

# The influence of initial impurities and irradiation conditions on defect production and annealing in silicon for particle detectors

Ionel Lazanu\* and Sorina Lazanu†

November 13, 2018

## Abstract

Silicon detectors in particle physics experiments at the new accelerators or in space missions for physics goals will be exposed to extreme radiation conditions. The principal obstacles to long-term operation in these environments are the changes in detector parameters, consequence of the modifications in material properties after irradiation.

The phenomenological model developed in the present paper is able to explain quantitatively, without free parameters, the production of primary defects in silicon after particle irradiation and their evolution toward equilibrium, for a large range of generation rates of primary defects. Vacancy-interstitial annihilation, interstitial migration to sinks, divacancy and vacancy-impurity complex ( $VP$ ,  $VO$ ,  $V_2O$ ,  $C_iO_i$  and  $C_iC_s$ ) formation are taken into account. The effects of different initial impurity concentrations of phosphorus, oxygen and carbon, as well as of irradiation conditions are systematically studied. The correlation between the rate of defect production, the temperature and the time evolution of defect concentrations is also investigated.

## 1 Introduction

The use of silicon detectors in high radiation environments, as to be expected in future high energy accelerators or in space missions, poses severe problems due to changes in the properties of the material, and consequently influences the performances of detectors.

As a consequence of the degradation to radiation of the semiconductor material, an increase of the reverse current due the reduction of the minority carrier lifetime, a reduction of the charge collection efficiency and a modification of the effective doping, due to the generation of trapping centres, are observed in the detector characteristics.

In this paper, the effects of irradiation conditions and various initial impurities in the starting material are discussed in the frame of the phenomenological model able to explain quantitatively defect production and evolution toward stable defects during and after irradiation in silicon. The model supposes three steps.

In the first step, the incident particle, having kinetic energies with values in the intermediate up to high energy range, interacts with the semiconductor material. The peculiarities of the interaction mechanisms are explicitly considered for each kinetic energy.

In the second step, the recoil nuclei resulting from these interactions lose their energy in the lattice. Their energy partition between displacements and ionisation is considered in accord with the Lindhard theory ([1] and authors' contributions [2]).

A point defect in a crystal is an entity that causes an interruption in the lattice periodicity. In this paper, the terminology and definitions in agreement with M. Lannoo and J. Bourgoin [3] are used in relation to defects. We denote the displacement defects, vacancies and interstitials, as primary point defects, prior to any further rearrangement. After this step the concentration of primary defects is calculated.

The mechanisms of interaction of the incident particle with the semiconductor lattice, accompanied by displacement defect production have been discussed in some papers, see, e.g. references [4, 5, 6]. The incident particle produces, as a consequence of its interaction with ions of the semiconductor lattice, cascades of displacements.

In silicon, vacancies and interstitials are essentially unstable and interact via migration, recombination, and annihilation or produce other defects.

The concentration of primary defects represents the starting point for the following step of the model, the consideration of the annealing processes, treated in the frame of the chemical rate theory. A review of previous works about the problem of the annealing of radiation induced defects in silicon can be found, e.g. in Reference [7].

Without free parameters, the model is able to predict the absolute values of the concentrations of defects and their time evolution toward stable defects, starting from the primary incident particle characterised by type and kinetic energy.

The first two steps have been treated extensively in previous papers [4, 5, 6], where the concentration of primary defects has been calculated. In this paper, the third step is discussed extensively and represents a generalisation of the previous results published in references [7, 8] including also the carbon contributions to defect kinetics.

The influence and the effects of different initial impurity concentrations of phosphorus, oxygen and carbon as well as of the irradiation conditions were systematically studied. Vacancy-interstitial annihilation, interstitial migration to sinks, vacancy - impurity complexes ( $VP$ ,  $V_2$ ,  $VO$ ,  $V_2O$ ,  $C_iO_i$ ,  $C_iC_s$ ) - only the stable defects confirmed experimentally in silicon for high energy physics applications were considered. The correlation between the rate of defect productions, the temperature and the time evolution of the defect concentrations was also investigated. Some conclusions about the possibilities to obtain semiconductor materials harder to radiation are given.

