ABSTRACT

The universal baryonic mass fraction (Ω_b/Ω_m) can be sensitively constrained using X-ray observations of galaxy clusters. In this paper, we compare the baryonic mass fraction inferred from measurements of the cosmic microwave background with the gas mass fractions (f_{gas}) of a large sample of clusters taken from the recent literature. In systems cooler than 4 keV, f_{gas} declines as the system temperature decreases. However, in higher temperature systems, $f_{\text{gas}}(r_{500})$ converges to $\approx (0.12 \pm 0.02) (h/0.72)^{-1.5}$, where the uncertainty reflects the systematic variations between clusters at r_{500} . This is significantly lower than the maximum-likelihood value of the baryon fraction from the recently released WMAP 3-year results. We investigate possible reasons for this discrepancy, including the effects of radiative cooling and non-gravitational heating, and conclude that the most likely solution is that Ω_m is higher than the best-fit WMAP value (we find $\Omega_m = 0.36^{+0.11}_{-0.08}$), but consistent at the 2σ level. Degeneracies within the WMAP data require that σ_8 must also be greater than the maximum likelihood value for consistency between the data sets.

Key words: cosmology: theory — galaxies: clusters: general — X-rays: galaxies: clusters

1 INTRODUCTION

For over a decade now cluster gas mass fractions as inferred from X-ray observations have been used as a probe of the universal ratio of baryon to total matter densities, Ω_b/Ω_m (e.g., White et al. 1993; David et al. 1995; Evrard 1997; Mohr et al. 1999; Roussel et al. 2000; Allen et al. 2002; Lin et al. 2003; Ettori 2003; Allen et al. 2004). Supplementing these gas mass fractions with constraints on Ω_b from, e.g., cosmic microwave background (CMB) measurements or a combination of Big Bang Nucleosynthesis (BBN) predictions and D/H measurements from high redshift quasars, therefor allows one to measure the total matter density Ω_m . The reliability of this test rests on the assumption that clusters have been able retain the original baryon inventory assigned to them in the early universe. So-called "non-radiative" cosmological simulations, which include a hydrodynamic treatment of the baryons but neglect sources or sinks such as radiative cooling, star formation, and feedback, indeed indicate that clusters retain nearly all their baryons until the present day (e.g., Frenk et al. 1999; Kay et al. 2004; Crain et al. 2006). The same is generally true for simulations with

cooling and feedback. Although the fraction of baryons in the hot phase depends strongly on the model, most recent simulations predict a mild increase in the hot gas fraction with cluster mass, and little evolution with redshift (e.g., Tornatore et al. 2003; Kravtsov et al. 2005; Ettori et al. 2006).

Although the cluster baryon fraction test has been examined previously in many studies, there are several good reasons for revisiting it. First, new high-quality data obtained from the Chandra and XMM-Newton telescopes now allow us to probe both the surface brightness and temperature profiles of clusters out to large radii. As a result, both the statistical and systematic observational uncertainties on the gas mass fraction are substantially improved. Second, much improved (e.g., K-band) measurements of the stellar content of clusters are now available. Third, cosmological simulations can now robustly predict the baryon fractions within r_{500} , which is roughly the same radius the latest Xray measurements reliably extend out to. Fourth, analyses of mock observations of realistic cosmological simulations allow us to, e.g., quantify the observational bias introduced by assuming strict hydrostatic equilibrium (HSE) in the derivation of X-ray gas mass fractions. Finally, analysis of the recently released WMAP 3-year cosmic microwave background

2 I. G. McCarthy et al.

(CMB) data has yielded very tight constraints on the universal baryon fraction (Spergel et al. 2007). As a result, there is now an excellent opportunity to check for consistency (or lack of) between these two very different tests. We note that Ettori (2003) previously found evidence for a slight discrepancy between the universal baryon fraction inferred from the first year WMAP data and cluster baryon fractions inferred from BeppoSAX X-ray data. It is interesting to see whether or not this discrepancy remains when one makes use of the better observational data and improved theoretical predictions that are now available.

In this paper we analyse the best literature X-ray data in a homogeneous way, and compare the results with the universal baryon fraction inferred from the recently released *WMAP* 3-year data (Spergel et al. 2007).

Unless otherwise stated, we assume a Λ CDM cosmology with h = 0.72.

