Abstract

Scintillation produced in liquid xenon by alpha particles and gamma rays has been studied as a function of applied electric field. For back scattered gamma rays with energy of about 200 keV, the number of scintillation photons was found to decrease by $64\pm2\%$ with increasing field strength. Consequently, the pulse shape discrimination power between alpha particles and gamma rays is found to reduce with increasing field, but remaining non-zero at higher fields.

1 Introduction

There is much recent interest in xenon as a target for Weakly Interacting Massive Particle (WIMP) detectors. It has a high atomic mass of 131 amu, good for maximising the energy deposition from a WIMP collision. This is due to a close match between the nuclear mass and the most favoured WIMP mass according to SUSY models. Xenon is a scintillator, giving $\sim 52 \times 10^3$ photons/MeV for recoiling electrons in our energy range of interest [1,2]. The

emitted photons are VUV, from an emission band centred at 176.7 nm [3], which can be detected with photomultiplier tubes.

The observed scintillation pulse shape has a fast rise (\sim few ns) followed by an exponential-like decay. The decay time is indicative of the incident particle, allowing discrimination between gamma rays, alpha particles and nuclear recoils [4,5]. This property is exploited by ZEPLIN I [6], the Boulby Dark Matter Collaboration's liquid xenon dark matter detector. The scintillation pulse shape is used to differentiate between background gamma rays and recoiling nuclei produced by scattering WIMPs.

The next generation of xenon dark matter detectors are two-phase systems; ZEPLINs II [7] and III [8]. Such detectors measure both scintillation and ionisation produced by interacting particles separately. They comprise a liquid xenon target and gaseous xenon layer. An applied electric field removes electrons from the primary interaction site and extracts them into the gas phase. Whilst crossing the gas layer, the electrons have sufficient kinetic energy to excite the xenon gas atoms producing electroluminescence. VUV signals are produced by both the primary scintillation and the subsequent secondary electroluminescence. In a uniform electric field, the electroluminescence signal is directly proportional to the number of electrons removed from the interaction site. The ratio of primary to secondary signal sizes is used as a discrimination tool for the two-phase system.

This work presents a study of the scintillation signal, produced by alpha particles from an ²⁴¹Am source and gamma rays from a ⁶⁰Co source, as a function of applied electric field.

The VUV scintillation signal from liquid xenon is produced by the de-excitation to ground of the two lowest excited molecular states; $^1\Sigma^+_u$ and $^3\Sigma^+_u$. These states can be produced initially through excitation, or via recombination [4]. The lifetimes of these states are found to be 4.3 ± 0.6 ns and 22.0 ± 2.0 ns for alpha particles [9] and 2.2 ± 0.3 ns and 27 ± 1 ns for recoiling electrons [4]. In addition, there is a long recombination time of ~ 15 ns for recoiling electrons [4]. These effects are convoluted into a pulse shape that can be approximated as a single exponential decay. This is particularly true with low numbers of photons where the Poisson width blurs any distinction between the respective components. In this work, the overall decay profile for recoiling electrons has a measured mean time constant of 48.4 ± 0.2 ns compared to 15.0 ± 0.2 ns for alpha particles.

Under an electric field, the gamma ray induced (or recoiling electron) pulse shape and area changes. This is due to the removal of electrons from the interaction site, suppressing the recombination component of the scintillation [10]. Understanding the behaviour of gamma ray signals under an electric field is

vital to two-phase xenon detectors in order to calibrate the energy scale, and estimate background contributions etc. To predict the primary and secondary signal sizes the number of electrons removed from a gamma ray interaction as a function of energy deposit and electric field strength is needed. For charge measurements, a linear relationship is observed between the inverse of the charge extraction and the inverse of the electric field [11,12]. Using this functional form, the proportion of scintillation lost (or charge gained) can be found for an infinite electric field. In the work presented here, recombination is found to be responsible for 64 ± 2 % of the total scintillation signal for gamma rays. Normalising by this quantity allows direct comparison between previous charge measurements. The proportion of the recombination component removed by the electric field, $N_e(\infty)$, is defined as 1 at an infinite electric field. The behaviour of the quantity (N_e) versus electric field (E) is dependent on the deposited gamma ray energy (E_{γ}) . Charge measurement data of Voronova [13], with gamma ray energies of 15.3, 17.3, 21.4 and 662 keV, show this dependence. It is possible to parametrise their data as follows [14]:

$$\frac{1}{N_e} = \left(\frac{30.07}{E_{\gamma}} + 0.40\right) \frac{1}{E} + 1,\tag{1}$$

where E_{γ} is the energy of the incident gamma ray in keV and E is the electric field strength in kV/cm.

