We model  $d$ -wave ceramic superconductors with a three-dimensional lattice of randomly distributed  $\pi$  Josephson junctions with finite self-inductance. The linear and nonlinear ac resistivity of the  $d$ -wave ceramic superconductors is obtained as function of temperature by solving the corresponding Langevin dynamical equations. We find that the linear ac resistivity remains finite at the temperature  $T_p$  where the third harmonics of resistivity has a peak. The current amplitude dependence of the nonlinear resistivity at the peak position is found to be a power law. These results agree qualitatively with experiments. We also show that the peak of the nonlinear resistivity is related to the onset of the paramagnetic Meissner effect which occurs at the crossover temperature  $T_p$ , which is above the chiral glass transition temperature  $T_{cg}$ .

## I. INTRODUCTION

The interplay of superconductivity and disorder in granular superconductors has been of great interest, particularly regarding their magnetic properties and glassy behavior.<sup>1,2</sup> Granular superconductors are usually described as a random network of superconducting grains coupled by Josephson weak links.<sup>1-4</sup> In the last years, there has been a renewed interest in the study of this problem in high temperature ceramic superconductors (HTCS). Several experimental groups have found a paramagnetic Meissner effect (PME) at low magnetic fields.<sup>5</sup> Sigrist and Rice<sup>6</sup> proposed that this effect could be a consequence of the intrinsic unconventional pairing symmetry of the HTCS of  $d_{x^2-y^2}$  type.<sup>7</sup> Depending on the relative orientation of the superconducting grains, it is possible to have weak links with negative Josephson coupling<sup>6,7</sup>. These negative weak links, which are called  $\pi$ -junctions, can give rise to the PME according to Ref. 5,6. In fact, a model  $d$ -wave granular superconductor, consisting on a network of Josephson junctions with a random concentration of  $\pi$ -junctions and including magnetic screening, has been able to explain the paramagnetic Meissner effect observed at low fields.<sup>8</sup> Also in this model, a phase transition to a *chiral glass* has been predicted for zero magnetic fields.<sup>9-12</sup> The frustration effect due to the random distribution of  $\pi$  junctions leads to a glass state of quenched-in “chiralities”, which are local loop supercurrents circulating over grains and carrying a half-quantum of flux. Evidence of this transition has been related to measurements of the nonlinear ac magnetic susceptibility.<sup>13</sup> Moreover, the random  $\pi$ -junction model has also been adequate to explain several dynamical phenomena observed in HTCS such as the anomalous microwave absorption,<sup>14</sup> the so called compensation effect<sup>15</sup> and the effect of applied electric fields in the apparent critical current.<sup>16</sup>

In recent experiments Yamao *et al.*<sup>17</sup> have measured

the ac linear resistivity,  $\rho_0$ , and the nonlinear resistivity,  $\rho_2$ , of ceramic superconductor YBa<sub>2</sub>Cu<sub>4</sub>O<sub>8</sub>.  $\rho_0$  and  $\rho_2$  are defined as the first and third coefficient of the expansion of the voltage  $V(t)$  in terms of the external current  $I_{ext}(t)$ :

$$V = \rho_0 I_{ext} + \rho_2 I_{ext}^3 + \dots \quad (1)$$

When the sample is driven by an ac current  $I_{ext}(t) = I_0 \sin(\omega t)$ , one can relate  $\rho_0$  and  $\rho_2$  to the first harmonics,  $V'_{\omega}$ , and third harmonics,  $V'_{3\omega}$ , in the following way

$$\begin{aligned} \rho_0 &= V'_{\omega}/I_0, \quad \rho_2 = -4V'_{3\omega}/I_0^3, \\ V'_{n\omega} &= \frac{1}{2\pi} \int_{-\pi}^{\pi} V(t) \sin(n\omega t) d(\omega t), \quad n = 1, 3 \quad (2) \end{aligned}$$