## 2 Production of primary defects

The basic assumption of the present model is that the primary defects, vacancies and interstitials, are produced in equal quantities and are uniformly distributed in the material bulk. They are produced by the incoming particle, as a consequence of the subsequent collisions of the primary recoil in the lattice, or thermally (only

Frenkel pairs are considered). The generation term  $G$  is the sum of two components:

$$G = G_R + G_T \quad (1)$$

where  $G_R$  accounts for the generation by irradiation, and  $G_T$  for thermal generation. The concentration of the primary radiation induced defects per unit fluence  $CPD$  in silicon has been calculated as the sum of the concentration of defects resulting from all interaction processes, and all characteristic mechanisms corresponding to each interaction process, using the explicit formula (see details, e.g. in references [9, 10]):

$$CPD(E) = \frac{N_{Si}}{2E_{Si}} \int \sum_i \left( \frac{d\sigma}{d\Omega} \right)_{i,Si} L(E_{Ri})_{Si} d\Omega = \frac{1}{N_A} \frac{N_{Si} A_{Si}}{2E_{Si}} NIEL(E) \quad (2)$$

where  $E$  is the kinetic energy of the incident particle,  $N_{Si}$  is the atomic density in silicon,  $A_{Si}$  is the silicon atomic number,  $E_{Si}$  - the average threshold energy for displacements in the semiconductor,  $E_{Ri}$  - the recoil energy of the residual nucleus produced in interaction  $i$ ,  $L(E_{Ri})$  - the Lindhard factor that describes the partition of the recoil energy between ionisation and displacements and  $(d\sigma/d\Omega)_i$  - the differential cross section of the interaction between the incident particle and the nucleus of the lattice for the process or mechanism  $i$ , responsible in defect production.  $N_A$  is Avogadro's number. The formula gives also the relation with the non ionising energy loss ( $NIEL$ ) the rate of energy loss by displacement  $(dE/dx)_{ni}$  [3, 11].

In Figure 1, the kinetic energy dependence of  $CPD$  for different particles is presented: for pions the values are calculated in accord with equation (1) and are from reference [12], and for the other particles these are evaluated from the published  $NIEL$  calculations, as follows: for protons - reference [6, 13], for neutrons - reference [14], for electrons - reference [6, 13] and for photons from [6]. The main source of errors in the calculated concentration of primary defects comes from the modelling of the particle - nucleus interaction and from the number and quality of the experimental data available for these processes.

Due to the important weight of annealing processes, as well as to their very short time scale,  $CPD$  is not a measurable physical quantity. In silicon, vacancies and interstitials are essentially unstable and interact via migration, recombination, and annihilation or produce other defects. In the simplifying hypothesis of random distribution of  $CPD$  for all particles, used in the present paper, the identity of the particle is lost after the primary interaction, and two different particles could produce the same generation rate ( $G_R$ ) for vacancy-interstitial pairs if the following condition:

$$G_R = [(CPD)_{part.a}(E_1)] \cdot \Phi_{part.a}(E_1) = [(CPD)_{part.b}(E_2)] \cdot \Phi_{part.2}(E_2) \quad (3)$$

is fulfilled. Here,  $\Phi$  is the flux of particles ( $a$ ) and ( $b$ ) respectively, and  $E_1$  and  $E_2$  their corresponding kinetic energies.

### 3 The kinetics of radiation induced defects

Silicon used in high energy physics detectors is n-type high resistivity ( $4 \div 6 \text{ K}\Omega \text{ cm}$ ) phosphorus doped FZ material.

The effect of oxygen in irradiated silicon has been a subject of intensive studies in remote past. In the last decade a lot of studies have been performed to investigate the influence of different impurities, especially oxygen and carbon, as possible ways to enhance the radiation hardness of silicon for detectors in the future generation

Figure 1: Energy dependence of the concentration of primary defects on unit fluence induced by protons, pions, electrons, photons and neutrons in silicon - see text for details.

of experiments in high energy physics - see, e.g. references [15, 16]. Some people consider that these impurities added to the silicon bulk modify the formation of electrically active defects, thus controlling the macroscopic device parameters. Empirically, it is considered that if the silicon is enriched in oxygen, the capture of radiation-generated vacancies is favoured by the production of the pseudo-acceptor complex vacancy-oxygen. Interstitial oxygen acts as a sink for vacancies, thus reducing the probability of formation of the divacancy related complexes, associated with deeper levels inside the gap.

