Received: date / Revised version: date

Abstract. The absolute strengths of the $E_\alpha = 1175$ keV resonance in the ${}^6\text{Li}(\alpha, \gamma){}^{10}\text{B}$ reaction and of the $E_\alpha = 814$ keV resonance in the ${}^7\text{Li}(\alpha, \gamma){}^{11}\text{B}$ reaction have been measured to $\omega\gamma = 366 \pm 38$ meV and $\omega\gamma = 300 \pm 32$ meV, respectively, in good agreement with previous values. These resonances can be used to measure the absolute acceptance of the recoil separator ERNA to a precision of about 10%.

PACS. 24.30.-v Resonance reactions – 25.40.Lw Radiative capture – 26.20.+f Hydrostatic stellar nucleosynthesis

1 Introduction

The ${}^{12}\text{C}(\alpha, \gamma){}^{16}\text{O}$ reaction ($Q = 7.16$ MeV) is one of the key reactions of nuclear astrophysics [1]. For this reason its cross section at the relevant Gamow energy of $E_0 = 0.3$ MeV must be known with a precision of at least 10%. In spite of tremendous experimental efforts over the last thirty years one is still far from this goal. To improve the situation, a new experimental approach is in preparation at the 4 MV Dynamitron tandem accelerator in Bochum, called ERNA – European Recoil separator for Nuclear Astrophysics [2]. In this approach, the reaction is

studied in inverse kinematics, ${}^4\text{He}({}^{12}\text{C}, \gamma){}^{16}\text{O}$, *i.e.* a ${}^{12}\text{C}$ ion beam is guided into a windowless ${}^4\text{He}$ gas target and the ${}^{16}\text{O}$ recoils are counted in a ΔE -E telescope placed in the beam line at the end of the separator, which filters the intense ${}^{12}\text{C}$ projectiles from the ${}^{16}\text{O}$ recoils. One of the most important separator characteristics is its acceptance in angle and energy. Due to the emission of the capture γ -rays, the recoils emerging from the gas target have sizable angular and energy spreads. In order to make a reliable cross section measurement, ERNA must transport the ${}^{16}\text{O}$ recoils (of chosen charge state) with 100% transmission from the gas target to the telescope.

^a uncertainty not given

One way of determining the acceptance experimentally is to use nuclear reactions with well known absolute cross sections, such as resonant α -capture reactions involving the ${}^4\text{He}$ gas target of ERNA. If a reaction with a chosen resonance energy has similar kinematics as ${}^4\text{He}({}^{12}\text{C}, \gamma){}^{16}\text{O}$, the angular and energy spreads of the ${}^{16}\text{O}$ recoils can be simulated. This condition is fulfilled by the narrow and strong resonances at $E_{\text{R,c.m.}} = 706 \text{ keV}$ in ${}^4\text{He}({}^6\text{Li}, \gamma){}^{10}\text{B}$ ($Q = 4.46 \text{ MeV}$, $\Gamma_{\text{R}} = 1.7 \text{ eV}$) and $E_{\text{R,c.m.}} = 518 \text{ keV}$ in ${}^4\text{He}({}^7\text{Li}, \gamma){}^{11}\text{B}$ ($Q = 8.66 \text{ MeV}$, $\Gamma_{\text{R}} = 1.8 \text{ eV}$). However, the strength $\omega\gamma$ of these resonances is not known with sufficient precision, *i.e.* better than 10% (table 1). Thus, we remeasured both strengths.

2 Experimental procedure

The experiments were carried out at the 5 MV Van de Graaff accelerator of the ATOMKI, Debrecen, Hungary, with an energy stability and energy spread of about 1 keV. The resonance strengths were measured using an α beam

Fig. 1. Decay scheme of the $E_x = 5164 \text{ keV}$ level in ${}^{10}\text{B}$. The relative intensities (branchings) of the different transitions - taken from Table 10.6 of Ref. [7] - are also indicated.

