Abstract

We present a non-perturbative study of the massive Schwinger model. We use a Hamiltonian approach, based on a momentum lattice corresponding to a fast moving reference frame, and equal time quantization. We present numerical results for the mass spectrum of the vector and scalar particle. We find good agreement with chiral perturbation theory in the strong coupling regime and also with other non-perturbative studies (Hamer et al., Mo and Perry) in the nonrelativistic regime. The most important new result is the study of the θ -action, and computation of vector and scalar masses as a function of the θ -angle. We find excellent agreement with chiral perturbation theory. Finally, we give results for the distribution functions. We compare our results with Bergknoff's variational study from the infinite momentum frame in the chiral region.

1 Introduction

In order to study QCD non-perturbatively, lattice gauge theory has been most successful. However, there are some observables, where computational progress in lattice gauge theory has been slow. Examples are: Higher excited states of hadrons and mesons, finite density thermodynamics (quark-gloun plasma), dynamical scattering calculations of cross sections or phase-shifts and hadron structure functions, in particular in the region of small Q^2 and small x_B (10⁻² to 10⁻⁵). In our opinion a non-perturbative Hamiltonian approach may be a viable alternative. In deep inelastic lepton-hadron scattering, the success of the parton model suggests the physical idea to use a fast moving frame also for a computational study of those processes. The parton model can be justified using the operator product expansion. In equal-time quantization, the Breit-frame is the most convenient choice of frame in order to interpret structure functions. In Ref.[1] the authors have proposed such a scheme based on equal-time quantization, using a lattice Hamiltonian on a momentum lattice corresponding to a fast moving frame (Breit-frame). It has been applied to the scalar ϕ^4 theory in 3+1 dimensions. Distribution functions and the mass spectrum in the close neighbourhood of the critical line of the second order phase transition have been computed.

Here we study QED_{1+1} , the so-called massive Schwinger model, in this framework. This model is physically interesting due to the following properties: (i) It is super-renormalizable. (ii) It has a limit where the model is analytically soluble: the massless limit [2]. (iii) It has an (axial) anomaly. (iv) One can study the topological properties associated with θ -actions and θ -vacua. Most of the analytic work on this model has been presented in Refs.[3]-[9]. This model is a widely studied benchmark problem for new methods. It has been studied by a variational method in the infinite-momentum frame [10], in discretized light-cone quantization [12], on the light-cone using orthogonal functions [13], on a finite lattice in equal time quantization [11] and by strong coupling series expansion [14].

The purpose of this work is to show: (a) The use of a fast moving frame, such that v < c, in conjunction with *equal-time* quantization works well also in QED_{1+1} . It is not necessary to go to the infinite momentum frame or to quantize on the light-cone. We obtain quite precise results in the ultra-relativistic region $m/g \to 0$. It has been claimed that low energy states of

the massive Schwinger model are not well approximated in equal-time field theory. We show here that the problem is not equal-time quantization, but the use of the rest-frame, which we avoid to do here. (b) We consider as most important new results of this work the non-perturbative results of the dependence of the vector and scalar mass on the θ -angle.

2 Method

Starting from the Lagrangian, we use the axial gauge $A^3 = 0$ to obtain the Hamiltonian

$$H = \int_{-L}^{L} dx^{3}(\bar{\psi}\gamma^{3}i\partial_{3}\psi + \bar{\psi}\psi) + \frac{g^{2}}{2}\int_{-L}^{L} dx^{3}(\psi^{\dagger}\psi)\frac{1}{-\partial_{3}^{2}}(\psi^{\dagger}\psi).$$
(1)

One introduces a space-time lattice given by spacing a with $N = \frac{2L}{a}$ lattice nodes. Via discrete Fourier transformation one goes over to a momentum lattice, with cut-off $\Lambda = \frac{\pi}{a}$ and resolution $\Delta p = \frac{\pi}{L}$. Motivated by the parton picture we make the assumption that left-moving particles are not dynamically important, if physical particles are considered from a reference frame characterized by a velocity $v = \frac{P}{E}$ which is close to the velocity of light. We thus consider a momentum lattice where $0 \leq p^0, p^3 \leq P$. In order to minimize the number of virtual particle pairs created from the vacuum, we choose a small lattice size. The reason for this is that the number of vacuum pairs is roughly proportional to a vacuum density times the lattice size. On the other hand, a fast-moving physical particle is Lorentz contracted; thus it fits in a small lattice volume (when compared to the rest-frame).