The key finding of Ref. 17 is that  $\rho_0$  does not vanish even at and below the intergrain ordering temperature  $T_{c2}$ . On the other hand,  $\rho_2$  has a peak near this temperature, which was found to be negative. In the chiral glass phase the  $U(1)$  gauge symmetry is not broken and the phase of the condensate remains disordered.<sup>9-11</sup> The chiral glass phase, therefore, should not be superconducting but exhibit an Ohmic behavior with a finite resistance. Based on these theoretical predictions Yamao *et al.*<sup>17</sup> speculated that their results give further support to the existence of the chiral glass phase, in addition to previous results from magnetic susceptibility measurements.<sup>13</sup>

Another interesting result of Yamao *et al.*<sup>17</sup> is the power law dependence of  $|V'_{3\omega}(T_p)/I_0^3|$  (or of  $\rho_2$ ) at its maximum position  $T_p$  on  $I_0$ :  $|V'_{3\omega}(T_p)/I_0^3| \sim I_0^{-\alpha}$ . The experimental value of the power law exponent was  $\alpha \approx 1.1$ .<sup>18</sup>

The goal of our paper is two-fold. First, we try to reproduce the experimental results<sup>17</sup> using the model of the Josephson junctions between  $d$ -wave superconducting grains<sup>8,9</sup> where the screening of the external field by supercurrents is taken into account. Second, we discuss the

question if the temperature  $T_p$  of the nonlinear resistivity peak and the transition temperature  $T_{cg}$  to the chiral glass phase<sup>10,11</sup> are related. We calculate the linear and nonlinear ac resistivity by a Langevin dynamics simulation. In agreement with the experimental data<sup>17</sup> we find that  $\rho_0$  remains finite below and at the temperature  $T_p$  where  $\rho_2$  has a peak. Furthermore, the maximum value of  $|V'_{3\omega}(T_p)/I_0^3|$  is found to scale with  $I_0$  with a power law exponent  $\alpha = 1.1 \pm 0.6$ , which is close to the experimental value.<sup>17</sup> However, we find that  $T_p$  is above the equilibrium chiral glass transition temperature  $T_{cg}$ .

## II. MODEL

We neglect the charging effects of the grains and consider the following Hamiltonian<sup>8,9</sup>

$$\begin{aligned} \mathcal{H} = & - \sum_{\langle ij \rangle} J_{ij} \cos(\theta_i - \theta_j - A_{ij}) + \\ & \frac{1}{2\mathcal{L}} \sum_p (\Phi_p - \Phi_p^{ext})^2, \\ \Phi_p = & \frac{\phi_0}{2\pi} \sum_{\langle ij \rangle} A_{ij}, \quad A_{ij} = \frac{2\pi}{\phi_0} \int_i^j \vec{A}(\vec{r}) d\vec{r}, \end{aligned} \quad (3)$$

where  $\theta_i$  is the phase of the condensate of the grain at the  $i$ -th site of a simple cubic lattice,  $\vec{A}$  is the fluctuating gauge potential at each link of the lattice,  $\phi_0$  denotes the flux quantum,  $J_{ij}$  denotes the Josephson coupling between the  $i$ -th and  $j$ -th grains,  $\mathcal{L}$  is the self-inductance of a loop (an elementary plaquette), while the mutual inductance between different loops is neglected. The first sum is taken over all nearest-neighbor pairs and the second sum is taken over all elementary plaquettes on the lattice. Fluctuating variables to be summed over are the phase variables,  $\theta_i$ , at each site and the gauge variables,  $A_{ij}$ , at each link.  $\Phi_p$  is the total magnetic flux threading through the  $p$ -th plaquette, whereas  $\Phi_p^{ext}$  is the flux due to an external magnetic applied along the  $z$ -direction,

$$\Phi_p^{ext} = \begin{cases} HS & \text{if } p \text{ is on the } \langle xy \rangle \text{ plane} \\ 0 & \text{otherwise,} \end{cases} \quad (4)$$

where  $S$  denotes the area of an elementary plaquette. For the  $d$ -wave superconductors we assume  $J_{ij}$  to be an independent random variable taking the values  $J$  or  $-J$  with equal probability ( $\pm J$  or bimodal distribution), each representing 0 and  $\pi$  junctions.

