(Dated: November 26, 2024)

Detailed differential measurements of the elliptic flow for particles produced in Au+Au and Cu+Cu collisions at  $\sqrt{s_{NN}}$  = 200 GeV are presented. Predictions from perfect fluid hydrodynamics for the scaling of the elliptic flow coefficient  $v_2$  with eccentricity, system size and transverse energy are tested and validated. For transverse kinetic energies  $KE_T \equiv m_T - m$  up to  $\sim 1$  GeV, scaling compatible with the hydrodynamic expansion of a thermalized fluid is observed for all produced particles. For large values of  $KE_T$ , the mesons and baryons scale separately. A universal scaling for the flow of both mesons and baryons is observed for the full transverse kinetic energy range of the data when quark number scaling is employed. In both cases the scaling is more pronounced in terms of  $KE_T$  rather than transverse momentum.

PACS numbers: PACS numbers: 25.75.Dw

Quantum Chromodynamics calculations performed on the lattice (LQCD) indicate a transition from a lowtemperature phase of nuclear matter, dominated by hadrons, into a high-temperature plasma phase of quarks and gluons (QGP) [\[1](#page-5-0)]. For matter with zero net baryon density, this phase transition has been predicted to occur at an energy density of  $\sim 1 \text{ GeV}/\text{fm}^3$  or for a critical temperature $T_c \sim 170$  MeV [[2\]](#page-5-0). Recent estimates from transverse energy  $(E_T)$  measurements at the relativistic heavy ion collider (RHIC) have indicated energy densities ofat least  $5.4 \text{ GeV}/\text{fm}^3$  in central Au+Au collisions [[3\]](#page-5-0). Thus, an important prerequisite for QGP production is readily fulfilled at RHIC. Indeed, there is much evidence that thermalized nuclear matter has been created at unprecedented energy densities in heavy ion collisions at RHIC[[3, 4, 5, 6, 7](#page-5-0), [8](#page-5-0), [9](#page-5-0), [10](#page-5-0)].

Hydrodynamics provides a link between the fundamental properties of this matter (its equation of state (EOS) and transport coefficients) and the flow patterns evidenced in the measured hadron spectra and azimuthal anisotropy [\[11](#page-5-0), [12, 13](#page-5-0), [14, 15](#page-5-0)]. Experimentally, such a momentum anisotropy is commonly characterized at mid-rapidity, by the even order Fourier coefficients [[16, 17\]](#page-5-0),

$$
v_n = \left\langle e^{in(\phi_p - \Phi_{RP})} \right\rangle, \ n = 2, 4, \dots
$$
 (1)

where  $\phi_p$  represents the azimuthal emission angle of a particle,  $\Phi_{RP}$  is the azimuth of the reaction plane and the brackets denote statistical averaging over particles and events.

At low transverse momentum  $(p_T \lesssim 2.0 \text{ GeV}/c)$  the magnitude and trends of elliptic flow, measured by the second Fourier coefficient  $v_2$ , is found to be underpredicted by a hadronic cascade model [\[18](#page-5-0)]. By contrast, a broad selection of the data showed good quantitative agreement with perfect fluid (very low ratio of viscosity

to entropy) hydrodynamics[[9, 10](#page-5-0), [12, 15](#page-5-0)] and a transport model calculation which incorporates extremely large opacities [\[19](#page-5-0)]. For higher  $p<sub>T</sub>$ , quark coalescence from a thermalized state of flowing partonic matter[[20\]](#page-5-0) has been found to be consistent with the data[[21, 22](#page-5-0)]. Together, these results provide evidence for the production of a strongly interacting QGP whose subsequent evolution is similar to that of a "perfect" fluid [\[7](#page-5-0), [8](#page-5-0), [9](#page-5-0), [10\]](#page-5-0).

Systematic theoretical and experimental studies of the influence of model parameters are now required to gain more quantitative insight on the transport coefficients and the EOS for this strongly interacting matter. The range of validity of perfect fluid hydrodynamics is affected by the degree of thermalization [\[23\]](#page-5-0) and the onset of dissipative effects[[23, 24, 25\]](#page-5-0). These questions can be addressed by investigating several scaling predictions of perfect fluid hydrodynamics [\[15, 23](#page-5-0), [26](#page-5-0), [27](#page-5-0), [28](#page-5-0)].

In the hydrodynamic model, elliptic flow can result from pressure gradients due to the initial spatial asymmetry or eccentricity  $\epsilon = (\langle y^2 - x^2 \rangle) / (\langle y^2 + x^2 \rangle)$ , of the high energy density matter in the collision zone. The initial entropy density  $S(x, y)$ , can be used to perform an average over the  $x$  and  $y$  coordinates of the matter in the plane perpendicular to the collision axis. Here,  $x$  points along the impact vector and  $y$  is orthogonal to  $x$ . For a system of transverse size  $\overline{R}$   $(1/\overline{R} = \sqrt{1/\langle x^2 \rangle + 1/\langle y^2 \rangle}),$ this flow develops over a time scale  $\sim \bar{R}/\langle c_s \rangle$  for matter with an average speed of sound  $c_s$ . Thus, the initial energy density controls how much flow develops globally, while the detailed development of the flow patterns are largely controlled by  $\epsilon$  and  $c_s$ .