(about 5 and $10 \mu\text{A}$) on Li targets. The targets were prepared by evaporating LiF with natural isotopic abundances onto 0.2 mm thick Ta backings. The thickness of the targets was estimated from the evaporation procedure to be about $150 \mu\text{g}/\text{cm}^2$, consequently the α energy loss in the target ($\sim 200 \text{ keV}$ at $E_\alpha = 1175 \text{ keV}$) is much larger than the widths of the resonances and the energy spread of the α -beam. The collected charge was measured with a precision current integrator. A suppression voltage was

applied at the entrance of the target chamber to minimize the effects of secondary electrons. The target was cooled by air flow. The γ -ray yield was observed with a 40% High Purity Germanium detector. This detector was placed at 55° with respect to the beam direction, with the front face of the detector at a distance of 3.5 cm from the target. At γ -energies below 4 MeV (relevant to ${}^6\text{Li}(\alpha, \gamma){}^{10}\text{B}$), the absolute efficiency of the detector was measured using calibrated radioactive sources. In this energy region the measured points were fitted with a $\eta = a \times E^b$ function, where E is the γ -energy and a and b are constants. At γ -energies above 4 MeV (relevant to ${}^7\text{Li}(\alpha, \gamma){}^{11}\text{B}$) resonant reactions emitting cascade γ -rays were used to determine the efficiency: ${}^{27}\text{Al}(p, \gamma){}^{28}\text{Si}$ (at $E_{\text{R,lab}} = 767$ and 992 keV), ${}^{23}\text{Na}(p, \gamma){}^{24}\text{Mg}$ ($E_{\text{R,lab}} = 1318$ and 1417 keV) and ${}^{39}\text{K}(p, \gamma){}^{40}\text{Ca}$ ($E_{\text{R,lab}} = 1344$ keV). When the low energy member of the emitted cascade fell into the energy region of the radioactive sources, the efficiency was matched to the above function. The measured high energy points were fitted with a 3rd degree polynomial matching the low energy function at about 3 MeV.

2.1 The ${}^6\text{Li}(\alpha, \gamma){}^{10}\text{B}$ reaction

The $E_{\text{R,c.m.}} = 706$ keV ($E_{\text{R,lab}} = 1175$ keV) resonance in ${}^6\text{Li}(\alpha, \gamma){}^{10}\text{B}$ populates the 5164 keV excited state in ${}^{10}\text{B}$. Fig.1 shows how this state decays to the ground state. The most intensive cascade transitions at $E_\gamma = 414$ and 718 keV (Figs. 1 and 3) were used for the strength determination. We scanned the resonance energy region at $E_{\text{R,lab}} = 1175$ keV in 1 keV steps in order to measure the

Fig. 2. Resonance profile of the $E_{\text{R,lab}} = 1175$ keV resonance in ${}^6\text{Li}(\alpha, \gamma){}^{10}\text{B}$ derived from the yield of the $E_\gamma = 414$ and 718 keV lines.

Fig. 3. Sample γ -spectrum taken on top of the 1175 keV resonance in ${}^6\text{Li}(\alpha, \gamma){}^{10}\text{B}$. The 414 and 718 keV γ -lines used for the analysis as well as some other strong lines are identified.

resonance profile. On top of the resonance we used larger energy steps (2 to 3 keV) in order to prove that the target is sufficiently thick, *i.e.* there is a horizontal plateau at energies above $E_{\text{R,lab}}$. Figure 2 shows the resonance profile measured with the 414 and 718 keV γ -lines.

2.2 The ${}^7\text{Li}(\alpha, \gamma){}^{11}\text{B}$ reaction

The $E_{\text{R,c.m.}} = 518$ keV ($E_{\text{R,lab}} = 814$ keV) resonance in ${}^7\text{Li}(\alpha, \gamma){}^{11}\text{B}$ populates the $E_x = 9182$ keV excited state in

Fig. 4. Resonance profile of the $E_{R,\text{lab}} = 814$ keV resonance in ${}^7\text{Li}(\alpha, \gamma){}^{11}\text{B}$ derived from the yield of the 4445 and 4737 keV γ -lines.

${}^{11}\text{B}$ which cascades predominantly (86.6%) via the 4.44 MeV excited state to the ground state emitting an $E_\gamma = 4737$ keV primary and an $E_\gamma = 4445$ keV secondary γ -ray. The 4445 keV line has a small contribution (12.5%) also from the deexcitation through the $E_x = 6743$ keV level. These branching ratios are taken from Table 11.4 of Ref. [12]. The resonance strength was derived from the yield of these two γ -radiations. Figure 4 shows the resonance profile measured with the two γ -radiations. As can be seen, the requirement of a thick target is fulfilled also in this case.