In order to study the dynamical response and transport properties, we model the current flowing between two grains with the resistively shunted junction (RSJ) model,<sup>3,4</sup> which gives:

$$I_{ij} = \frac{2e}{\hbar} J_{ij} \sin \theta_{ij} + \frac{\hbar}{2eR} \frac{d\theta_{ij}}{dt} + \eta_{ij}(t) \quad (5)$$

Here we add to the Josephson current the contribution of a dissipative ohmic current due to an intergrain resistance  $R$  and the Langevin noise current  $\eta_{ij}(t)$  which has correlations

$$\langle \eta_{ij}(t) \eta_{i'j'}(t') \rangle = \frac{2kT}{R} \delta_{i,i'} \delta_{j,j'} \delta(t-t') \quad (6)$$

The dynamical variable in this case is the gauge invariant phase difference  $\theta_{ij} = \theta_i - \theta_j - A_{ij}$ . The total flux through each plaquette  $p$  depends on the mesh current  $C_p$ :

$$\Phi_p = \Phi_p^{ext} + \mathcal{L} C_p \quad (7)$$

The mesh currents  $C_p$ , the link currents  $I_{ij}$  and the external current  $I_{ext}$  are related through current conservation. At this point, it is better to redefine notation: the site of each grain is at position  $\mathbf{n} = (n_x, n_y, n_z)$  (i.e.  $i \equiv \mathbf{n}$ ); the lattice directions are  $\mu = \hat{\mathbf{x}}, \hat{\mathbf{y}}, \hat{\mathbf{z}}$ ; the link variables are between sites  $\mathbf{n}$  and  $\mathbf{n} + \mu$  (i.e. link  $ij \equiv$  link  $\mathbf{n}, \mu$ ); and the plaquettes  $p$  are defined by the site  $\mathbf{n}$  and the normal direction  $\mu$  (i.e. plaquette  $p \equiv$  plaquette  $\mathbf{n}, \mu$ , for example the plaquette  $\mathbf{n}, \hat{\mathbf{z}}$  is centered at position  $\mathbf{n} + (\hat{\mathbf{x}} + \hat{\mathbf{y}})/2$ ). The current  $I_\mu(\mathbf{n})$  is related to the mesh currents  $C_\nu(\mathbf{n})$  and the external current in the  $y$ -direction as

$$I_\lambda(\mathbf{n}) = \varepsilon_{\lambda\mu\nu} \Delta_\mu^- C_\nu(\mathbf{n}) + \delta_{\lambda,y} I_{ext} \quad (8)$$

where  $\varepsilon_{\lambda\mu\nu}$  is the Levi-Civita tensor,  $\Delta_\mu^-$  is the backward difference operator,  $\Delta_\mu^- C_\nu(\mathbf{n}) = C_\nu(\mathbf{n}) - C_\nu(\mathbf{n} - \mu)$ , and repeated indices are summed. It is easy to verify that Eq.(8) satisfies current conservation. The magnetic flux  $\Phi_\lambda(\mathbf{n})$  and the gauge invariant phases  $\theta_\nu(\mathbf{n}) = \Delta_\nu^+ \theta(\mathbf{n}) - A_\nu(\mathbf{n})$  are related as

$$\Phi_\lambda(\mathbf{n}) = -\frac{\Phi_0}{2\pi} \varepsilon_{\lambda\mu\nu} \Delta_\mu^+ \theta_\nu(\mathbf{n}) \quad (9)$$

with the forward difference operator  $\Delta_\mu^+ \theta_\nu(\mathbf{n}) = \theta_\nu(\mathbf{n} + \mu) - \theta_\nu(\mathbf{n})$ .