2 CLUSTER GAS FRACTIONS

We select high quality data from a few recent studies in the literature where the mass profiles have been reliably estimated out to $\sim r_{500}$. Vikhlinin et al. (2006), hereafter V06, have measured the gas and total mass profiles for a sample 13 relaxed "cool core" observed with *Chandra*. From this sample, we select all but two clusters¹. In addition to the above, we also select a sample of 10 relaxed "cool core" clusters observed with *XMM-Newton* for which Pointecouteau et al. (2005), Arnaud et al. (2005) and Pratt et al. (2006a) (hereafter collectively referred to as PAP) have computed gas and total mass profiles. Therefore, in total we have compiled a sample of 21 sets of mass profiles from 19 different clusters (i.e., the samples have two clusters in common).

Both V06 and PAP computed the gas and total mass profiles of their clusters in a similar manner, by fitting parametric forms of the gas density and (3D) temperature profiles of the ICM (see eqns. 3 and 6 of V06 and Appendix A of Pratt et al. 2006a) to the observed, projected surface brightness and temperature profiles. The purpose of these parametric models is to produce a smooth description of the data and hence reduce the noise in the spatial derivatives; the exact form of the models is irrelevant as long as they fit the data well. Note that the assumption of smooth gas in HSE can lead to a small overestimate of the baryon fraction (Mathiesen et al. 1999; Mohr et al. 1999; Rasia et al. 2006), which strengthens our conclusions.

We use the parametric models and associated best-fit parameters listed in V06 and PAP to reconstruct the observed mass profiles. In both studies the total mass distributions were fitted with the Navarro, Frenk & White (1997, NFW) profile derived from cosmological dark matter simulations. Both V06 and PAP demonstrate that the NFW profile fits their data exceptionally well, with an inferred massconcentration parameter relation that is in good agreement with the results of cosmological simulations.

Figure 1. Comparison of the observed integrated gas mass fractions [i.e., $f_{\rm gas} \equiv M_{\rm gas}(<\Delta)/M_{\rm tot}(<\Delta)$] as a function of overdensity (Δ) with WMAP 3-year constraints on the universal baryon fraction Ω_b/Ω_m (assuming a flat power-law ACDM cosmology). Solid and dashed lines represent fits to the Chandra data of V06 and XMM-Newton data of PAP, respectively. Red and black lines represent systems with mean spectral temperatures below and above 4.5 keV, respectively. The magenta line represents PAP's fit to A1413. Also shown (data points), are weighted averages of the gas mass fraction determinations of Ettori et al. (2002) (blue squares), Allen et al. (2004) (green triangle), Sadat et al. (2005) (magenta circle), LaRoque et al. (2006) (yellow pentagon), and Afshordi et al. (2007) (open cyan circle). Typically, the associated statistical measurement uncertainty for individual clusters is of order 10% for overdensities within which the temperature and surface brightness profiles can be reliably measured. The vertical dotted line indicates an overdensity of 500 (i.e., corresponds to r_{500}). The shaded cyan region corresponds to the 68% confidence region for Ω_b/Ω_m from WMAP, while the long dashed line shows the best fit value (Spergel et al. 2007).

Presented in Figure 1 is a comparison of the observed integrated gas mass fractions as a function of overdensity, Δ , where $\Delta \equiv 3M_{\rm tot}(\langle r)/[4\pi r^3 \rho_{\rm crit}(z)]$. In general, the clusters all show a mildly rising gas fraction with decreasing overdensity. However, there is considerable scatter in the gas fraction at fixed overdensity that is worth exploring. First, it is evident that the gas mass fractions measured by PAP are systematically larger than those measured by V06. Given that the gas density profiles from the two samples are quite similar (see McCarthy et al. 2007), the implication is that the temperature profiles measured by PAP and V06 differ systematically from each other. Indeed, V06 generally find temperature profiles that decline relatively rapidly with radius, dropping by roughly a factor of 2 from the peak $(at \ r \sim 0.1 - 0.2r_{200})$ to $0.5r_{200}$ (see also Vikhlinin et al. 2005), while PAP find a much more gradual decline, with some clusters showing approximate isothermality. Through the equation of HSE, a flatter temperature gradient translates into a reduced normalisation of the total mass profile

¹ We exclude A2390, which V06 have demonstrated to be highly asymmetric owing to the presence of a set of large X-ray cavities nearly 400 kpc in diameter, and the low-temperature system USGC S152, for which V06 do not provide enough information to reconstruct its mass profile.

