Abstract

The bias dependent interface charge is considered as the origin of the observed non-ideality in current-voltage and capacitance-voltage characteristics. Using the simplified model for the interface electronic structure based on defects interacting with the continuum of interface states, the microscopic origin of empirical parameters describing the bias dependent interface charge function is investigated. The results show that in non-ideal metal-semiconductor contacts the interface charge function depends on the interface disorder parameter, density of defects, barrier pinning parameter and the effective gap center. The theoretical predictions are tested against several sets of published experimental data on bias dependent ideality factor and excess capacitance in various metal-semicoductor systems.

1 Introduction

The Schottky barrier heights at the metal-semiconductor interfaces are usually found to be only weakly dependent on the metal work function [1]. The failure to comply with the Schottky-Mott rule [2, 3], where the Schottky barrier height, ϕ_b , is equal to the difference between the metal work function, ϕ_m , and semiconductor electron affinity, χ_s , is often termed Fermi level pinning. This phenomenon has stimulated extensive debate over the past few decades, resulting in several proposed models, and has recently again attracted considerable attention in the scientific community [4, 5, 6, 7]. Interface properties enter these models in the form of the charge localized near the interface resulting from the finite density of states in the band gap and/or defect levels. It has been recently shown [9, 8, 6] that delibarate introduction of metal atoms into the thin semiconductor layer near the metal-semicoductor interface utilizing ionized cluster beam deposition [10, 11, 12, 9], enables identification of the origin and analysis of non-ideality in certain metal-semiconductor contacts.

The non-ideality is a consequence of the interlayer present in the structure between the metal and the semiconductor substrate. In ionized cluster beam deposited samples, this interlayer consists of the penetrated metal atoms embedded in the host semiconductor lattice where they introduce disorder into the lattice and may act as additional deep impurities. The incident beam in ionized cluster beam deposition is comprised of neutral and, to smaller extent, also ionized metal atoms [10, 11, 12]. The small number of neutral and ionized metal clusters of various sizes which are simultaneously present in the incident beam, on account of the very low energy shared by each cluster atom (of the order of about 60 eV per atom for an avarage cluster size of 16 atoms and 1 keV translational energy) can be safely neglected. The additionally gained energy, up to few keV in some cases, enables the metal ions to enter into semiconductor bulk and come to rest within and up to their penetration length (L) typically a few nm in depth. In such a non-ideal metal-semiconductor structure one can identify two distinct interfaces, one situated at the metal/disordered interlayer, and the other at the disordered layer/regular semiconductor junction [8]. It was shown that the electronic properties of such a non-ideal Schottky structure determine its low-frequency capacitance and Fermi level pinning behaviour [6, 8].

Closely connected to the questions of the microscopic properties of the m/s interface is the problem of the excess capacitance [13, 14, 15, 16, 8, 9] in Schottky junctions. Recently [8] we have been able to show that the observed excess capacitances in non-ideal Schottky junctions arise on account of the bias dependent localized charge density induced at the appropriate interface in the structure. The model function for the interface charge was chosen to be:

$$\sigma(U) = b \exp[-(K + qU/U_0)^2],$$
(1)

where the constants b, K, and U_0 were determined by comparison with the experimental capacitance-voltage dependence of different systems [8]. The differential capacitance is in this model given by [8]:

$$C(U) = \frac{\epsilon_s}{W} + \left(\frac{L}{W} - 1\right)\frac{d\sigma}{dU},\tag{2}$$

where L is the width of the disordered layer, and W is the width of the depletion layer. Here, the dielectric constants of the disordered layer and the homogenuous semiconductor (ϵ_s) are taken to be equal. As an example, we show on figure 1 the measured low frequency capacitance (plotted as $C^{-2}(U)$) of e-beam deposited Al/n-Si (data taken from refs. [17, 18]) and of ICB deposited Pb/p-Si (our own samples) Schottky structures as a function of applied bias. The full line is the calculated capacitance-voltage characteristics based on eqs. 1 and 2. For further details we refer the reader to reference [8].