Then, from equations (5), (6), (8) and (9) we obtain the following dynamical equations:

$$\begin{aligned} \frac{\hbar}{2eR} \frac{d\theta_\mu(\mathbf{n})}{dt} = & -\frac{2e}{\hbar} J_\mu(\mathbf{n}) \sin \theta_\mu(\mathbf{n}) - \delta_{\mu,y} I_{ext} \\ & -\frac{\hbar}{2e\mathcal{L}} \Delta_\nu^- [\Delta_\nu^+ \theta_\mu(\mathbf{n}) - \Delta_\mu^+ \theta_\nu(\mathbf{n})] \\ & -\eta_\mu(\mathbf{n}, t) \end{aligned} \quad (10)$$

which represent the RSJ dynamics of a three dimensional Josephson junction array with magnetic screening.<sup>4,8</sup>

We can also obtain these equations from Eq. (3) if we add to  $\mathcal{H}$  the external current term:  $\mathcal{H}_T = \mathcal{H} + \sum_{\mathbf{n}} \frac{\hbar}{2e} I_{ext} \theta_y(\mathbf{n})$ . Then an equation of the Langevin form is obtained by taking derivatives with respect to the gauge invariant phase difference:

$$\frac{\hbar}{2eR} \frac{d\theta_\mu(\mathbf{n})}{dt} = -\frac{2e}{\hbar} \frac{\delta \mathcal{H}_T}{\delta \theta_\mu(\mathbf{n})} - \eta_\mu(\mathbf{n}, t), \quad (11)$$

leading to the RSJ dynamical equations of (10).<sup>19</sup>

In what follows we will consider currents normalized by  $I_J = 2eJ/\hbar$ , time by  $\tau = \phi_0/2\pi I_J R$ , voltages by  $RI_J$ , inductance by  $\phi_0/2\pi I_J$  and temperature by  $J/k_B$ . We consider open boundary conditions for magnetic fields and currents in the same way as defined in Ref. 4,8.

### III. RESULTS

The system of differential equations (10) is integrated numerically by a second order Runge-Kutta algorithm. We consider the system size  $L = 8$  and the self-inductance  $\mathcal{L} = 1$ . Depending on values of  $I_0$  and  $\omega$  the number of samples used for the disorder-averaging ranges between 15 and 40. The number of integration steps is chosen to be  $10^5 - 5 \times 10^5$ .

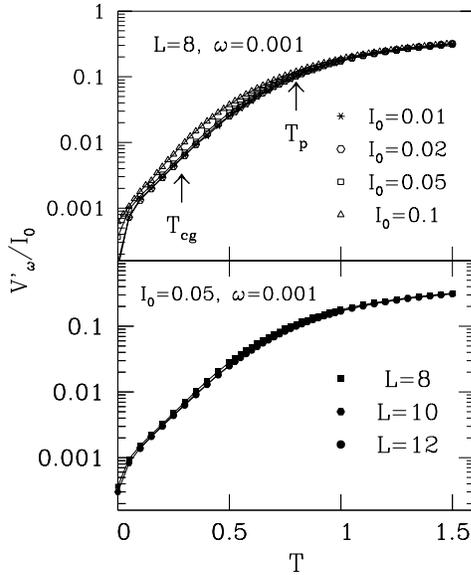

FIG. 1. a) Upper panel: the temperature dependence of  $V'_\omega/I_0$  for  $L = 8, \mathcal{L} = 1$  and  $\omega = 0.001$ . The open triangles, squares and hexagons correspond to  $I_0 = 0.1, 0.05, 0.02$  and  $0.01$ . The arrows correspond to  $T_p = 0.8$  and  $T_{cg} = 0.286$ , respectively. b) Lower panel: the size dependence of  $V'_\omega/I_0$  for  $I_0 = 0.05, \mathcal{L} = 1$  and  $\omega = 0.001$ . The number of time steps is equal to  $10^5$ . The results are averaged over 15 - 40 samples.