For the purpose of computing the mass spectrum, we need to determine the vacuum energy. Because the vacuum has the quantum number $\vec{P} = 0$, the vacuum energy (and only this) is computed in the rest frame. Because the model is super-renormalizable, one can perform the continuum limit $a \to 0$. The only renormalization necessary is the subtraction of the vacuum energy. On a space-time lattice, one has to satisfy a physical condition (scaling window) $a < \xi a < L$, where ξ is the correlation length in dimensionless units, related to the physical mass of the ground state by $M = \frac{1}{\xi a}$. In a strongly relativistic system, $M \ll P$, thus when $a \to 0$ the scaling window is replaced by 1/P < 1/M < L. For more details compare with Ref.[1].

3 Numerical results

3.1 Mass spectrum

We diagonalize the Hamiltonian in a sector with momentum $\vec{P} = 0$ to obtain the vacuum energy E_{vac} . Then we diagonalize the Hamiltonian in a sector $\vec{P} \neq 0$ corresponding to a relativistic velocity. This yields an energy spectrum E'_n . The physical energies are obtained from $E_n = E'_n - E_{vac}$. The mass spectrum is then given by $M_n = \sqrt{E_n^2 - \vec{P}^2}$. The low lying states of the massive Schwinger model are a vector state and next a scalar state [13, 14]. The behaviour in the ultra-relativistic region $m/g \to 0$ has been computed in chiral perturbation theory up to second order by Adam [16] and Vary et al. [17]. The vector particle mass behaves as

$$\left(\frac{M_v}{M^{(0)}}\right)^2 = 1 + A\cos(\theta)\frac{m}{M^{(0)}} + [B - C\cos(2\theta)](\frac{m}{M^{(0)}})^2 + O((\frac{m}{M^{(0)}})^3),$$

$$A = 2e^{\gamma} \approx 3.5621, \quad B \approx 5.4807, \quad C \approx 2.0933,$$
(2)

where $M^{(0)} = g/\sqrt{\pi}$ is the boson mass of the massless Schwinger model. The mass of the vector boson in the chiral region is shown in Fig.[1]. The vector particle is almost entirely a fermion-antifermion $(q\bar{q})$ bound state. In our lattice results presented in Fig.[1] only this $q\bar{q}$ sector has been taken into account. We find good agreement with chiral perturbation theory [16, 17] and with finite lattice results by Hamer et al. [14]. Fitting our data to a second order polynomial in m/g yields the coefficients A = 0.56, B = 1.74 and C =0.22. Results for the binding energy $M_v - 2m$ of the vector boson in the nonrelativistic region are shown in Fig.[2]. We compare our results with finite lattice results [14] and with results by Mo and Perry [13] using light-cone quantization with an expansion in orthogonal functions. The corresponding results for the binding energy $M_s - 2m$ of the scalar boson are shown in Fig.[3]. Our results correspond to the $q\bar{q}$ sector. For small masses, i.e. $m/g \approx 1/2$ to 1/8, the $qq\bar{q}\bar{q}$ sector becomes important. Thus our results have a larger error in that region. Results on the scalar mass in the ultra-relativistic region $m/g \ll 1$ taking into account the $qq\bar{q}\bar{q}$ sector are shown in Figs.[4,5].