The concentrations of interstitial oxygen  $O_i$  and substitutional carbon  $C_i$  in silicon are strongly dependent on the growth technique. In high purity Float Zone Si, oxygen interstitial concentrations are around  $10^{15} \text{ cm}^{-3}$ , while in Czochralski Si these concentrations can reach values as high as  $10^{18} \text{ cm}^{-3}$ . Because Czochralski silicon is not available in detector grade quality, an oxygenation technique developed at BNL produces Diffusion Oxygenated Float Zone in silicon, obtaining a  $O_i$  concentration of the order  $5 \times 10^{17} \text{ cm}^{-3}$ . These materials can be enriched in substitutional carbon up to  $1.8 \times 10^{16} \text{ cm}^{-3}$ .

After the irradiation of silicon, the following stable defects have been identified (see References [3, 17]):  $S_i$ ,  $VP$ ,  $VO$ ,  $V_2$ ,  $V_2O$ ,  $C_iO_i$ ,  $C_i$ ,  $C_iC_s$ . The pre-existing thermal defects and those produced by irradiation, as well as the impurities, are assumed to be randomly distributed in the solid. An important part of the vacancies and interstitials annihilate. The sample contains certain concentrations of impurities, which can trap interstitials and vacancies respectively, and form stable defects.

Vacancy-interstitial annihilation, interstitial migration to sinks, divacancy, vacancy and interstitial impurity complex formation are considered. The role of phos-

phorus, oxygen and carbon is taken into account, and the following stable defects :  $VP$ ,  $VO$ ,  $V_2$ ,  $V_2O$ ,  $C_iO_i$ ,  $C_i$ ,  $C_iC_s$  are considered. Other possible defects as  $V_3O$ ,  $V_2O_2$ ,  $V_3O_3$  [18], are not included in the present model.

The following picture describes in terms of chemical reactions the mechanisms of production and evolution of the defects considered in the present paper:

$VO$  is the  $A$  centre.

$VP$  is the  $E$  centre.

Some considerations about the determination of the reaction constants are given in references [7, 8].

The reaction constants  $K_i$  ( $i = 1, 3 \div 9$ ) have the general form:

$$K_i = C\nu \exp(-E_i/k_B T) \quad (14)$$

with  $\nu$  the vibration frequency of the lattice,  $E_i$  the associated activation energy and  $C$  a numerical constant that accounts for the symmetry of the defect in the lattice.

The reaction constant related to the migration of interstitials to sinks could be expressed as:

$$K_2 = \alpha\nu\lambda^2 \exp(-E_2/k_B T) \quad (15)$$

with  $\alpha$  the sink concentration and  $\lambda$  the jump distance.

The system of coupled differential equations corresponding to the reaction scheme (4)  $\div$  (13) cannot be solved analytically and a numerical procedure was used.

The following values of the parameters have been used:  $E_1=E_2 = 0.4$  eV,  $E_3 = 0.8$  eV,  $E_4 = 1.4$  eV,  $E_5 = 1.1$  eV,  $E_6 = 1.3$  eV,  $E_7 = 1.6$  eV,  $E_8 = 0.8$  eV,  $E_9 = 1.7$  eV,  $\nu = 10^{13}$  Hz,  $\lambda = 10^{15}$  cm<sup>2</sup>,  $\alpha = 10^{10}$  cm<sup>-2</sup>, in accord with standard constants characterising the silicon material, see for example the books of Lannoo and Bourgoin [3] or Damask and Dienes [19].

## 4 Results, discussion, comparison with experimental data and predictions

The formation and time evolution of stable defects depends on various factors, e.g. the concentrations of impurities pre-existent in the sample, the rate of generation, and the temperature.

In Figures 2 a ÷ f, and 3 a ÷ f the formation and time evolution of the vacancy-oxygen, vacancy-phosphorus, divacancy, divacancy-oxygen, carbon interstitial - oxygen interstitial and carbon interstitial - carbon substitutional are modelled in silicon containing different initial concentrations of phosphorus, oxygen and carbon, and for two very different rates of generation.