An important prediction of perfect fluid hydrodynamics is that the relatively "complicated" dependence of azimuthal anisotropy on centrality, transverse momentum, rapidity, particle type, higher harmonics, etc can be scaled to a single function [\[15, 29](#page-5-0)]. Immediate con<span id="page-3-0"></span>sequences of this [\[15](#page-5-0), [23, 26, 29](#page-5-0)] are that: (i)  $v_2$  scaling should hold for a broad range of impact parameters for which the eccentricity varies, i.e.  $v_2(p_T)/\epsilon$  should be independent of centrality; (ii)  $v_2(p_T)$  should be independent of colliding system size for a given eccentricity; and (iii) for different particle species,  $v_2(KE_T)$  at midrapidity should scale with the transverse kinetic energy  $KE_T = m_T - m$ , where  $m_T$  is the transverse mass of the particle.

We use high statistics  $v_2$  data to test these scaling predictions and explore constraints for the range of validity of perfect fluid hydrodynamics. The measurements were made at  $\sqrt{s_{NN}}$  = 200 GeV with the PHENIX detec-tor [\[30](#page-5-0)] at RHIC. Approximately  $6.5\times10^8$  Au+Au and and  $8.0 \times 10^7$  Cu+Cu minimum-bias collisions were analyzed from the 2004 and 2005 running periods, respectively. The collision vertex z, along the beam direction was constrained to be within  $|z| < 30$  cm. The event centrality for Au+Au collisions was determined via cuts in the space of Beam-Beam Counter (BBC) versus Zero Degree Calorimeter analog response [\[31](#page-5-0)]. For  $Cu+Cu$ only the amplitude of the BBC analog response was used. Charged hadrons were detected in the two central arms  $(|\eta| \leq 0.35)$ . Track reconstruction was accomplished using the drift chambers and two layers of multi-wire proportional chambers with pad readout (PC1 and PC3) located at radii of 2 m, 2.5 m and 5 m, respectively[[30\]](#page-5-0).

The time-of-flight (TOF) detector positioned at a radial distance of 5.06 m, was used to identify pions  $(\pi^{\pm})$ , kaons  $(K^{\pm})$  and (anti)protons  $(\overline{p})p$ . The BBCs and TOFscintillators provided the global start and stop signals. These measurements were used in conjunction with the measured momentum and flight-path length to generate a mass-squared distribution[[32\]](#page-5-0). A momentum dependent  $\pm 2\sigma$  cut about each peak in this distribution was used to identify  $\pi^{\pm}$ ,  $K^{\pm}$  and  $(\overline{p})p$  in the range  $0.2 < p_T < 2.5$ GeV/c,  $0.2 < p_T < 2.5$  GeV/c and  $0.5 < p_T < 4.5$  $GeV/c$ , respectively. A track confirmation hit within a  $2.5\sigma$  matching window in PC3/TOF served to eliminate most albedo, conversions, and resonance decays.

The differential elliptic flow measurements for charged hadrons and identified particles were obtained with the reaction plane method. This technique correlates the azimuthal angles of charged tracks with the azimuth of the event plane  $\Phi_2$ , determined via hits in the two BBCs positioned symmetrically along the beam line, covering the pseudo-rapidity range  $3 < |\eta| < 3.9$  [\[21](#page-5-0)]. A large  $\eta$  gap between the central arms and the particles used for reaction plane determination reduces the influence of possible non-flow contributions, especially those from jets. Values of  $v_2$  were calculated via the expression

$$
v_2 = \frac{\langle \cos(2(\phi_p - \Phi_2)) \rangle}{\langle \cos(2(\Phi_2 - \Phi_{RP})) \rangle},\tag{2}
$$

where the denominator represents a resolution factor that corrects for the difference between the estimated  $\Phi_2$  and

FIG. 1:  $v_2$  vs.  $p_T$  for charged hadrons obtained in (a) Au+Au and (b) Cu+Cu collisions for the centralities indicated. (c)  $v_2(centrality, p_T)$  divided by  $k=3.1$  (see text) times the  $p_T$ -integrated value  $v_2(centrality)$  for Au+Au and Cu+Cu.

the true azimuth  $\Phi_{RP}$  of the reaction plane [\[21](#page-5-0), [33\]](#page-5-0). The estimated resolution factor of the combined reaction plane from both BBCs[[21\]](#page-5-0) has an average of 0.33 (0.16) over centrality with a maximum of about 0.42 (0.19) for Au+Au (Cu+Cu). The estimated correction factor for the  $v_2$  measurements (i.e. the inverse of the resolution factor) ranges from  $2.4$  (5.5) to  $5.0$  (13). Relative systematic errors for these  $v_2$  values are estimated to be  $\sim 5\%$ and  $\sim 10\%$  for Au+Au and Cu+Cu, respectively.

