plausible value consists of a random draw from their estimated proficiency distribution. As is customary in ILSA studies, we use the reported sets of five plausible values to measure of CIL. To do so, we estimate parameters of interest five times, each with one plausible value, and report the average over the five estimates. Von Davier et al. (2009) provides a general discussion of the underlying methodology of this type of assessment design and how to incorporate it into the estimation of population parameters. In the remainder of this section, we follow this standard practice in the estimation of population parameters but do not address this issue in our discussion, as it is a measurement concern that is beyond the scope of our focus here on student non-participation.

We also emphasize that in these illustrative applications, as in the theoretical discussion above, we abstract from the problem of statistical inference associated with finite sample sizes. Therefore, the estimates below do not include any measure of uncertainty, as typically represented by confidence intervals. In other words, these estimates do not respond to the question: what can we learn about student mean achievement in an education system from the observed, data provided that a random process has drawn a finite number of students from it to be assessed. Instead, they respond to the question: what can we learn about student mean achievement in an education system from the observed data if all students could be sampled but some would not take part in the assessment? We begin by reflecting on the ambiguity generated by student non-participation from an internationally comparative perspective. We then use data from Germany to showcase how one may bring in stronger assumptions on non-participation to reduce ambiguity.

5.1 An internationally comparative illustration

For each education system assessed in ICILS 2018, Figure 1 reports findings on E[y] under two alternative identification strategies, each one restricting achievement in the population of non-participating students—in particular, E[y|z = 0]—differently. First, each vertical line depicts estimates of E[y] under

assumption A1 with $\alpha = 0.05$. It is therefore assumed that, within each reported education system, the mean among the non-participating population lies within the interval bounded by the 5th and 95th percentile of the achievement distribution among the participating population. This assumption leads to interval estimates of E[y] described in Expression 20. Second, for each education system, each dot depicts estimates of E[y] under the standard model applied by the ICILS International Report to account for non-participation (Tieck, 2020b), which results in point estimates of E[y] described in Expression 23. We note that in both strategies we use solely data derived from originally sampled schools and disregard the data coming from replacement schools (see discussion in section 4.1). In Table A1 in the Appendix, we report all necessary components for the estimation of the lower and upper bound of each interval, as well as the point-estimate of E[y].

Figure 1 shows that, under assumption A1, estimation of E[y] is more ambiguous in education systems where the rate of student non-participation is relatively high. For example, in the USA it is estimated that about 38% of the student population would not participate whenever sampled, which is the highest rate across all education systems assessed by ICILS. The USA also has the widest interval estimate of E[y] i.e., the most ambiguous estimate—with a length of about 102 score points. Interestingly, Uruguay has the second widest interval estimate, despite having a lower rate of student non-participation (26%) than Denmark (35%), Germany (31%), and Portugal (31%). Since the length of each vertical line in Figure 1 is given by $(1 - \hat{p}) * (\hat{q}_{95} - \hat{q}_5)$, then it must be that $(\hat{q}_{95} - \hat{q}_5)$ is larger in Uruguay than in Denmark, Germany, and Portugal. That is, the estimated set of logically possible values that E[y|z=0] can take under assumption A1 is larger in Uruguay than in these other countries, because the estimated spread of the achievement distribution among participating students is wider in Uruguay.²⁰

Figure 1 Estimation of mean CIL with alternative assumptions on E[y|z=0].

²⁰ The non-participation rates reported in this paragraph are estimated using Expression 18, which are used to construct the interval estimates of Figure 1 (see Table A1 in the Appendix).

We note here that Figure 1 reports estimates of E[y] under the two extreme alternatives discussed in Section 3. First, estimation under assumption A1 with a small value of α is likely to be the most credible to the extent that it imposes the weakest restrictions on E[y|z = 0]—but also the most ambiguous. On the other hand, estimation under the ICILS non-response model is unambiguous but the most restrictive about E[y|z = 0] and therefore pushes the Law of Decreasing Credibility to its limit. In other words, the ICILS non-response model eliminates all ambiguity in the estimation that arises from student non-response at the potential expense of credibility.

It is also worth noting that, even under weak assumptions on achievement among non-participants, notable differences arise across countries if one were to abstract from concerns about sampling imprecision. For instance, the interval estimates for Finland, Korea, and Moscow each lie above the interval for Italy, which lies well above the interval for Kazakhstan.

5.2 Estimation under stronger assumptions in Germany

Using data from Germany, we carry on by estimating different identification regions of E[y], each reflecting a different set of assumptions. Overall, there were a total of 229 sampled schools in Germany, from which 193 participated; hence, 36 schools did not participate, out of which 16 were replaced. We emphasize that, unless otherwise stated, data derived from replacement schools is not included in the estimation. Moreover, within the 193 participating schools, a total of 3,391 students participated and 426 students did not participate.