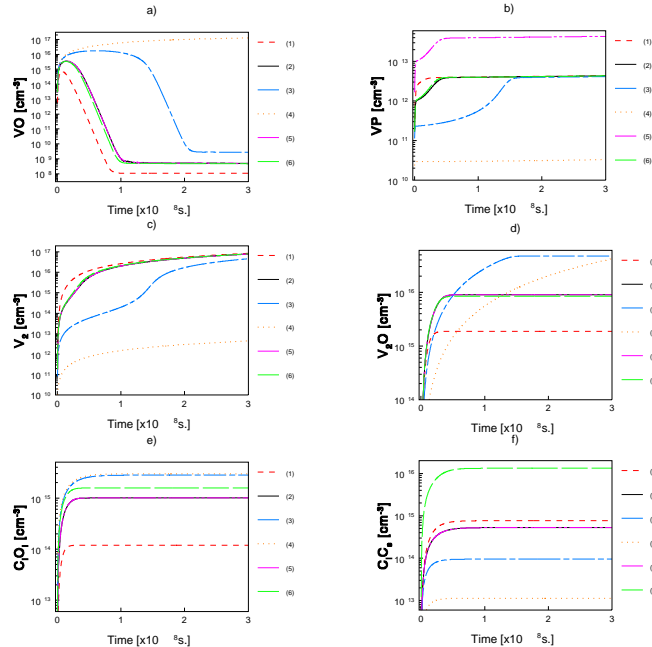

Figure 2: Time dependence of the concentrations of a)  $VO$ , b)  $VP$ , c)  $V_2$ , d)  $V_2O$ , e)  $C_iO_i$  and f)  $C_iC_s$  induced in silicon with the following concentrations of impurities: (1):  $10^{14}$  P/cm<sup>3</sup>,  $2 \times 10^{15}$  O/cm<sup>3</sup>, and  $3 \times 10^{15}$  C/cm<sup>3</sup>; (2):  $10^{14}$  P/cm<sup>3</sup>,  $10^{16}$  O/cm<sup>3</sup>, and  $3 \times 10^{15}$  C/cm<sup>3</sup>; (3):  $10^{14}$  P/cm<sup>3</sup>,  $5 \times 10^{16}$  O/cm<sup>3</sup>, and  $3 \times 10^{15}$  C/cm<sup>3</sup>; (4):  $10^{14}$  P/cm<sup>3</sup>,  $4 \times 10^{17}$  O/cm<sup>3</sup>, and  $3 \times 10^{15}$  C/cm<sup>3</sup>; (5):  $10^{15}$  P/cm<sup>3</sup>,  $10^{16}$  O/cm<sup>3</sup>, and  $3 \times 10^{15}$  C/cm<sup>3</sup> (6):  $10^{14}$  P/cm<sup>3</sup>,  $10^{16}$  O/cm<sup>3</sup>, and  $3 \times 10^{16}$  C/cm<sup>3</sup> by a generation rate  $G_R = 7 \times 10^8$  VI pairs/cm<sup>3</sup>s, at 20°C.

In Figure 2, the evolution of defect concentrations during high rate irradiation ( $G_R = 7 \times 10^8$  VI pairs/cm<sup>3</sup>s) is presented. This corresponds, in the model hypothesis, to order of magnitude of the radiation levels estimated for the forward tracker region at the future LHC accelerator.

The increase of the initial oxygen concentration in silicon, from  $2 \times 10^{15}$  O/cm<sup>3</sup> to  $4 \times 10^{17}$  O/cm<sup>3</sup>, conduces, after ten years of operation in the field characterised by a high and constant generation rate, to the increase of the concentrations of  $VO$  and  $C_iO_i$  centres, and to the decrease of the concentrations of  $V_2$ ,  $VP$  and  $C_iC_s$  ones. With the increase of oxygen concentration, a variation of the  $V_2O$  generation rate is observed, so that, from the studied cases, the maximum concentration for this defect is obtained for  $5 \times 10^{16}$  O/cm<sup>3</sup> initial oxygen. The increase of initial phosphorus is seen in the increase of concentration of  $VP$  centres, while the increase of initial carbon concentration has important consequences on the concentrations of  $C_iC_s$  centres. It is interesting to observe that in almost all cases, an equilibrium is reached between generation and annealing, and a plateau is obtained in the time dependence of the concentrations. The slowest is, in this respect,  $V_2O$ , that has the highest binding energy.