Figure 1 shows the differential  $v_2(p_T)$  for charged hadrons obtained in Au+Au and Cu+Cu collisions. The  $v_2(p_T)$  results exhibit the familiar increase as collisions become more peripheral and the  $p_T$  increase [\[3, 4, 5\]](#page-5-0). We test these data for eccentricity scaling by dividing the differential values shown in Fig. 1 by the  $v_2$  integrated over the  $p_T$  range 0.3-2.5 GeV/c for each of the indicated centrality selections. The hydrodynamic model

<span id="page-4-0"></span>

FIG. 2: (a)  $v_2$  vs  $p_T$  and (b)  $v_2$  vs  $KE_T$  for identified particle species obtained in minimum bias Au+Au collisions. The STAR data are from Refs. [\[22](#page-5-0), [37](#page-5-0)].

predicts that this ratio is constant with centrality and independent of colliding system because  $\epsilon$  is proportional to the p<sub>T</sub>-integrated v<sub>2</sub> values (i.e.  $\epsilon = k \times v_2$ ). The latter proportionality has been observed for Au+Au col-lisions[[34, 35\]](#page-5-0). A Glauber model estimate of  $\epsilon$  [\[35](#page-5-0)] gives  $k = 3.1 \pm 0.2$  for the cuts employed in this analysis. This method of scaling leads to a scale invariant variable and cancels the systematic errors associated with estimates of the reaction plane resolution and the eccentricity.

The resulting scaled  $v_2$  values for Cu+Cu and Au+Au collisions, are shown in Fig. [1\(](#page-3-0)c). To facilitate later comparisons with the model calculations of Ref.[[23\]](#page-5-0), they are divided by  $k = 3.1$ . These scaled values are clearly independent of the colliding system size and show essentially perfect scaling for the full range of centralities (or  $\epsilon$ ) presented. The  $v_2$  are also in accord with the scale invariance of perfect fluid hydrodynamics [\[23, 27\]](#page-5-0), which suggests that rapid local thermalization [\[9](#page-5-0), [10\]](#page-5-0) is achieved.

The magnitude of  $v_2/\epsilon$  depends on the sound speed  $c_s$ [[23\]](#page-5-0). As a reasonable first approximation we compare our measured  $v_2/\epsilon$  at an integrated  $\langle p_T \rangle$  0.45 GeV/c and the results of Fig. 2 of[[23\]](#page-5-0). This results in a speed of sound  $c_s \sim 0.35 \pm 0.05$ . Note that the calculations are done at fixed b=8 fm and a constant speed of sound. Thus, since we expect the speed of sound to vary as a function of time, one might view this  $c_s$  value as the approximate average value over the time period 2  $\bar{R}/c_s$ , the time over which the flow develops. This value suggests an effective EOS, which is softer than that for the high temperature QGP[[36\]](#page-5-0) but does not reflect a strong first order phase transition in which  $c_s = 0$  during an extended hadronization period.

Figures 2 and 3 show that the distinctive features of the  $v_2$  for identified particles provide another detailed set of scaling tests. Fig.  $2(a)$  shows a comparison of the mea-

FIG. 3: (a)  $v_2/n_q$  vs  $p_T/n_q$  and (b)  $v_2/n_q$  vs  $K E_T/n_q$  for identified particle species obtained in minimum bias Au+Au collisions. The STAR data are from Refs.[[22](#page-5-0), [37](#page-5-0)].

sured differential anisotropy  $v_2(p_T)$ , for several particle species obtained in minimum bias Au+Au collisions at  $\sqrt{s_{NN}}$  = 200 GeV. The results are in good agreement (better than 3%) with those of our previous measure-ments [\[21](#page-5-0)]. The values for neutral kaons  $(K_s^0)$ , lambdas  $($ A) and the cascades  $($  $\Xi)$  show results from the STAR collaboration [\[22](#page-5-0), [37\]](#page-5-0). The STAR  $v_2$  values were multiplied by the factor 1.1 to account for a small difference between the average centralities for minimum bias events from the two experiments. PHENIX and STAR  $v_2(p_T)$ results (for  $\pi^{\pm}$ ,  $p(\bar{p})$  and K) for 10% centrality bins are essentially identical.