Figure 5 shows a typical γ -spectrum measured on top of the resonance. The $E_\gamma = 4445$ and 4737 keV lines together with their escape peaks are indicated by arrows.

Fig. 5. Sample γ -spectrum taken on top of the 814 keV resonance in ${}^7\text{Li}(\alpha, \gamma){}^{11}\text{B}$. The 4445 and 4437 keV γ -lines used for the analysis are indicated together with their escape peaks.

3 Analysis and results

Using the thick target yield y , the resonance strength $\omega\gamma$ can be calculated using the formula

$$\omega\gamma = \frac{M_T}{M_P + M_T} \frac{\epsilon}{2\pi^2\lambda^2} y \quad (1)$$

where M_T and M_P are the masses of target and projectile, respectively, ϵ is the stopping power of the target at the resonance energy, and λ is the de Broglie wavelength of the projectile. The stopping power was obtained from the SRIM code [13]. The thick target yield is derived from the step in the resonance function, *i.e.* the difference of the number of detected γ -s above and below the resonance divided by the number of incident particles and corrected for the branching ratio of the used transition and for the detector efficiency. Because of the relatively close target-detector geometry and of the γ -rays emitted in cascade transitions, summing corrections (about 10% and 5% for ${}^6\text{Li}(\alpha, \gamma){}^{10}\text{B}$ and ${}^7\text{Li}(\alpha, \gamma){}^{11}\text{B}$, respectively) were necessary in the case of both resonances [14].

Experimental angular distributions are available in the literature for all four studied transitions in the two reactions [3,10,15]. The results show that the gamma yield measured at 55 degrees represents the angle integrated yield with better than 1% accuracy in the studied four transitions. This together with the error arising from the finite detector size has been incorporated in the 7% uncertainty of the detector efficiency.

3.1 Results for the ${}^6\text{Li}(\alpha, \gamma){}^{10}\text{B}$ reaction

The strength of the $E_{\text{R,lab}} = 1175$ keV resonance was determined from the γ -yields of the $E_\gamma = 414$ and 718 keV transitions: $\omega\gamma_{414} = 371 \pm 29$ meV and $\omega\gamma_{718} = 362 \pm 22$ meV. The quoted errors contain only the uncertainties of the thick target yield determination and of the reported branching ratio of a given transition. These uncertainties are specific for the two independent analyses. The weighted average of these two values is $\omega\gamma = 366 \pm 17$ meV. To give the final uncertainty, systematic errors which are common for both analyses have to be included. These are from the stopping power (5%), current integration (3%) and detector efficiency (7%). Adding these components quadratically, we get our final result $\omega\gamma = 366 \pm 38$ meV.

3.2 Results for the ${}^7\text{Li}(\alpha, \gamma){}^{11}\text{B}$ reaction

Similarly, the strength of the $E_{\text{R,lab}} = 814$ keV resonance was determined using the yields of the 4445 and 4737 keV γ -lines: $\omega\gamma_{4445} = 316 \pm 18$ meV and $\omega\gamma_{4737} = 285 \pm 16$ meV.

The weighted average including systematic errors leads to $\omega\gamma = 300 \pm 32$ meV.

4 Conclusions

Our result for the strength of the $E_\alpha = 1175$ keV resonance in ${}^6\text{Li}(\alpha, \gamma){}^{10}\text{B}$ is within the uncertainty range of the adopted value $\omega\gamma_{\text{adopted}} = 400 \pm 40$ meV [7]. Based on the weighted average of the results of all available measurements we propose a new standard value $\omega\gamma_{\text{new}} = 387 \pm 27$ meV which is consistent with all measurements but its uncertainty is reduced from 10% to 7%. Our new value for the strength of the $E_\alpha = 814$ keV resonance in ${}^7\text{Li}(\alpha, \gamma){}^{11}\text{B}$ is in excellent agreement with the adopted value $\omega\gamma_{\text{adopted}} = 310 \pm 47$ meV based on a single measurement. Averaging these two values we propose as a new standard value $\omega\gamma_{\text{new}} = 304 \pm 26$ meV, where the uncertainty is reduced from 15% to 9%.

With the results from previous and present work the precision of the strength of the two resonances has become better than 10% allowing for the ERNA project (and other recoil separators) to perform a reliable acceptance measurement based on these resonant reactions.