In Figure 2 we use the empirical evidence gathered in P(y|z = 1) to explore how the identification region of E[y] tightens up as we restrict the set of logically possible values that E[y|z = 0] can take by assumption. Here, again, interval estimates of E[y] are derived using Expression 20. As reference, the first vertical line depicts the same interval estimate as in Figure 1 for Germany. One could argue, for instance, that $Q_5(y|z = 1) \le E[y|z = 0] \le Q_{95}(y|z = 1)$ is a loose assumption and it would be credible to restrict E[y|z = 0] to be between the 10th and 90th percentiles, or perhaps between the 25th and 75th percentiles. The corresponding identification regions under these assumptions are estimated and plotted in the second and third vertical line; that is, with $\alpha = 0.10$ and $\alpha = 0.25$, respectively. The first line in Figure 2 has a length of 80 score points, while the second and third have length of 62 and 32 score points, respectively. That is, half of the ambiguity in the estimation of E[y] was eliminated only by tightening assumption A1 from $\alpha = 0.05$ to $\alpha = 0.25$. If we take assumption A1 to the limit and let $\alpha = 0.50$, the upper and lower bound of the identification region coincide and E[y] is point-identified with E[y] = E[y|z = 1]P(z =1) + Median[y|z = 1]P(z = 0). This last example is shown in the fourth column of Figure 2 with a dot.²¹ All necessary components for the estimation of the lower and upper bound of each interval in Figure 2 are estimated and reported in Table A2 in the Appendix.

Figure 2 is useful to recognize the identifying power that assumptions can have at the expense of credibility. It is straightforward to see how conclusions about E[y] become less ambiguous as we move from left to right in Figure 2. That is, by making stronger restrictions on E[y|z=0]—choosing a different α —we eliminate ambiguity. This inevitably comes at the expense of credibility, as it is harder to justify the assumption that E[y|z=0] = Median[y|z=1] relative to the assumption that $Q_5(y|z=1) \leq$

²¹ Note that a point estimate generated under this assumption will deviate from the point estimate generated under the pair of assumptions A2 and A3, as reported in Figure 1, when the sample median of achievement scores among participating students does not equal the sample mean.

 $E[z|z=0] \le Q_{95}(y|z=1)$. This is simply because the former restriction logically entails the latter; that is, the median must be between the 5th and 95th percentiles.

Figure 2 Estimation of mean CIL in Germany across different values of α in Assumption 1

We continue now by gradually building up to the standard non-response model applied in ILSA studies. These results are summarized in Figure 3. Again, for comparison purposes, the first vertical line depicts the interval estimate for Germany as in Figure 1. All necessary components for the estimation of the lower and upper bound of each interval are estimated and reported in Table A3 in the Appendix.

To begin the comparison, the second column of Figure 3 depicts the interval estimate of E[y] under assumption A1.1. This assumption incorporates information known for participating and non-participating schools into the estimation, by using auxiliary variables used for stratifying the school population before sampling. For ICILS, the German school population was stratified by 'school track', using three categories: (1) "Gymnasium' which are schools that prepares students for tertiary education, (2) schools for students with special needs, and (3) all other tracks. Hence, in this second identification strategy, the unobserved mean of y is restricted using the achievement distribution of participating students within each school track w (i.e., $Q_5(y|z = 1, w) \le E[y|z = 0, w] \le Q_{95}(y|z = 1, w)$. The width of this second interval is about 70 score points, implying that, in the German context, about 12% of the ambiguity in E[y] under Assumption 1 was eliminated by making this assumption stratum specific.

Next, the third column of Figure 3 depicts the interval estimate of E[y] under assumptions A1.2 and A2. Asserting that within each participating school j the event probability that a student participates is statistically independent of their achievement in the assessment leads to an interval estimate that is about 46 score points wide, corresponding to about half the width of the estimate in the baseline strategy. It is worth noting that the average student non-participation rate across participating schools in Germany is about 13%,²² which generates about half of the ambiguity in E[y] under Assumption 1.

The fourth column of Figure 3 depicts the point estimate of E[y] generated by adding assumption A3 to the identification analysis. Assumption 3 asserts that, within each stratum w, school-level non-response is statistically independent of student achievement in the assessment. Consequently, assumption A3,

²²This follows from Expression 18, with 0.13 = 1 - (0.69/0.79).

together with A2, makes assumption A1.2 unnecessary. In this scenario, E[y] is point-identified and estimated to be 517 score points.