As underlined above, vacancy-oxygen formation in oxygen enriched silicon is favoured in respect to the generation of  $V_2$ ,  $V_2O$  and  $VP$ . This is an important feature that could be used for detector applications, determining the decrease of the leakage current [8]. At high oxygen concentrations, the concentration of  $VO$  centres attains a plateau during the 10 years period considered.

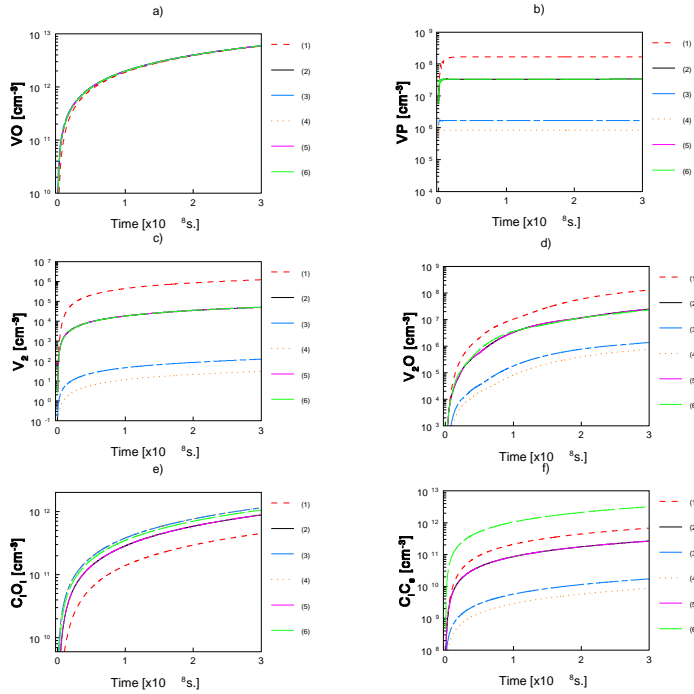

Figure 3: Same as Figure 2,  $G_R = 200$   $VI$  pairs/cm<sup>3</sup>s.

The other extreme situation corresponds to a generation rate  $G_R = 200$  VI pairs/cm<sup>3</sup>s, equivalent with a rate of defect production by protons from the cosmic ray spectra in the orbit near the Earth, at about 400 Km, as will be the position of the International Space Station. The same concentrations of  $P$ ,  $O$  and  $C$  have been considered as pre-existent in silicon as in Figure 2. For this generation rate, the increase of the oxygen concentration produces the decrease of the concentration of all centres, with the exception of the  $VO$  concentration, that, at these rates, it is not influenced by the oxygen content, and of the  $C_iO_i$  concentration, where an increase is observed. As could be seen from Figure 3, as a consequence of the small rate of generation rate of vacancy - interstitial pairs, after ten years of operation the equilibrium between generation and annealing is not reached, the concentrations of defects being, with the exception of  $VP$  (that has a relatively low binding energy), slightly increasing functions of time.

All curves, both from Fig. 2 and Fig. 3, have been calculated for 20°C temperature. Thermal generation has been taken into account in both cases, although it is important only for the silicon exposed to low rates of defect production.

The influence of the generation rate of primary defects on the concentration of stable defects and on their time evolution has also been investigated. In Figure 4 a ÷ f, the time evolution of the  $VO$ ,  $VP$ ,  $V_2$ ,  $V_2O$ ,  $C_iO_i$  and  $C_iC_s$  concentrations is presented for six decades of generation rates of defects ( $G_R=7 \times 10^5 \div 7 \times 10^{10}$  VI pairs/cm<sup>3</sup>s), for silicon containing the following concentrations of impurities:  $10^{14}$  P/cm<sup>3</sup>,  $10^{16}$  O/cm<sup>3</sup>, and  $3 \times 10^{15}$  C/cm<sup>3</sup> at 20°C temperature. At small times, the curves corresponding to different generation rates are all parallel and equidistant in a log-log representation. Starting from the highest generation rates, they start to increase slower ( $V_2$ ,  $VP$ ), attain a plateau  $V_2O$ , or event start to decrease ( $VO$ ,  $C_iO_i$ ,  $C_iC_s$ ). The maximum attained can be the same, independent on the generation rate as is the case of  $VO$  concentration, or could be generation dependent  $C_iO_i$ ,  $C_iC_s$ .