The temperature dependence of the linear resistivity  $\rho_0 = V'_\omega/I_0$  for different values of  $I_0$  is shown in Fig. 1 (upper panel). At low temperatures we observe a weak dependence on  $I_0$ , but for currents small enough  $\rho_0$  becomes independent of current. From the lower panel of Figure 1 it is clear that the  $V'_\omega/I_0$  becomes size-independent for  $L > 10$ . Thus, the linear resistivity is nonzero for all temperatures  $T > 0$  in the thermodynamic limit. This is in good agreement with the result that the U(1) symmetry is not broken in the chiral glass state,<sup>9-11</sup> and therefore there is no superconductivity for any finite  $T$ . We note that a similar result was obtained

for the vortex glass state when the magnetic screening is taken into account.<sup>20</sup>

In Fig. 2 we analyze the non-linear resistivity  $\rho_2 = -4V'_{3\omega}(T)/I_0^3$ . We find that it has a negative maximum at a temperature  $T_p$ . This characteristic maximum depends on  $I_0$ , but we can fit its position in temperature at  $T_p = 0.8 \pm 0.05$  for all values of  $I_0$  presented in Fig. 2. The arrow in Fig. 1 also indicates the position of the temperature  $T_p$ . We see that for  $T \gg T_p$  the linear resistivity  $\rho_0$  is independent of current for a large range of currents  $I_0$ . On the other hand, below  $T_p$  the resistivity  $\rho_0$  is current dependent for an intermediate range of  $I_0$  and only for very low currents  $\rho_0$  becomes current independent.

We identify  $T_p$  to correspond to the intergrain ordering transition temperature above which the thermoremanent magnetization disappears in the experiment of Ref. 17. In order to verify this, we study in Fig.3 the magnetization at a finite magnetic field  $f = HS/\phi_0 = 0.1$ . We show both the zero-field cooling (ZFC) and field cooling (FC) curves.<sup>8</sup> We can see that  $T_p$  is the temperature where there is an onset of positive magnetization, i.e. the paramagnetic Meissner effect starts to be observed. On the other hand, the irreversibility point occurs at temperatures lower than  $T_p$ , and its position is dependent on the heating or cooling rate. It should also be noted that above  $T_p$  the real part of the linear magnetic susceptibility vanishes (see Fig. 18 from Ref. 9).

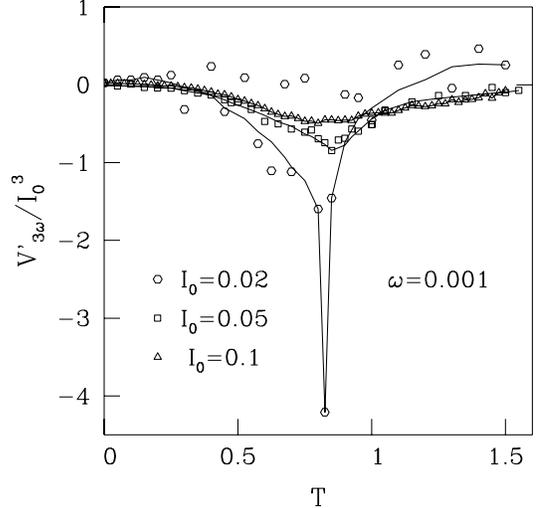

FIG. 2. The same as in Fig. 1 but for  $|V'_{3\omega}(T_p)/I_0^3|$ .