Finally, in the fifth column of Figure 3, we plot the point-estimate of E[y] as reported in the ICILS International Report for Germany—i.e., 518 score points (Fraillon et al., 2019, p. 75). This estimation strategy is very similar to the preceding one, with the subtle difference being that, before maintaining assumptions A2 and A3, data from 16 non-participating schools are imputed with data from 16 replacement schools. Thus, this approach brings in supplemental data under the supplemental assumption that mean achievement in a non-participating school is identical to its replacement.

Figure 3 Estimation of mean CIL in Germany under alternative standard assumptions on E[y|z=0].

Lastly, in Figure 4 we report estimates of E[y] in Germany under the assumption that the mean is missing monotonically, as described in Section 4.3. Again, the first vertical line in Figure 4 depicts the interval estimate of the mean under assumption A1 with $\alpha = 0.05$. In the second vertical line (Scenario 2), we depict the interval estimate of E[y] under the maintained pair of assumptions A1 and A4. The monotonicity assumption renders all values larger than the point-estimate of the mean among participants to be logically not possible²³. That is, the identification region is bounded from above using an estimate of E[y|z = 1]. The length of the second interval estimate is about half the length of the baseline. The third vertical line (Scenario 3) depicts the interval estimate of E[y] under the pair of assumption A1.1 and A4.1. That is, under the assumption that the mean is missing monotonically within each school track w; and the assumption that the mean among those students that would not participate whenever sampled is at least at the 5th percentile of the achievement distribution among those students that would participate whenever sampled within each school track w. Overall, the extension presented in Scenario 3 seems to have no substantial identifying power relative to Scenario 2, to the extent that the length of the vertical lines is nearly the same. It is worth noting that, as pointed out at the end of Section 3.3, the estimated lower bound in Scenario 3 coincides with the estimated lower bound when assumption A1.2 is maintained (i.e., second column of Figure 3), while the estimated upper bound of scenario 3 is the weighted average across strata of the estimated mean CIL among participating students.

²³ We rule out the extreme case in which $Q_{1-\alpha}(y|z=1) \le E[y|z=1]$ as discussed in Section 3.3.

All necessary components for the estimation of the lower and upper bound of each interval are estimated and reported in Table A4 in the Appendix.

Figure 4 Estimation of mean CIL in Germany with monotonicity assumptions.

6. Conclusions

To introduce the framework of partial identification of probability distributions to the field of ILSA studies of educational achievement, this article examines the identification problem arising from student non-participation in these studies. This methodological framework provides a useful strategy for reporting estimates of population parameters that explicitly reflect the ambiguity arising from non-participation. The article also inspects the standard non-response model typically maintained in ILSA studies and places it within the partial identification framework. Finally, the research article provides some examples of how to incorporate alternative assumptions that could be used to identify and estimate population parameters in ILSA studies. To this end, we do not argue that such identification strategies should necessarily be preferred over the standard non-response model but instead we draw attention to their identifying power.

We see two possible and immediate extensions to the analysis we present in this article. The first one would incorporate statistical inference into the estimation approach presented. Tamer (2010) provides a notable review of the literature in this topic, emphasizing the use of subsampling techniques to construct confidence regions of a (partially) identified parameter. He notes that this strand of research is divided into approaches that construct confidence regions for an identified set-valued parameter (see, for example, Chernozhukov et al. (2007)) and approaches that construct confidence regions for a "true" parameter even though it cannot be point identified (see, for example, Imbens and Manski (2004)). In the context of ILSAs, we see an immediate application for the former approach as one could, for example, use re-sampling techniques to approximate the sampling variance of the estimated bounds derived in this article. Techniques such as the Jackknife Repeated Replication (Tukey, 1958) could be useful for this, as they are already being employed in ILSA studies when engaging in statistical inference.

Second, we focus here on reporting interval estimates of population parameters. We recognize, however, that many will find such reporting insufficient, having become accustomed to seeing and using point estimates with an associated standard error, confidence interval, or so-called *margin of error*. Dominitz and Manski (2017) considered the problem of predicting the partially identified population mean from

sample data where non-participation is not known to be ignorable. For point prediction, they proposed a midpoint predictor—in particular, the midpoint of the interval estimate—and show that the maximum mean square error (MSE) of this predictor is smaller than that of the sample mean among participants. Moreover, if the interval were known rather than estimated, then the midpoint predictor would be the point predictor that minimizes maximum MSE among all point predictors.

Dominitz and Manski (2024) apply this approach to election polls, arguing that a midpoint estimate should be reported along with a *total margin of error* (TME) measured based on the maximum MSE of the midpoint predictor under maintained assumptions on non-sampling error, including non-participation in the poll. The TME accounts for both sampling variation and potential bias that may arise from non-participation. If non-participation is ignorable, then the TME reduces to the usual margin of error. The same methodology could be applied to the results of ILSA studies, which would then satisfy desires for the reporting of point estimates along with a measure that characterizes estimation error.