Figure 2. Comparison of the observed integrated gas mass fractions within an overdensity of $\Delta = 1500$ as a function of mean ICM temperature with WMAP 3-year constraints on the universal baryon fraction Ω_b/Ω_m . Solid squares represent the Chandra data of V06 and open triangles represent the XMM-Newton data of PAP.

and hence an increased gas mass fraction. While it would be useful to sort out the exact nature of the temperature discrepancy², we point out that the typical level of difference between the two is relatively small (compared to the offset of both from the *WMAP* result, see §3). The one exception to this appears to be A1413, which was observed by both V06 and PAP. Within r_{500} , V06 find a total mass that is roughly 50% larger than that found by PAP. Increasing the total mass of A1413 by this factor would bring it more in line with the other systems studied by PAP. However, we note that good agreement between PAP and V06 is found for A1991, the only other system in common between the two samples.

Fig. 1 also shows that the gas fraction depends on system temperature, which presumably reflects total system mass. In particular, systems with mean temperatures below 4.5 keV (red lines) have systematically lower values for $f_{\rm gas}$ within virtually all overdensities compared with hotter systems (black lines). This trend has been noticed previously (e.g., Mohr et al. 1999; Roussel et al. 2000; Neumann & Arnaud 2001) and would seem to indicate that non-gravitational heat sources are relatively more important in mediating the properties of the ICM in low mass than in high mass clusters. In Figure 2, we plot the gas mass fraction within an overdensity of 1500 (typically corresponding to a physical radius of ≈ 800 kpc) versus mean system temperature. We have chosen this radius so that all the clusters in the sample (including the coolest systems) have reliable data. Note that if non-gravitational heating is unimportant at r_{1500} it will be even less significant at r_{500} . A trend with temperature is clearly visible at low temperatures. However, above ≈ 4 keV both the *Chandra* and XMM-Newton data show no evidence for a further increase, and the gas fraction appears to have converged, suggesting that non-gravitational physics is largely unimportant for the most massive systems (at least out at large radii). This is fully consistent with previous results based on ROSAT and ASCA data (Roussel et al. 2000; Lin et al. 2003), as well as newer XMM-Newton data (Sadat et al. 2005). It is also consistent with the findings of McCarthy et al. (2007), that above ~ 3 keV the gas density and entropy profiles of "cool core" systems follow the scaling expected for selfsimilar gravitational heating at large radius.

We have elected to focus on the data of V06 and PAP since their measurements extend out to $\sim r_{500}$. As noted earlier, cosmological simulations can now reliably predict the baryon fraction within this radius. However, measuring the properties of the ICM at such large radii is not easy. The rapidly declining surface brightnesses of the clusters at large radii means that an extremely careful treatment of the background is crucial. For this reason, a number of groups have limited their analyses to smaller radii (higher surface brightnesses) in an attempt to mitigate any potential systematic effects associated with the background modelling. While we are encouraged by the similarity of the results of V06 and PAP at large radii (note also that Chandra and XMM-Newton have different background characteristics), it is useful to check these results against other (mainly smallradii) data from the recent literature.

With the above in mind, we include some other recent X-ray gas mass fraction determinations (within various fixed overdensities) of hot clusters from the literature (data points) in Figure 1. In particular: the (yellow) pentagon represents a weighted average of $f_{\rm gas}(r_{2500})$ for the 38 clusters (spanning 0.14 < z < 0.89) observed by LaRoque et al. (2006) with Chandra [note that LaRoque et al. actually use both Chandra X-ray data and BIMA/OVRO Sunyaev-Zeldovich effect data to constrain $f_{gas}(r_{2500})$]; the (green) triangle represents a weighted average of $f_{gas}(r_{2500})$ for the 26 clusters (spanning 0.07 < z < 0.9) observed by Allen et al. (2004) with Chandra; the (blue) squares represent weighted averages of $f_{gas}(r_{2500})$ and $f_{gas}(r_{1000})$ for the 22 clusters (spanning 0.01 < z < 0.1) observed by Ettori et al. (2002) with BeppoSAX, and; the (magenta) circle represents a weighted average of $f_{gas}(r_{500})$ for the 8 clusters (at $z \approx 0.5$) observed by Sadat et al. (2005) with XMM-Newton.

Although there is some scatter in the averaged $f_{\rm gas}$ values from these different studies, Fig. 1 demonstrates that they are, by and large, consistent with the profiles of V06 and PAP. The one exception is the data of Ettori et al. (2002), which are systematically lower than the others. Since this is the data Ettori (2003) used to show there was only a very small discrepancy between cluster baryon fractions and the first-year *WMAP* results, we discuss the studies of Ettori et al. (2002) and Ettori (2003) in a bit more detail in §3.

 $^{^2}$ It now appears that the discrepancy between temperature profiles derived with *Chandra* and those with *XMM-Newton* may be nearly resolved. Using a larger sample of clusters observed with *XMM-Newton* and an improved model for background subtraction, Pratt et al. (2006b) now find steeper temperature declines at large radii which are quite similar to those of V06 (G. W. Pratt, private communication). See also Vikhlinin et al. (2005).