The current-voltage characteristics of non-ideal metal-semiconductor contacts do not usually follow the characteristics predicted by thermionic emission transport theory. The observed discrepance is often treated by introducing the ideality factor into the current-voltage characteristic defined by [2]:

$$n^{-1} = 1 - \frac{d\phi_b}{qdU},\tag{3}$$

where ϕ_b is the barrier height.

In what follows we show that the bias dependence of the ideality factor used to describe the non-ideality of the current-voltage characteristics can be traced back to the interface charge causing the non-ideality and later on we discuss the microscopic origin of the parameters in the interface charge functions. The derived expressions are used on experimental sets of data published by different authors, and some of the values of microscopic parameters are extracted.

2 Ideality factor and interface charge in non-ideal Schottky contacts

In a non-ideal metal-semiconductor system we can quite generally describe the nonideality with the macroscopic charge situated near the metal-semiconductor interface. The charge neutrality of the system demands:

$$Q_m + Q_{sc} + Q_i = 0, (4)$$

where Q_m , Q_{sc} , and Q_i are the surface charge densities on the metal in the depletion region of the semiconductor, and at the interface.

For the non-ideal metal-semiconductor structures with the disordered interlayer and the bias dependent charge density the charge neutrality is written as:

$$Q_m + Q_{sc} + Q_i = Q_m + qn_2W + q(n_2 + n_1)L + \sigma(U) = 0,$$
(5)

where n_2 is the concentrations of the ionized bulk semiconductor dopants, n_1 is the concentrations of the ionized defects in the disordered interlayer, and L is the width of the disordered interlayer. The bias dependent localized charge density residing at the disordered layer/homogenous semiconductor interface is here introduced with $\rho_i = \sigma(U)\delta(z-L)$.

The electrostatic analysis of the model yielded the following expression for the width of the depletion layer:

$$W = \sqrt{L^2 \left(1 - \frac{n_1}{n_2}\right) + \frac{\epsilon_s}{q^2 n_2} \left(\frac{-q\sigma}{\epsilon_s}L - qU + \phi_{b,0} - \chi_s\right)},\tag{6}$$

where U is the applied bias, $\phi_{b,0}$ is the Schottky barrier height (potential barrier at the metal/disordered layer interface).

The potential at the disordered layer/semiconductor interface is defined as the effective Schottky barrier height in non-ideal contact:

$$\phi_b = \frac{q^2 n_2}{2\epsilon_s} \left(L - W\right)^2 + qU + \chi_s. \tag{7}$$

Using this and the definition of the ideality factor (eq. (3)) we arrive at the following expression for the bias dependent ideality factor in non-ideal metal-semiconductor

systems:

$$n(U) = \frac{1}{\left(1 - \frac{L}{W(U)}\right) \left(1 + \frac{Ld\sigma(U)}{\epsilon_s dU}\right)}.$$
(8)

This result limits to the well known result of Card and Rhoderick [19] when $L \ll W$. If we introduce depletion and interlayer geometric capacitances $C_d = \epsilon_s/W$, $C_i = \epsilon_s/L$, we obtain:

$$n(U) = \frac{1 + C_d/C_i}{1 + \frac{d\sigma}{C_i dU}}.$$
(9)

Card and Rhoderick [19] proposed the division of the interface states into two groups: one in equilibrium with the metal, and the other in equilibrium with the semiconductor. Gomila and Rubi [20, 16] have considered the problem of the bias dependence of ideality factor in case of nonequilibrium, and using a kinetic model derived appropriate bias dependence of these partial densities of states.

The detailed electronic structure of the non-ideal metal-semiconductor contact must be complex involving possible defect, metal and disorder induced densities of states. The charging mechanisms at the interface are therefore quite complicated. For instance, Wu, Yang, and Evans [21] described the observed excess and negative capacitance in NiSi₂/n-Si(100) Schottky diode using the modified occupation function of the interface states. They introduced modification causing the decreasing of the interface charge with the forward bias on account of the decreasing of the occupancy of the interface states below the metal Fermi energy.