The results presented in Fig. 1, 2 and 3 are in good agreement with the experimental data.<sup>17</sup> From this point of view our findings and the experimental results<sup>17</sup> may seem compatible with the chiral-glass picture.<sup>11</sup> However,  $T_p$  is remarkably higher than the chiral glass temperature  $T_{cg}$  obtained previously (for  $\mathcal{L} = 1, T_{cg} = 0.286$ , see Ref. 10). Then we conclude that the peak of  $\rho_2$  has no relation to the chiral glass phase transition. Thus,  $T_p$  just

separates the normal state phase from a “chiral paramagnet” where there are local chiral magnetic moments. These local moments can be polarized under an external magnetic field, and therefore one can observe the paramagnetic Meissner effect under a low external field below  $T_p$ . At a lower temperature, collective phenomena due to the interactions among the chiral moments will start to be important, leading to the transition to the chiral glass state. This last transition should show in the nonlinear chiral glass susceptibility which should diverge at  $T_{cg}$ ,<sup>10,11</sup>. The chiral glass transition may also be reflected in the irreversibility point in the FC and ZFC magnetizations. Although our model is different from the corresponding gauge glass model<sup>20</sup> one can expect that here the screening spoils any glassy phase except the chiral glass. The linear resistivity is, therefore, nonzero for finite temperatures.

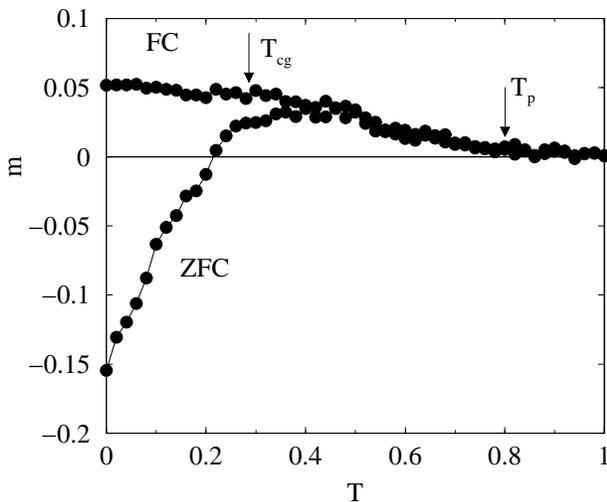

FIG. 3. The temperature dependence of the magnetization  $m$  in FC and ZFC regimes for the  $d$ -wave superconductors.  $L = 8$  and  $\mathcal{L} = 1$ . The results are averaged over 25 samples.

Our calculation of the nonlinear ac resistivity  $\rho_2$  is a non-equilibrium calculation at a finite frequency  $\omega$  and finite ac current amplitude  $I_0$ . Therefore, one should be concerned on the finite  $\omega$  and finite  $I_0$  effects. In particular, one may ask if it is possible that the temperature  $T_p$  of the peak in  $\rho_2$  will tend to  $T_{cg}$  in the limit  $\omega \rightarrow 0$ ,  $I_0 \rightarrow 0$ . We have carefully studied this possibility. Fig. 4 shows the temperature dependence of  $\rho_2$  for various values of  $\omega$  and  $I_0 = 0.1$ . From Fig. 2 and 4 it is clear that the position of  $T_p$  depends on  $I_0$  and  $\omega$  very weakly. It is, therefore, unlikely that  $T_p$  tends to  $T_{cg}$  as  $\omega \rightarrow 0$  and  $I_0 \rightarrow 0$ .

In accordance with the experiments of Yamao *et al.*,<sup>17</sup> the negative maximum of  $V'_{3\omega}(T_p)/I_0^3$  is shown up. Furthermore, the height of peaks of  $|V'_{3\omega}(T_p)/I_0^3|$  increases with the decrease of  $\omega$  and saturates at small frequencies (see Fig. 4). Such tendency was also observed experimentally.<sup>17</sup>

In order to get more insight on the nature of  $T_p$

we have calculated the specific heat,  $C_v$ , which is defined as proportional to the energy fluctuations,  $C_v = \langle (\delta E)^2 \rangle / k_B T^2$ . The results are shown in Fig. 5. There is a broad peak in  $C_v$  located at  $T_p$  and well above  $T_{cg}$ . Similar to the spin glass case where the peak of specific heat is positioned higher than the critical temperature to the glass phase,<sup>21</sup> we conclude that  $T_p$  does not correspond to a phase transition to a long-range ordered phase.