The comparison in Fig.  $2(a)$  shows the well known particle identification (PID) ordering of  $v_2(p_T)$  at both low and high  $p_T$  values. At low  $p_T$  ( $p_T \lesssim 2 \text{ GeV}/c$ ), one can see rather clear evidence for mass ordering. If this aspect of  $v_2$  is driven by a hydrodynamic pressure gradient, the prediction is that the differential  $v_2$  values observed for each particle species should scale with  $KE_T$ . The pressure gradient that drives elliptic flow is directly linked to the collective kinetic energy of the emitted particles. For higher values of  $p_T$  ( $p_T \sim 2-4$  GeV/c), Fig. 2(a) indicates that mass ordering is broken and  $v_2$  is more strongly dependent on the quark composition of the particles than on their mass, which has been attributed to the dominance of the quark coalescence mechanism for  $p_T \sim 2 - 4 \text{ GeV}/c \; [20, 21, 22].$  $p_T \sim 2 - 4 \text{ GeV}/c \; [20, 21, 22].$  $p_T \sim 2 - 4 \text{ GeV}/c \; [20, 21, 22].$  $p_T \sim 2 - 4 \text{ GeV}/c \; [20, 21, 22].$  $p_T \sim 2 - 4 \text{ GeV}/c \; [20, 21, 22].$  $p_T \sim 2 - 4 \text{ GeV}/c \; [20, 21, 22].$  $p_T \sim 2 - 4 \text{ GeV}/c \; [20, 21, 22].$ 

Figure 2(b) shows the same  $v_2$  data presented in Fig. 2(a) plotted as a function of  $KE_T$ . Note that  $KE_T$ is a robust scaling variable because it takes into account relativistic effects, which are especially important for the lightest particles. In contrast to the PID ordering observed in Fig.  $2(a)$ , all particle species scale to a common set of elliptic flow values for  $KE_T \lesssim 1$  GeV, confirming<br>the streps influence of hydrodynamic pressure specients the strong influence of hydrodynamic pressure gradients. For  $KE_T \gtrsim 1$  GeV, this particle mass scaling (observed <span id="page-5-0"></span>for all particle species) gives way to a clear splitting into a meson branch (lower  $v_2$ ) and a baryon branch (higher  $v_2$ ). Since both of these branches show rather good scaling separately, we interpret this as an initial hint for the degrees of freedom in the flowing matter at an early stage.

Figure [3](#page-4-0) shows the results obtained after quark number scaling of the  $v_2$  values shown in Fig. [2](#page-4-0). That is,  $v_2$ ,  $p_T$  and  $KE_T$  are divided by the number of constituent quarks  $n_q$  for mesons  $(n_q = 2)$  and baryons  $(n_q = 3)$ . Fig. [3](#page-4-0)(a) indicates rather poor scaling for  $p_T/n_q \lesssim 1 \text{ GeV}/c$ and much better scaling for  $p_T/n_q \gtrsim 1.3 \text{ GeV}/c$ , albeit with large error bars. In contrast, Fig. [3\(](#page-4-0)b) shows excellent scaling over the full range of  $KE_T/n_q$  values. We interpret this as an indication of the inherent quark-like degrees of freedom in the flowing matter. These degrees of freedom are gradually revealed as  $KE_T$  increases above  $\sim 1$  GeV (cf. Fig. [2](#page-4-0)(b)) and are apparently hidden by the strong hydrodynamic mass scaling, which predominates at low  $KE_T$ . The fact that  $v_2/n_q$  shows such good scaling over the entire range of  $KE_T/n_q$  and does not for  $p_T/n_q$ , serves to highlight the fact that hydrodynamic mass scaling is preserved over the domain of the linear increase in  $KE_T$ . Fig. [3](#page-4-0)(b) should serve to distinguish between different quark coalescence models.

In summary, we have presented the results from detailed tests of hydrodynamic scaling of azimuthal anisotropy in Au+Au and Cu+Cu collisions at  $\sqrt{s_{NN}}$ = 200 GeV. For a broad range of centralities, eccentricity scaling is observed for charged hadrons for both the  $Cu+Cu$  and  $Au+Au$  systems. For a given eccentricity,  $v_2$ is also found to be independent of colliding system size. The observed scaling for identified particles in Au+Au collisions, coupled with  $\epsilon$  scaling, gives strong evidence for hydrodynamic scaling of  $v_2$  over a broad selection of the elliptic flow data. For  $KE_T \sim 1-4$  GeV universal hydrodynamic scaling is violated, but baryons and mesons are found to scale separately. Quark number scaling  $(v_2/n_q \text{ vs. } KE_T/n_q)$  in this domain leads to comprehensive overall scaling of the data, with substantially better scaling behavior than that found for  $v_2/n_a$  vs.  $p_T/n_a$ . The scaling with valence quark number may indicate a requirement of a minimum number of objects in a localized space that contain the prerequisite quantum numbers of the hadron to be formed. Whether the scaling further indicates these degrees of freedom are present at the earliest time is in need of more detailed theoretical investigation.