4 I. G. McCarthy et al.

X-ray observations are not the only way one can constrain the gas mass fractions of clusters. Increasingly, the Sunyaev-Zeldovich (SZ) effect is also being used for this purpose. For example, LaRoque et al. (2006) found very similar results for $f_{gas}(r_{2500})$ when fitting to both *Chandra* X-ray data and BIMA/OVRO SZ effect data simultaneously (vellow pentagon in Fig. 1) or when fitting to the SZ effect data alone. More recently, Afshordi et al. (2007) have stacked the SZ effect signals of 193 clusters in the WMAP 3-year data to constrain the thermal energy of the ICM. With the aid of hydrodynamic simulations, they converted this thermal energy into an estimate of the gas fraction of clusters within r_{200} . Their result, represented by the open (cyan) square in Fig. 1, is in excellent accordance with the X-ray-derived results. This is very encouraging since the systematics involved in the derivation of this result are obviously very different from those associated with X-ray measurements.

3 IMPLICATIONS

In cosmological simulations the baryon fraction within r_{500} has converged to 90-95% of the universal value in the case of non-radiative simulations (e.g., Frenk et al. 1999; Kay et al. 2004; Crain et al. 2006) and slightly higher than this when radiative cooling and star formation is included (e.g., Kravtsov et al. 2005; Ettori et al. 2006). It is only possible to drive a substantial fraction of the baryons beyond r_{500} if the energy input from non-gravitational heating (such as AGN powered jets and bubbles; e.g., Churazov et al. 2002) is comparable to the binding energy of the cluster gas (we quantify the energy requirement in §3.2). In the absence of such high levels non-gravitational heating, the baryon fractions derived at r_{500} should be nearly representative of the universal value.

Independent measurements of the universal baryon fraction Ω_b/Ω_m can be derived from the power spectrum of CMB anisotropies. In Figs. 1 and 2 we show the value of Ω_b/Ω_m constrained by the WMAP 3-year data (Spergel et al. 2007). From Fig. 1 it is immediately apparent that, with the exception of PAP's estimate of $f_{\rm gas}$ for A1413, the observational gas mass estimates do not achieve consistency with the WMAP measurements of the baryon fraction within any (observable) overdensity. This is true despite the fact that the XMM-Newton data of PAP extend out to nearly r_{500} (note that, typically, $r500 \sim 1$ Mpc) and slightly beyond for the Chandra data of V06. At the lowest observable overdensity (largest radii), the data indicate a gas mass fraction that is roughly 40% lower than Ω_b/Ω_m inferred from WMAP 3-year data. Fig. 2 demonstrates that the observed gas mass fractions at > r_{1500} have converged for systems above ≈ 4 keV, and still lie well below the WMAP 3-year constraints. We now examine the possible origins of this sizeable discrepancy. For ease of discussion, we break up the possible solutions into three broad categories.

3.1 Stars and cool baryons

X-ray data by itself constrains only the fraction of a cluster's mass in the form of hot $(T > 10^{6.5} \text{ K})$ gas. A proper comparison to the universal *WMAP* baryon fraction therefore requires that we take into account the fraction of cluster's

baryons locked up in cool gas (that doesn't emit X-rays), stars and baryonic dark matter. If clusters manage to significantly cool $\approx 40\%$ of their baryons this would potentially resolve the discrepancy described above. Indeed, cosmological simulations that take into account the effects of radiative cooling and star formation demonstrate that clusters can potentially cool out such large quantities of their baryons (e.g., Davé et al. 2002; Kravtsov et al. 2005). But such simulations are at odds with near-infrared (K-band) observations of clusters, which typically indicate that the total (resolved) stellar mass is at most 5-14% of the ICM gas mass in hot (> 4 keV) clusters and only slightly higher than this in cooler systems³ (e.g., Balogh et al. 2001; Lin et al. 2003). Recent deep optical observations limit the contribution of diffuse intracluster light to between $\sim 10 - 30\%$ of the total stellar luminosity (e.g., Gonzalez et al. 2005; Zibetti et al. 2005). Low mass stars and brown dwarfs (or "rocks") are also likely to be a significant, undetected component of the mass budget, but there is no strong evidence that they are more abundant than expected from standard initial mass functions used to extrapolate the observed stellar mass functions (Fuchs, Jahreiss & Flynn 1998; Gizis et al. 2000; Lucas et al. 2005; Levine et al. 2006). Radio, infrared, and ultraviolet surveys for atomic, molecular, and ionised gas (respectively) limit the contribution of cool ($T < 10^{5.5}$ K) diffuse baryons to less than a percent or so of the hot X-ray-emitting ICM (e.g., O'Dea et al. 1998; Donahue et al. 2000; Edge 2001; Edge & Frayer 2003; Bregman et al. 2006). Finally, Ettori (2003) have suggested that a significant fraction of cluster baryons could lie at temperatures between $10^5 < T < 10^7$ K and they cite possible evidence for this in the form the observed "soft X-ray excess". However, it now appears that this excess was the result of inadequate modelling of the Galactic foreground (Bregman & Lloyd-Davies 2006). Furthermore, it is unclear physically how such large quantities of gas in this temperature range could resist cooling down to 10^4 K or being mixed or heated to the ambient ICM temperature.