3.2 Dependence on θ -angle

The massive Schwinger model has θ -vacua and one can study its θ -action. The θ -physics of the massive Schwinger model on a circle has been discussed by Manton [9]. The wavefunction is invariant under local gauge transformations. The θ -angle is a parameter, which characterizes the behavior of the wavefunction under global gauge transformations $\Psi[A] \to e^{in\theta} \Psi[A]$, where $n = 0, \pm 1, \pm 2, \cdots$ One can also transform Hilbert space such that this common phase factor disappears and the wavefunction becomes completely invariant under local as well as global gauge transformations. This corresponds to introducing a θ -action $S[A, \theta] = S[A] - \theta q[A]$, where q[A] is the topological charge, or an equivalent θ -Hamiltonian. The mass spectrum of low-lying states as a function of the θ -angle is shown in Figs.[4,5]. Fig.[4] shows results (raw data), where the usual vacuum energy $E_{vac}(\theta = 0)$ has been subtracted in all θ -sectors, which is unphysical, e.g., for $\theta = \pi$. It shows, however, the behavior of the vector mass for $\theta = \pi$ when increasing the lattice from N = 6 to 24. One observes a cusp in the curves, becoming more pronounced when N increases. This behavior is due to level crossings with higher lying states (not shown in the Fig.). Fig.[5] shows the same results when the vacuum energy $E_{vac}(\theta)$ has been subtracted in the corresponding θ -sector. One observes agreement with first order chiral perturbation theory in the ultra-relativistic regime (m/g < 0.04 for N = 6 and m/g < 0.01 forN = 24). The slope of those curves is related to the expectation value of the chiral condensate. The Feynman-Hellmann theorem relates the fermion condensate $\langle \psi \psi \rangle$ to the derivative of the vacuum energy with respect to the fermion mass. Adam [15] has computed the condensate in lowest order of chiral perturbation theory,

$$\frac{\langle \psi\psi\rangle}{M^{(0)}} = a\cos(\theta) + [b - c\cos(2\theta)]\frac{m}{M^{(0)}} + O(\frac{m}{M^{(0)}})^2).$$

$$a = \frac{e^{\gamma}}{2\pi} \approx 0.2835, \quad b \approx 0.7825, \quad c \approx 0.7163.$$
(3)

Eqs.(2,3) imply

$$\langle \bar{\psi}\psi \rangle = \frac{M^{(0)}}{2\pi} \frac{\partial}{\partial m} M_v \Big|_{m=0},$$
(4)

which in analogy to the Feynman-Hellmann theorem relates the condensate to the vector mass. When we extract the slope $\partial M_v / \partial m$ from Fig.[5], we obtain $\langle \bar{\psi}\psi \rangle /g = 0.16 \cos(\theta)$, compared to the exact result of the massless Schwinger model given by

$$\frac{\langle \bar{\psi}\psi\rangle}{g} = \frac{e^{\gamma}}{2\pi\sqrt{\pi}}\cos(\theta) \approx 0.1599\cos(\theta).$$
(5)

The θ -dependence and global gauge transformations have been treated in standard lattice gauge theory based on compact link variables $U_{\mu}(x)$ by Hamer et al. [18]. Our results are in agreement with theirs.

3.3 Distribution functions

In the Hamiltonian approach it is easy to compute the wave function of a lowlying state. From the wave function one can obtain information on its parton structure, i.e., the number of partons and their momentum distribution. The distribution function of the vector boson is given by

$$f(x_B) = \langle \Psi_v(P) \mid \frac{1}{2} \left[b_k^{\dagger} b_k + d_k^{\dagger} d_k \right] \mid \Psi_v(P) \rangle, \tag{6}$$

where $x_B = k/P$ is the fraction of momentum of the vector boson carried by the parton, i.e., fermion. In Fig.[6] we display our lattice results for m/g = 0to 0.28. In the massless limit the distribution function has the shape of a box. Our results are compared with variational calculations using the infinitemomentum frame by Bergknoff [10] and also with those by Mo and Perry [13] using the light-cone. The most sensitive region is the ultra-relativistic region. We find agreement in shape with Mo and Perry's results and very good agreement with Bergknoff's results as shown in Fig.[7]. The agreement with Mo and Perry's results becomes even better than the agreement with Bergknoff if their distribution function is normalized to one. In Fig.[8] we also display the convergence behavior of the vector distribution function for m/g = 32, i.e., in the non-relativistic region. It can be seen that a reasonably large lattice ($N \approx 200$) is needed to resolve this function (which has a sharp peak at $x_B = 1/2$ when $m/g \to \infty$).

4 Summary

In this work we have applied a Hamiltonian lattice approach in a fast moving reference frame to study the massive Schwinger model. We find that the method works well for the computation of the low-lying mass spectrum, also in the presence of the θ -action, and distribution functions. Here we have investigated only $\theta = 0, \pi$. It is interesting to further study the dependence on other θ -angles and higher-lying states. More θ -angles can be studied, e.g. by adding one negative momentum state to the basis. Those investigations are feasible, but would require a higher computational effort.