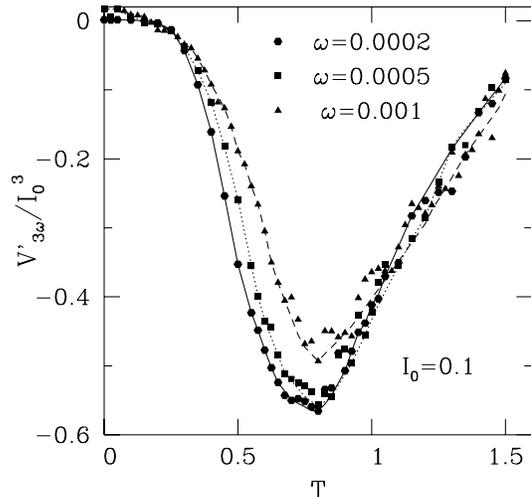

FIG. 4. The temperature dependence of  $V'_{3\omega}(T)/I_0^3$ . The solid triangles, squares and hexagons correspond to  $\omega = 0.001, 0.0005$  and  $0.0002$ , respectively.  $L = 8, \mathcal{L} = 1$  and  $I_0 = 0.1$ . The results are averaged over 15 samples.

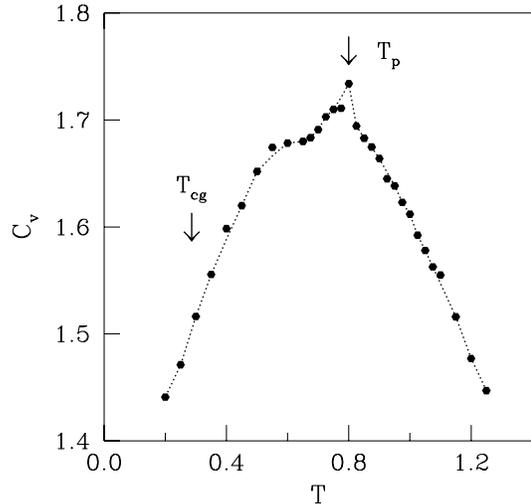

FIG. 5. The temperature dependence of  $C_v$  obtained by Monte Carlo simulations for  $L = 8$  and  $\mathcal{L} = 1$ . The results are averaged over 20 samples. The error bars are smaller than symbol sizes.

A more convincing conclusion about the nature of the

peak in the nonlinear susceptibility should be obtained from a finite size analysis. Fig. 6 shows the dependence of  $\max|V'_{3\omega}/I_0^3|$  on the system size  $L$  for  $I_0 = 0.05$  and  $\omega = 0.001$ . Clearly, the height of the peak does not diverge as  $L \rightarrow \infty$ . In other words the peak in the nonlinear resistivity does not correspond to a phase transition in the thermodynamic limit.

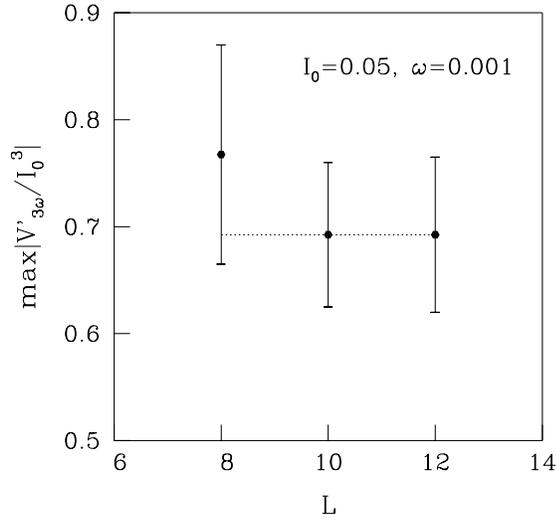

FIG. 6. The dependence of the maximal values of  $|V'_{3\omega}(T_p)/I_0^3|$  on the system size  $L$ .  $I_0 = 0.005$ ,  $\mathcal{L} = 1$  and  $\omega = 0.001$ . The results are averaged over 15 - 40 samples.