Furthermore, one can place limits on any hidden cold baryonic component by considering its gravitational effects on the properties of the ICM. In particular, if the hidden material is centrally concentrated, as one would expect if its origin is linked to cooling, this will deepen the potential well which, in turn, will heat the ICM through simple gravitational compression. The observed temperature profiles can therefore be used to place constraints on the amount of hidden cold material in clusters. We have tested this as follows. In particular, we assume the dark matter follows a NFW distribution with a typical concentration parameter $c_{200} = 4$. We further assume the gas density profile follows a distribution typical of observed "cool core" clusters (see V06; McCarthy et al. 2007). Finally, we try different hidden cold mass distributions. The predicted ICM temperature distributions are computed by placing the gas in HSE. In the case where there is no hidden component, we find

 $^{^3}$ We note that some previous studies (e.g., Ettori 2003; Voevodkin & Vikhlinin 2004) estimated slightly higher stellar fractions (typically 15-20%) based on V- and B-band cluster observations. However, due to uncertain age and metallicity effects, conversion to stellar mass from the V- and B-bands is less reliable than converting from the K-band.

the resulting temperature profiles quantitatively match the observed ones. This is not unexpected, given the results of McCarthy et al. (2007) (see §3.1 of that study). However, the predicted temperature profiles are quite sensitive to the addition of a centrally-concentrated cold component. In particular, if we require that the predicted temperature profiles are within the observational uncertainties (typically, binned temperature profiles have a 10% measurement uncertainty), we can rule out a cold component weighing $> \approx 3 \times 10^{12} M_{\odot}$ within the central 50 kpc or $> \approx 5 \times 10^{12} M_{\odot}$ within the central 100 kpc. (Note that our results at a fixed radius are not sensitive to the distribution of the cold component, only to the total enclosed mass within that radius.) This is small compared to the $\sim 5 \times 10^{13} M_{\odot}$ required to resolve the cluster vs. CMB discrepancy for a massive $10^{15} M_{\odot}$ cluster. The only way to reconcile the cluster vs. CMB discrepancy and maintain consistency with the observed temperature profiles is if the hidden component is very spatially-extended. However, such a configuration seems physically contrived.

It therefore appears that the stellar/cool baryon contribution to the total cluster baryon budget too small to account for the cluster vs. CMB discrepancy. In particular, the resolved stellar/cold baryon component is a approximately factor of 3 smaller than required. Moreover, we have demonstrated that any hidden component cannot be very massive, otherwise this would violate the observed temperature profiles of relaxed clusters.

3.2 Non-gravitational heating

As discussed above, the small fraction of cooled baryons observed, relative to the predictions of cooling-only simulations, implies that some form of non-gravitational heating ("feedback") is at work in the ICM. Without significant feedback to prevent this overcooling, theoretical models are unable to account for the observed cut-off of the galaxy luminosity function at the bright end or the fact that BCGs are, by and large, "red and dead" (e.g., Benson et al. 2003; Bower et al. 2006), nor would it be possible to explain the lack of Xray emission from intracluster gas with temperatures below about 1 keV (e.g., Peterson et al. 2003). Non-gravitational heating also appears to be necessary to account for the Xray scaling properties of clusters (e.g., Kaiser 1991; Evrard & Henry 1991; Babul et al. 2002; Voit et al. 2002; McCarthy et al. 2004). Injecting thermal energy into the ICM will cause it to expand (while leaving the dark matter in-tact) and therefore will reduce the gas mass fraction within a given radius. Can this heating explain the discrepancy between cluster and CMB measurements?