Here we use a much simpler model for the complex electronic structure which however gives suprisingly good description of the functional bias dependence of the excess charge. The two defect levels are considered as two sharp electronic levels ϵ_1 and ϵ_2 interacting with the partial densities of states in equilibrium with the metal and semiconductor. This mechanism is in some respect similar to the description of the interaction of the metal clusters on the semiconductor surface[22]. The important difference is that in our case we consider a single defect coupled to the interface states, so that the transferred charge cannot be screened out as it is the case in the metal cluster [22].

The random distribution of the metal atoms in the disordered interlayer causes the fluctuations of the potential at leads to broadening of the sharp defect levels. In the high density limit the distribution function of the potential $V(\vec{r})$ can be approximated by the gaussian:

$$P(V) = \frac{1}{\sqrt{\pi}U_0} \exp(-V^2/(U_0)^2), \tag{10}$$

where the parameter U_0 from the charge model function was immediately recognized as the width of the distribution function. The disordered density of states in semiclassical approximation yields[23, 24]:

$$\rho_1(\epsilon) = \frac{1}{\sqrt{\pi}U_0} \left(\exp(-(\epsilon - \epsilon_1)/U_0)^2) \right).$$
(11)

$$\rho_2(\epsilon) = \frac{1}{\sqrt{\pi}U_0} \left(\exp(-(\epsilon - \epsilon_2)/U_0)^2) \right).$$
(12)

If the impurity density is n then we obtain for the excess charge density using the low temperature limit $(T \rightarrow 0)$ for simplicity:

$$\sigma(\epsilon_f) = \frac{qn^{2/3}}{2} \left(\operatorname{erf}[(\epsilon_f - (\epsilon_d - \Delta\epsilon))/U_0] + \operatorname{erf}[(\epsilon_d + \Delta\epsilon - \epsilon_f)/U_0] \right), \quad (13)$$

where ϵ_f is the semiconductor Fermi energy, n is the defect concentration, ϵ_d is the mean defect level, and $2\Delta\epsilon$ is the separation between the two defect levels. If the shift of the defect levels from the mean value is small compared to the disorder parameter U_0 , i.e. $\Delta\epsilon/U_0 \ll 1$, then we have approximately:

$$\sigma(\epsilon_f) \approx \frac{2qn^{2/3}\Delta\epsilon}{\sqrt{\pi}U_0} \exp[-(\epsilon_f/U_0 - \epsilon_d/U_0)^2].$$
 (14)

The difference between the Fermi energy in the metal and the Fermi energy in the semiconductor far from interface equals the applied bias:

$$\epsilon_f = \epsilon_{fm} + qU. \tag{15}$$

In equilibrium, the Fermi energy at the interface is found to be pinned near the midgap of the semiconductor. In one dimension it tends to fall near the branch point in the complex band structure. In three dimensions the pinning point is found to be given by the gap center of the minimum indirect gap, ϵ_g , corrected with spin-orbit splitting [25], and including the shift from the defined center depending on the metal δ_m :

$$\epsilon_{fm} = \frac{1}{2}\epsilon_g + \delta_m. \tag{16}$$

Using (4), and (5) in the expression for the interface charge density (3), one can define an effective gap center, $\epsilon_{0,eff}$, in the presence of the disorder and defects in the semiconductor:

$$\epsilon_{0,eff} = KU_0 = \frac{1}{2}\epsilon_g + \delta_m - \epsilon_d = \frac{1}{2}\epsilon_g - \delta\epsilon_{m,d}.$$
(17)

This shows that the parameter K of the model charge function (1) identifies the position of the effective gap center at non-ideal metal-semiconductor interface. The Schottky barrier height is in most models describing the Fermi level pinning [1, 5, 4] given as an interpolation between the Schottky-Mott and Bardeen limit:

$$\varphi_{b,p} = c(I_s - \phi_m) + (1 - c)\epsilon_{0,eff}.$$
(18)

Here, $I_s = E_g + \chi_s$ is the semiconductor ionization potential, and c is the pinning parameter which depends on the details of the pinning mechanism. As the pinning parameter changes its value from 1 to 0, the Schottky barrier height goes from totally unpinned to fully pinned value.