The temperature is another important factor determining the time evolution of defects. In Figure 5 a ÷ f and 6 a ÷ f, the effect of the temperature is studied for the same generation rates of primary defects as in Figures 2 and 3 respectively, for five temperatures: 20°C, 10°C, 0°C, -10°C, and -20°C. The concentrations of pre-existing impurities in silicon are as follows:  $10^{14}$  P/cm<sup>3</sup>,  $10^{16}$  O/cm<sup>3</sup>, and  $3 \times 10^{15}$  C/cm<sup>3</sup>. The decrease of the temperature decreases the generation rate of stable defects, with the exception of  $VP$ , where the highest values correspond to the lowest temperature. The maximum values of the  $VO$  concentration are temperature independent; the values of the concentration on the plateau decrease with the decrease of temperature for  $C_iO_i$  and  $C_iC_s$  and increase for  $V_2O$ .

For silicon exposed to low rates of defect production the same amount of time (Figure 6), the process of defect production is slowed down. The most unexpected time dependence is for  $V_2$ , that has the highest values at the lowest temperature.

In a previous paper [8], we demonstrated in concrete cases the importance of the sequence of irradiation process, considering that the same total fluence can be attained in different situations: the ideal case of instantaneous irradiation, irradiation in a single pulse followed by relaxation, and respectively continuous irradiation process. As expected, after instantaneous irradiation the concentrations of defects are higher in respect with "gradual" irradiation.

After this analysis, the specific importance of the irradiation and annealing history (initial material parameters, type of irradiation particles, energetic source spectra, flux, irradiation temperature, measurement temperature, temperature and time between irradiation and measurement) on defect evolution must be to underline.

The model predictions have been compared with experimental measurements. A difficulty in this comparison is the insufficient information in published papers

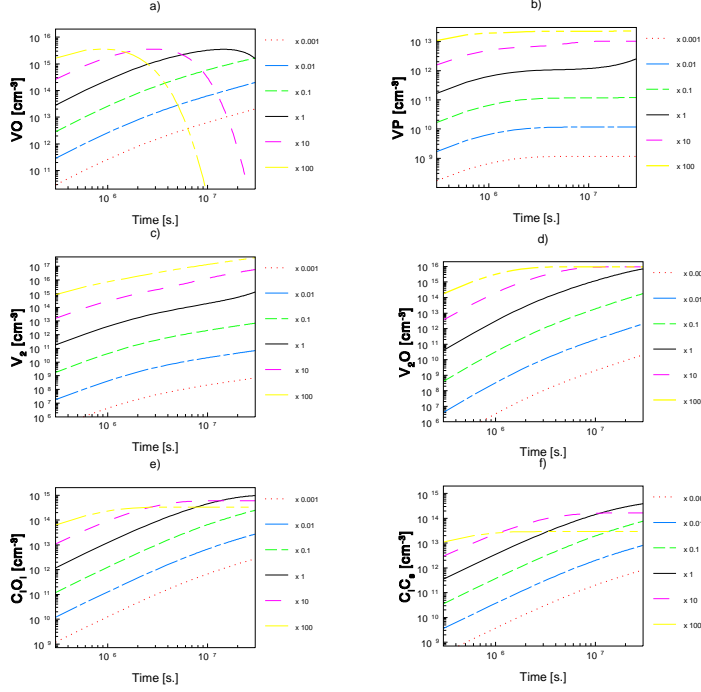

Figure 4: Time dependence of the concentrations of a)  $VO$ , b)  $VP$ , c)  $V_2$ , d)  $V_2O$ , e)  $C_iO_i$  and f)  $C_iC_s$  induced in silicon with:  $10^{14}$  P/cm<sup>3</sup>,  $10^{16}$  O/cm<sup>3</sup>, and  $3 \times 10^{15}$  C/cm<sup>3</sup> by continuous irradiation.

regarding the characterisation of silicon, and on the irradiation parameters and conditions for most of the data.