To test this, we have computed the bulk energy required to transform clusters with the universal baryon fraction (all in hot gas) into the observed systems. For our *baseline model clusters*, we assume the gas traces the total matter at all radii and, therefore, within any radius the integrated gas mass fraction is always the best-fit *WMAP* 3-year value $\Omega_b/\Omega_m = 0.176$. The total mass profiles (which are dominated by dark matter) are assumed to be the same as those measured by V06 and PAP, thus we construct a baseline model cluster for each of the observed systems. The temperature profiles are determined by placing the gas in HSE. Calculating the total energy of the gas in these systems (i.e., the summation of the total internal and potential energies) is then straightforward. For the observed systems, we extrapolate the gas and total density profiles beyond the maximum radius to which they can be observed, until the integrated gas mass fraction is the universal ratio. (Note that we also extrapolate the baseline models to this radius to ensure that both the baseline and observed systems have the same integrated gas and total masses.). We assume the total density profiles continue to follow the NFW form fit by V06 and PAP. We try various different powerlaw extrapolations for the gas density profiles with plausible indices ranging from 0 to -2.5. We find that the minimum energy required to convert the baseline models into the observed systems occurs when the gas density is constant with radius outside the maximum observable radius. This configuration is perhaps unlikely, but it does provide a useful *lower limit* to the amount of heating required. Like the baseline models, we place the gas in the observed systems in HSE. Reassuringly, we verify that the resulting temperature profiles are in good agreement with the observed profiles. The total (minimum) energy required to heat the ICM is just the difference of the total energy of the observed and baseline model systems.

For hot $(T_{\text{spec}} > 4 \text{ keV})$ clusters, we find that a substantial amount of energy is required, ranging between $6 - 45 \times 10^{62}$ ergs with a mean of $\approx 2.2 \times 10^{63}$ ergs (assuming ρ_{qas} is constant outside the maximum observable radius - i.e., the minimum required energy). It is interesting to compare this minimum energy estimate with the energy that can potentially be deposited by AGN, the most powerful source of non-gravitational heating we know of in clusters of galaxies. (We note that the energy available from AGN far exceeds that available from stellar feedback.) We estimate the amount of AGN energy available to be tapped as follows. First, we convert Lin et al. (2003)'s observed relationship between stellar mass fraction and total mass within r_{500} (see equation 10 of that study⁴) into a stellar—total mass relation [i.e., $M_{\text{star}}(r_{500}) - M_{500}$] assuming a gas mass fraction of 0.12 within r_{500} (see Fig. 1). This relation can be converted into a relationship between the total mass in black holes within r_{500} by (optimistically) assuming that the entire stellar mass is contained in bulges and adopting the black hole—bulge mass $(M_{\rm BH} - M_{\rm bulge})$ relation of Häring & Rix (2004). This leads to the following $M_{\rm BH}(r_{500}) - M_{500}$ relation:

$$\log_{10}[M_{\rm BH}(r_{500}) \ (M_{\odot})] = 1.12 \log_{10} \left[\frac{f_{\rm gas}(r_{500})}{0.12} \right]$$
(1)
+ 0.84 \log_{10} \left[\frac{M_{500}}{5 \times 10^{14} M_{\odot}} \right] + 10.229

Finally, this is converted into an estimate of amount of AGN energy available via $E_{\text{AGN}} = \epsilon M_{\text{BH}}(r_{500})c^2$.

In Figure 3, we present a comparison of the minimum *specific* energy required to resolve the cluster vs. CMB discrepancy with the energy available to be tapped in black holes. (To facilitate comparison with the observations, we calculate the specific energy by dividing the total required

 $^{^4}$ We have slightly adjusted this relation by scaling up the total masses of Lin et al. by 1.26 to account for the normalisation difference between the *ASCA* total mass-temperature relation assumed by Lin et al. and the more accurate *Chandra* relation measured by V06.

Figure 3. Comparison of the minimum specific energy required to reduce cluster gas mass fractions from the universal value to the observed values with estimates of the amount of AGN energy available. Solid squares represent the *Chandra* data of V06 and open triangles represent the *XMM Newton* data of PAP. The three dotted lines represent theoretical estimates of $E_{\rm AGN}$, defined as $\epsilon M_{\rm BH}c^2$ where ϵ is the efficiency factor. The thick dashed line shows the amount of energy deposited into the ICM by the AGN in Hercules A, which is the most energetic AGN outburst known (Nulsen et al. 2005). The thin dashed line corresponds to the case where a given cluster experiences 10 such Hercules-like outbursts over its lifetime.