3 Results and discussion

Using the experimentaly observed values for the Schottky barrier height on p-type Si and the effective gap center deduced from the analyzed capacitance-voltage characteristics [8] one can obtain the pinning parameter for different metal-semiconductor systems that were analyzed [8]. If the pinning mechanisms depends on the continuum of the localized density of states in the band gap, then the pinning parameter of the following form is usually obtained [2] for nearly ideal systems:

$$c = \frac{1}{1 + \frac{q^2 D(\epsilon_{0,eff})\xi}{\epsilon_s}},\tag{19}$$

where $D(\epsilon_{0,eff})$ is the (two dimensional) density of states in the band gap at the effective gap center, ξ is the localization length of the states, and ϵ_s is the dielectric constant of the semiconductor.

When the disordered interlayer of width L is introduced between the metal and the bulk semiconductor, possibly extending over several atomic layer, the pinning parameter is given by [5]:

$$c = \operatorname{sech}\left(\sqrt{q^2 L^2 \rho(\epsilon_{0,eff})/\epsilon_s}\right),\tag{20}$$

where $\rho(\epsilon_{0,eff})$ is the density of disorder induced gap states.

The energy interval determining the properties of the non-ideal metal-semiconductor junction is estimated to be of the order of $\Delta \epsilon$. The density of the defect levels interacting with the continuum of localized states is then approximately given by:

$$D(\epsilon_{0,eff})\Delta\epsilon \approx n^{2/3}.$$
 (21)

Using (8) and (9) in eq. (3) gives the final expression for the interface charge density in nearly ideal systems:

$$\sigma(U) = \frac{2q^3 n^{4/3} \xi}{(1/c - 1)\sqrt{\pi}\epsilon_s U_0} \exp[-(\epsilon_{0,eff}/U_0 + qU/U_0)^2],$$
(22)

and the corresponding expression for the non-ideal systems:

$$\sigma(U) = \frac{2q^3 n^{4/3} L}{(\operatorname{arcsech}(c))^2 \sqrt{\pi} \epsilon_s U_0} \exp[-(\epsilon_{0,eff}/U_0 + qU/U_0)^2]$$
(23)

The expression for the interface charge density (eq. 10) as derived from the presented model shows that the crucial microscopic parameters determining the interface charge density in non-ideal metal-semiconductor contacts are: the disorder parameter U_0 , density of defects n, Schottky barrier pinning parameter c (or the density of states interacting with the defect level and localization length), and the effective gap center. The parameters b (the maximum of the interface charge density) and U_0 obtained from the analysis of the capacitance-voltage characteristics of non-ideal metal-semiconductor contacts [8] allows one to compute the number of defects per unit area, the density of corresponding continuum of states and the shift of the defect level interacting with the continuum of localized states. The results of the calculation are presented in tables 1 and 2. The calculated effective gap center for the series of metals on p-type Si (Ag, Pb, Al, Ti, Mo) reasonably well corresponds to the calculated avarage branch point, $\epsilon_0 = 0, 36$ eV, in the Si complex band structure [25], the maximum deviation being 0,1 eV.