It was underlined in the literature [20] that the ratio of  $VO$  to  $VP$  centres in electron irradiated silicon is proportional to the ratio between the concentrations of oxygen and phosphorus in the sample. For electron irradiation, in Ref. [21] a linear dependence of the  $V_2$  versus  $VO$  centre concentration has been found experimentally. In the present paper, the ratio of concentrations of  $V_2$  to  $VO$  centres and  $VO$  to  $VP$  ones has been calculated in the frame of the model, for the material with the characteristics specified in Ref. [21], and irradiated with 12 MeV electrons, in the conditions of the above mentioned article. The time dependence of these two ratios is represented in Figure 7. Annealing is considered both during and after irradiation. It could be seen that for the ratio of  $V_2$  and  $VO$  concentrations the curves corresponding to different irradiation fluences are parallel, while the ratio of  $VO$  to  $VP$  concentrations is fluence independent, in the interval  $2 \times 10^{13} \div 5.5 \times 10^{14}$  cm<sup>-2</sup>, in good agreement with the experimental evidence. The ratio between  $V_2$  and  $VO$  concentrations is determined by the generation of primary defects by irradiation, while the ratio between  $VO$  and  $VP$  concentrations is determined by the

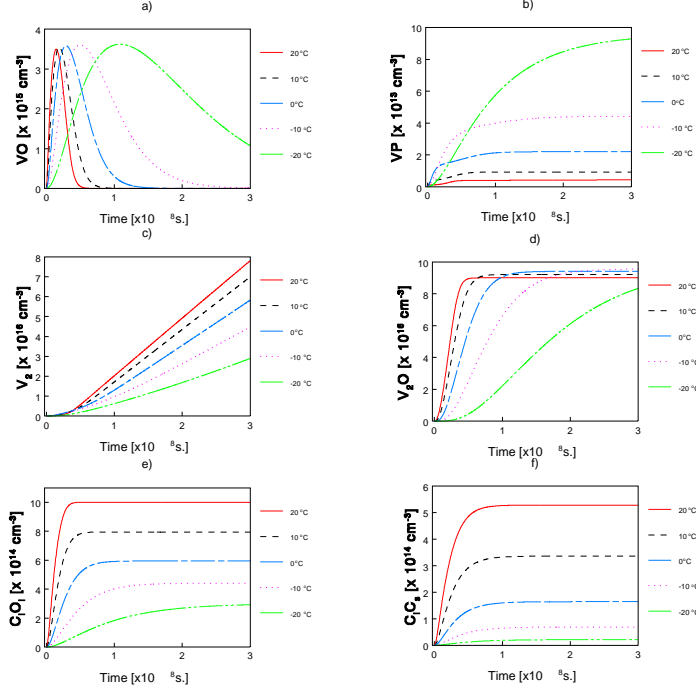

Figure 5: Time dependence of the concentrations of a)  $VO$ , b)  $VP$ , c)  $V_2$ , d)  $V_2O$ , e)  $C_iO_i$  and f)  $C_iC_s$  induced in silicon with:  $10^{14}$  P/cm<sup>3</sup>,  $10^{16}$  O/cm<sup>3</sup>, and  $3 \times 10^{15}$  C/cm<sup>3</sup> by continuous irradiation, in the same conditions as in Figure 2, at 20°C, 10°C, 0°C, -10°C, and -20°C.

concentrations of oxygen and phosphorus in silicon.

Our estimations are also in agreement with the measurements presented in reference [22], after electron irradiation, where defect concentrations are presented as a function of the time after irradiation. In Figure 8, both measured and calculated dependencies of the  $VO$  and  $VP$  concentrations are given. The irradiation was performed with 2.5 MeV electrons, up to a fluence of  $3 \times 10^{16}$  e/cm<sup>2</sup>. A good agreement can be observed for these concentrations. The dependencies put in evidence the important role played by the carbon-related defects. The relative values are imposed by the arbitrary units of experimental data.

Also, a good agreement has been obtained between the absolute values of concentrations of  $VP + V_2$  and  $C_iC_s$  predicted by the model, and the experimental results after neutron irradiation at a total fluence of  $5.67 \times 10^{13}$  cm<sup>-2</sup>, reported in reference [23]. The calculated  $1.5 \times 10^{13}$  cm<sup>-3</sup> and  $4.1 \times 10^{12}$  cm<sup>-3</sup> concentrations for  $VP + V_2$  and  $C_iC_s$  respectively, are in accord with the values of  $1.1 \times 10^{13}$  cm<sup>-3</sup> and  $3.8 \times 10^{12}$  cm<sup>-3</sup>, measured experimentally. For the  $VO$  concentration, a poorer concordance has been obtained.