energy by the typical *observed* mass of gas within r500. In particular, we assume $M_{gas}(r_{500}) = 0.12M_{500}$; see Fig. 1.). In order to explain the most massive systems, we calculate that a minimum energy of ~ 10 keV per particle is required. If one adopts an efficiency of $\epsilon = 0.1$, which is approximately the efficiency predicted by standard radiatively efficient accretion disk models (e.g., Shakura & Sunyaev 1973), there is potentially just enough energy available in black holes distributed throughout r_{500} to account for the observed gas mass fractions. (We use the term 'potentially' since we remind the reader that we have calculated the minimum energy required and furthermore have made optimistic assumptions about the mass of black holes available to heat the ICM.) This result agrees quite well with the more detailed calculations of Bode et al. (2007) (that include, e.g., the effects of asphericity and substructure), when one normalises their estimated required total energy to the same total mass of gas assumed above.

However, modelling of AGN-blown X-ray cavities suggests the typical cluster black hole efficiency is actually much lower than 0.1. The most energetic AGN outbursts known, in Hercules A (Nulsen et al. 2005) and MS0735.6+7421 (McNamara et al. 2005), have mean powers of $\approx 1.6 - 1.7 \times 10^{46}$ ergs s⁻¹. The typical age of such outbursts is ≈ 100 Myr, corresponding to a total energy of few times 10^{61} ergs or a specific energy of a few tenths of a keV per particle (see the thick dashed line in Fig. 3). This falls nearly two orders

of magnitude short of the required minimum to reduce a massive cluster's baryon fraction from the universal WMAP value to the observed fraction. Therefore, even if a typical cluster experiences 10 such powerful outbursts over its lifetime (say, once per Gyr over 10 Gyr) the energy injected into the ICM still falls short of the minimum required energy by up to an order of magnitude.

We therefore conclude that AGN heating is a highly implausible, but perhaps not impossible, solution to the cluster vs. CMB discrepancy. In addition to the exceptionally large energy requirements, we point out that the heating must be distributed in just such a way as to explain the convergence trend in Fig. 2 and the fact that the ICM properties at large radii in massive clusters follow the *gravitational* self-similar scalings (McCarthy et al. 2007).

3.3 Different cosmological parameters: Ω_m and h

The observed gas fractions are proportional to $h^{-1.5}$, while the WMAP constraint is independent of h. Thus, adopting a lower value of $h \approx 0.55$ would bring these two results into agreement. Indeed, this is why similar analyses by Roussel et al. (2000) and Sadat et al. (2005), who adopt h = 0.5, find higher gas fractions than we have shown here. However, the large body of independent evidence in favour of h > 0.6(e.g. York et al. 2005; Jones et al. 2005; Riess et al. 2005; Ngeow & Kanbur 2006) makes this solution seem unlikely.

We can use the observed baryon content of clusters to reverse-engineer the universal total matter density, Ω_m , via:

$$\Omega_m = \frac{b_{\rm dep}(r_{500})\Omega_b}{b_{\rm HSE} f_{\rm gas}(r_{500})[1 + M_{star}(r_{500})/M_{\rm gas}(r_{500})]}$$
(2)

where $b_{dep}(r_{500})$ is the baryon depletion factor within r_{500} and b_{HSE} is the observational bias introduced by assuming strict HSE (i.e., ignores pressure support due to turbulent motions), both of which can be estimated using gasdynamic cosmological simulations.

Adopting the WMAP baryon density of $\Omega_b h^2 = 0.0223^{+0.0007}_{-0.0009}$ (which is in good agreement with the latest QSO constraints; see O'Meara et al. 2006), $b_{dep}(r_{500}) = 0.95 \pm 0.05$ (Kravtsov et al. 2005; Ettori et al. 2006; Crain et al. 2006), $b_{HSE} \approx 0.9$ (Nagai et al. 2007), $M_{star}(r_{500})/M_{gas}(r_{500}) = 0.10 \pm 0.05$ (see §3.1), and $f_{gas}(r_{500}) = 0.115 \pm 0.015$ (see Fig. 1 - note that this spans both the Chandra and XMM-Newton results at r_{500}), we find:

 $\Omega_m = 0.36^{+0.11}_{-0.08}$

This is larger than the best-fit WMAP 3-year value of $\Omega_m = 0.238 \pm 0.03$, but is in good agreement with several previous X-ray analyses (e.g., Allen et al. 2002; Lin et al. 2003; Hicks et al. 2006).