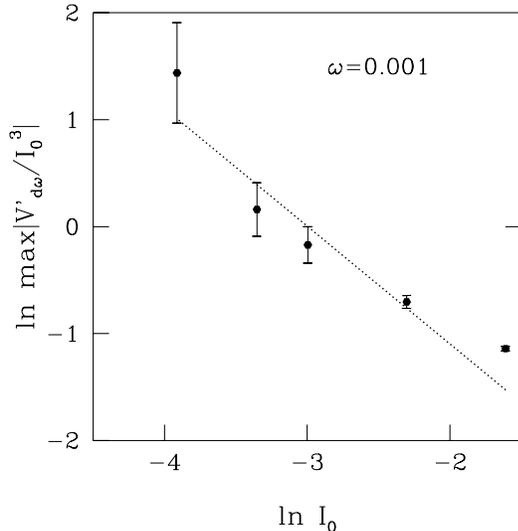

FIG. 7. The dependence of the maximal values of  $|V'_{3\omega}(T_p)/I_0^3|$  on  $I_0$ .  $L = 8$ ,  $\mathcal{L} = 1$  and  $\omega = 0.001$ . The results are averaged over 15 - 40 samples.

Fig. 7 shows the log-log plot for the dependence of the maximal values of  $|V'_{3\omega}(T_p)/I_0^3|$  on  $I_0$  for a fixed frequency  $\omega = 0.001$ . One can fit  $\max|V'_{3\omega}(T_p)/I_0^3| \sim I_0^\alpha$  with

$\alpha = 1.1 \pm 0.6$  giving more weight to small values of  $I_0$ . So within the error bars our estimate of  $\alpha$  agrees with that obtained by the experiments.<sup>17,18</sup>

## IV. DISCUSSION

In Ref. 17 it was argued that the peak of the nonlinear resistivity was a signal of the transition to the chiral glass state. The value of  $T_p$  obtained in our simulations is, however, considerably higher than the chiral glass transition temperature,  $T_{cg}$ . We conclude that the peak of  $\rho_2$  is not related to the transition to the chiral glass.  $T_p$  is found to coincide with the point for the onset of the paramagnetic Meissner effect, where the magnetization becomes positive. In this respect, our result agrees with the experimental result.<sup>17</sup> We interpret  $T_p$  as the crossover temperature from the normal state phase to a “chiral paramagnet” in which there are local chiral magnetic moments induced by the  $\pi$ -junctions. As the temperature is lowered down the system would have a phase transition from the chiral paramagnetic phase to the chiral glass state. At this critical point  $\rho_2$  does not show any particular feature. Furthermore, we found that the linear resistivity is always finite at  $T > 0$  due to screening effects, and therefore there is no superconductivity in the random  $\pi$  junction model.

In conclusion, the experimental results of Yamao *et al.*<sup>17</sup> can be reproduced by the XY-like model for the  $d$ -wave superconductors. Contrary to the speculation of Ref. 17 we expect that  $T_p$  does not correspond to the chiral glass transition.

Phys. Soc. Jpn **68**, 871 (1999).
- <sup>18</sup> We have extracted the experimental value of  $\alpha \approx 1.1$  from  
Fig. 7 of Ref. 17.
- <sup>19</sup> If the derivatives in Eq.(11) are taken with respect to the  
local phase  $\theta(\mathbf{n})$  instead of  $\theta_\mu(\mathbf{n})$ , the so-called time depen-  
dent Ginzburg-Landau (TDGL) dynamics is obtained. In  
the TDGL case there is on-site dissipation and current is  
not conserved.