We have also considered the negative and excess capacitance observed by Wu, Yang, and Evans [21] in their samples. The excess capacitance is in the case $L \ll W$ according to eq. 2 simply equal to derivative of the interface charge with respect to applied bias: $C_{excess} \approx -d\sigma/dU$. Using generalized model for the bias dependence of the interface charge eq.(14):

$$\sigma(U) = qn_1 \operatorname{erf}\left(\epsilon_0 + \Delta \epsilon - qU\right)/U_{0,1} + qn_2 \operatorname{erf}\left(qU - \epsilon_0 + \Delta \epsilon\right)/U_{0,2}\right), \quad (24)$$

we are able also to describe the results of Wu, Yang and Evans [21] within the framework of our model as it is shown in figure 2. The parameters used in calculation were: $\epsilon_0 = 0, 5 \text{ eV}, \Delta \epsilon = -0, 1 \text{ eV}, U_{0,1} = 0,065 \text{ eV}, U_{0,2} = 0,17 \text{ eV}, n_1 = 3,8 \times 10^{14} \text{ cm}^{-2}$ and $n_2 = 3, 1 \times 10^{14} \text{ cm}^{-2}$.

We now apply the derived results for the bias dependent ideality factor given by eq. (8) to two sets of published data measured in quite different non-ideal metal-semiconductor systems.

Maeda et al. [26] have observed bias dependent ideality factor in Au/n-GaAs metalsemiconductor system. The bias dependence of the ideality factor exhibited a pronounce peak at certain applied bias. We have used eqs. (1) and (8) and calculated the measured bias dependence of the ideality factor using the following set of parameters: $b = 4, 6 \times 10^{-3} \text{ As/m}^2$, $U_0 = 0, 33 \text{ eV}$, K = 0, 042, L = 2 nm. Figure 3 shows the measured set of data and the calculated bias dependence of the ideality factor. In tables 1 and 2 we present the computed density of defects, the shift of defects energy levels and the density of states.

In figure 4 we present the experimentally observed bias dependence of ideality factor as measured in Au/n-InP Schottky structure obtained from [27] (empty dots). In the applied voltage interval for the presented set of data [27] we can write for the derivative of the charge density:

$$-\frac{Ld\sigma}{\epsilon_s dU} = c_1 \exp\left(-(-qU/c_2 + c_3/c_2)^2\right) + c_5 + c_4 U,$$
(25)

with the following values of parameters: $c_1 = 0, 5, c_2 = U_0 = 0, 18 \text{ eV}, c_3 = \epsilon_d = 0, 11 \text{ eV}, c_4 = 0, 25 \text{ 1/V}, c_5 = 0, 19$. The width of the interlayer was L = 15 nm [27]. From these values we calculate the density of the defects $N_d = 2, 8 \times 10^{11} \text{ cm}^{-2}$ and the barrier height for Au/InP contact: $\varphi_{b,n} = 0, 76 \text{ eV}$ which agrees well with the results obtained from analysis of I-V curves in ref. [27].

4 Conclusions

In this work we have shown that the non-ideality in metal-semiconductor contacts which is observed either in current-voltage as bias dependent ideality factor or in capacitance voltage characteristics as excess capacitance can be described using a single model for the bias dependent interface charge.

The expression for the interface charge density is derived which showed that the crucial microscopic parameters determining the interface charge density in non-ideal metal-semiconductor contacts are: the disorder parameter U_0 , density of defects n, Schottky barrier pinning parameter c (or the density of states interacting with the defect level and localization length), and the effective gap center $\epsilon_{0,eff}$. The parameters b (the maximum of the interface charge density) and U_0 obtained from the analysis of the capacitance-voltage characteristics of non-ideal metal-semiconductor contacts [8] allows one to compute the number of defects per unit area and the shift of the defect level interacting with the continuum of localized states. The basic assumption was to condsider the random distribution of the metal atoms in the disordered layer causes the fluctuations of the potential in the layer resulting in broadening of the sharp defect levels. In the high density limit where the distribution function of the potential can be approximated by the gaussian.

The bias dependent charge residing at the metal-semiconductor interface is connected to the bias dependence of the ideality factor of the current-voltage characteristic. The comparison of the results computed from the theoretical model with the published experimental data enabled us to extract several microscopic properties of various metal-semiconductor contacts.