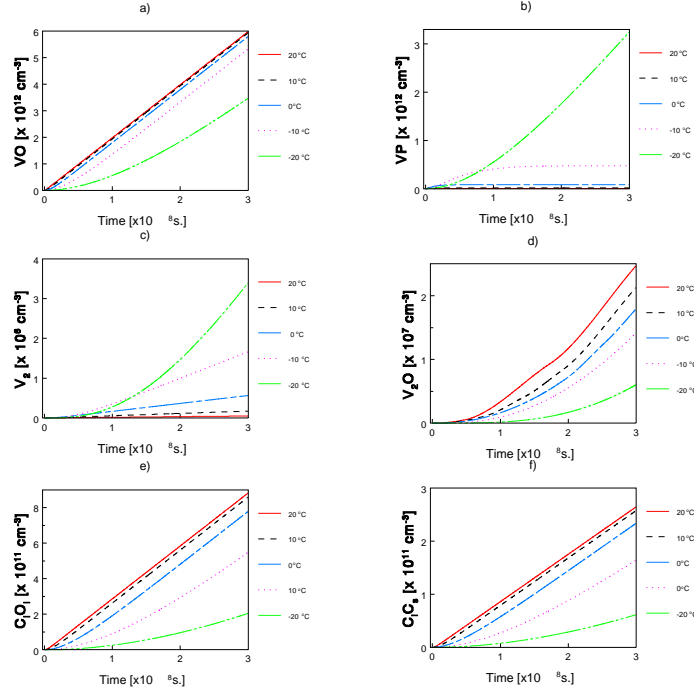

Figure 6: Time dependence of the concentrations of a)  $VO$ , b)  $VP$ , c)  $V_2$ , d)  $V_2O$ , e)  $C_iO_i$  and f)  $C_iC_s$  induced in silicon with:  $10^{14}$  P/cm<sup>3</sup>,  $10^{16}$  O/cm<sup>3</sup>, and  $3 \times 10^{15}$  C/cm<sup>3</sup> by continuous irradiation, in the same conditions as in Figure 3, at 20°C, 10°C, 0°C, -10°C, and -20°C.

## 5 Summary

A phenomenological model that describes silicon degradation due to irradiation from the point of view of the kinetics of produced defects toward equilibrium was developed.

The production of primary defects (vacancies and interstitials) in the silicon bulk was considered in the frame of the Lindhard theory, and the peculiarities of the particle - silicon nuclei interaction were taken into account.

The mechanisms of formation of stable defects and their evolution toward equilibrium was modelled, and the concentrations of defects were calculated solving numerically the system of coupled differential equations for these processes. Vacancy-interstitial annihilation, interstitial migration to sinks, vacancy-impurities complexes ( $VP$ ,  $VO$ ,  $V_2O$ ,  $C_iO_i$ ,  $C_iC_s$ ), and divacancy formation were considered in different irradiation conditions, for different concentrations of impurities in the initial semiconductor, in the temperature range  $-20 \div +20^\circ C$ .

The calculated results suggest the importance of the conditions of irradiation,

Figure 7: Time dependence for a)  $V_2/VO$  and b)  $VO/VP$  concentrations calculated for silicon with  $1.4 \times 10^{14}$  P/cm<sup>3</sup>,  $5 \times 10^{17}$  O/cm<sup>3</sup>, and  $3 \times 10^{15}$  C/cm<sup>3</sup> by 12 MeV electron irradiation, with the flux  $5.8 \times 10^{10}$  e/cm<sup>2</sup>s, up to the fluences:  $2 \times 10^{13}$  e/cm<sup>2</sup>,  $4 \times 10^{13}$  e/cm<sup>2</sup>,  $8 \times 10^{13}$  e/cm<sup>2</sup>,  $2 \times 10^{14}$  e/cm<sup>2</sup> and  $5.5 \times 10^{14}$  e/cm<sup>2</sup>, followed by relaxation (see reference [21]).

temperature and annealing history.

The model supports the experimental studies performed to investigate the influence of oxygen in the enhancement of the radiation hardness of silicon for detectors. The  $VO$  defects in oxygen enriched silicon are favoured in respect to the other stable defects, so, for detector applications it is expected that the leakage current decreases after irradiation. At high oxygen concentrations, this defect saturates starting from low fluences at high generation rates of defects.