However, our findings differ somewhat from those of Ettori (2003). He found evidence for only a marginal discrepancy between his cluster baryon fraction estimates (inferred from *BeppoSAX* X-ray data) and the first-year *WMAP* results (Spergel et al. 2003). This is somewhat surprising since Ettori (2003) used the data of Ettori et al. (2002), who actually find *lower* gas mass fractions than we have assumed above. A likely explanation for this discrepancy is that: (1) he assumed a slightly higher stellar mass fraction; (2) he invoked a large fraction of the cluster baryons being hidden at "warm" temperatures of $10^5 < T < 10^7$ K; and (3) he extrapolated his results well beyond the maximum observable radius (~ r_{1000}) to the virial radius assuming a King total mass profile for several of his systems. The first two are inconsistent with recent, more reliable data (see §3.1). Finally, extrapolation of the data out to the virial radius is highly uncertain. Since simulations and observations now reliably extend out to r_{500} , such large extrapolations are no longer required.

In addition to the agreement with several previous Xray studies, our results on Ω_m also agree with Sloan Digital Sky Survey (SDSS) measurements of the Lyman alpha forest power spectrum (Viel & Haehnelt 2005), the baryon acoustic peak of luminous red galaxies (Eisenstein et al. 2005), and the power spectrum of galaxies (Tegmark et al. 2004). We also note that combining WMAP 3-year joint constraints on $\Omega_m h^2$ and σ_8 (which are degenerate, see below) with weak lensing cosmic shear measurements (Hoekstra et al. 2006) results in an increased best-fit value for Ω_m that is in good agreement with our results (see Fig. 7 or Spergel et al. 2007). Finally, Li et al. (2006) have also recently reported that the "low" value of Ω_m reported by Spergel et al. (2007) is in discord with the number of observed strong lensing giant arcs, however a fiducial flat model with $\Omega_m = 0.3$ and $\sigma_8 = 0.9$ is able to match the lensing data.

On the other hand, several other cosmological tests tend to support the "low" value of Ω_m advocated by Spergel et al. (2007). These include measurements of the motions within the local supercluster (Mohayaee & Tully 2005), the power spectrum of galaxies in the 2dFGRS (Cole et al. 2005), and the mass function of galaxy clusters in the HIFLUGCS Xray flux-limited sample (Reiprich 2006).

Clearly, the relatively large scatter in the reported best fit values of Ω_m warrants further detailed investigation. While our own estimate of $\Omega_m = 0.36^{+0.11}_{-0.08}$ is marginally inconsistent with the WMAP 3-year constraints (and some of the other tests that support the WMAP result), we have argued that this discrepancy is a small price to pay for obtaining agreement with the observed cluster gas mass fractions. Finally, we point out that the discussion carries implications beyond the precise value of Ω_m . Since Ω_m and σ_8 are strongly degenerate in the CMB data, our results suggest that σ_8 is larger than the best-fit value of $0.74^{+0.05}_{-0.06}$ derived from WMAP data alone. It is interesting to note that a model with $\Omega_m = 0.28$ and $\sigma_8 = 0.8$ is within ~ 1-sigma of both the cluster gas mass fraction data and the WMAP joint constraints on these parameters.

4 CONCLUSIONS

Recent, good quality observations of massive clusters with *Chandra* and *XMM-Newton* put strong observational constraints on the gas mass fraction in massive clusters at large radius. In many cases the new data allow the fraction to be constrained out to r_{500} (the radius at which the cluster density contrast is 500). Simulations of clusters suggest that the cluster gas fraction at this radius should closely reflect the average baryon mass fraction in the universe as a whole.

We find $f_{\text{gas}}(r_{500}) \approx (0.12 \pm 0.02) (h/0.72)^{-1.5}$, where

the uncertainty reflects the systematic variations between clusters. This is lower than the best fit to the WMAP 3-year result of $f_b = 0.176 \pm 0.02$.

We consider whether the discrepancy could be due to a large fraction of the cluster gas cooling to form stars and cold gas clouds, or whether it could be due to strong nongravitational heating transporting ~ 30% of the cluster gas outside r_{500} . Observational limits on the stellar and cold gas content of clusters appear to rule out the first possibility. In order to investigate the second, we compute the energy budget required to rearrange the cluster gas. The energy required significantly exceeds the plausible energy input from black holes, unless their mass accretion history is always associated with efficient jet production.

The most likely explanation is that Ω_m lies in the range $0.36^{+0.11}_{-0.08}$. Such a relatively high Ω_m lies slightly above the 68 per cent confidence limits from WMAP, but is consistent with the current data at the 2σ level. Since the measurements of Ω_m and σ_8 are highly correlated in the WMAP analysis, this means that σ_8 is also likely to be higher than the formal best-fit value of 0.74. This has important implications for the abundance of collapsed objects prior to re-ionisation (Reed et al. 2007).