The gamma ray recombination component is suppressed by an applied electric field, causing the overall decay time of the scintillation pulse to reduce. The alpha particles pulse shapes show no discernable change with increasing the electric field strength up to $3.7~\rm kV/cm$. The gamma ray decay profile changes from a time constant of $48.4\pm0.2~\rm ns$ with no electric field to $23.7\pm0.2~\rm ns$ at $3.7~\rm kV/cm$. This change can be used in a diagnostic capacity in two phase detectors since gamma rays interacting in low electric field regions will present longer decay profiles. Such regions can be problematic in a two phase detector as interacting gamma rays may not suffer sufficient charge extraction to produce electroluminesence, or smaller electroluminesence signals may result. Whilst the gamma ray scintillation decay time is reduced by an electric field, under low fields it is still possible to discriminate between gamma rays and nuclear recoils using Pulse Shape Discrimination.

2 Experimental Setup

A prototype two phase liquid xenon dark matter detector was used for these studies, Figure 1. Inside the chamber is a photomultiplier tube immersed in liquid xenon, field shaping rings, two grids, an aluminium mirror (electrode)

Fig. 1. Schematic of the detector showing liquid nitrogen cryostat and the liquid xenon chamber containing the photomultiplier tube and electric field ring structure.

and a fixed ²⁴¹Am internal source. The total xenon mass is 4.5 kg. The sensitive liquid xenon volume is defined by the field rings and for this experiment fills the structure to the mirror (top electrode). The field rings have an internal radius of 3 cm. Figure 2 is a diagram of the sensitive volume of the xenon chamber, showing the electric field rings, top electrode (mirror), high voltage grids and photocathode of photomultiplier tube. The ²⁴¹Am source is fixed to the upper high voltage grid and sits upward facing inside a lead holder. Voltages are applied to the upper high voltage grid (-ve) and mirror (+ve), providing the drift field. The lower grid is kept at a low negative potential (-0.2 kV) primarily to shield the photocathode from the high voltage grid. The photomultiplier tube is quartz windowed (ETL 9829B) with a photocathode quantum efficiency of 23 % at 175 nm [15].

2.1 Xenon Purity

In order to drift electrons for centimetres without loss through xenon requires high purity (parts per trillion): in particular, free of electronegative contaminants such as O₂, N₂O, CO₂ and H₂O. The scintillation is also affected by

Fig. 2. Schematic of the internal structure, showing the electric field rings, top electrode (mirror), grids and face of the photomultiplier tube. The ²⁴¹Am source and holder are shown. The voltage loads are applied as shown on the right-hand side of the diagram.

the presence of impurities (shortening the total attenuation length) but to a lesser extent (parts per billion).

Purification apparatus and procedures have been developed to remove contaminants [16]. All components of the inner chamber were constructed from stainless steel, copper, quartz or high purity ceramic, and designed for ultrahigh vacuum use with residual pumped pressures below 10^{-8} mbar. The xenon was delivered to an Oxisorb cartridge [17] which removes O_2 and H_2O chemically. Xenon was distilled into the detector from a temperature controlled external bottle through a 0.5 μ m dust filter. This distillation procedure separates xenon from other trace impurities left solidified behind, particularly CO_2 , CH_4 and H_2O .

The xenon is kept cold via liquid nitrogen delivered to a cryostat directly above the main chamber. The chamber temperature is monitored at various locations, and with the use of heaters and a restrictive coupling the liquid temperature is actively maintained at -97°C.

The purity of the xenon is assessed via the measurement of the free electron lifetime. To do this, potential differences are applied between the high voltage grid and top electrode causing free electrons released by background gamma and cosmic ray interactions and alphas from the internal 241 Am source to drift towards the mirror. The electron drift is quantified with a calibrated charge sensitive amplifier (Amptek A250) connected to the top electrode (mirror). The outputed voltage is recorded as a function of time, triggered by the primary scintillation signal. The longest drift times are found to be in excess of $60~\mu s$ across a 21.75 mm drift path [16], indicating a very high purity, without any measurable loss of charge even at fields below 10~V/cm.

2.2 Applied Electric Field

The electric field is produced by applying negative voltages to the upper high voltage grid and positive voltages to the top electrode. The total potential difference between the upper high voltage grid and top electrode ranged from 0 to 8 kV. The corresponding electric field distribution was modelled using the finite element analysis code, ANSYS [18].

3 Calibration

The calibration was made with no applied electric field. Initially the scintillation spectrum from the internal source was measured. The 241 Am source is coated, producing alpha particles with a broad energy distribution peaking at 3.9 MeV. As the source is mounted in a lead source holder, the scintillation light produced by the alpha particles has no direct path to the phototube (maximum shadowing). Only light reflected by the mirror is seen. The peak of the alpha distribution contains ~ 1900 photoelectrons as shown in Figure 3 (upper spectrum). The resulting spectrum produced by a GEANT 4 [19] simulation of the full detector and 241 Am source is also shown (lower spectrum).

The 241 Am source produces 60 keV gamma and X-rays, resulting in a peak at ~ 180 photoelectrons. The low energy spectrum is shown in Figure 4 with the corresponding simulated spectrum. The 60 keV gamma rays are seen as 3 peaks; the uppermost (~ 180 photoelectrons) giving direct light to the phototube from gamma rays passing sideways through the lead source holder, the lowermost (~ 20 photoelectrons) from gamma rays emitted upwards being maximally shadowed by the source holder, and the intermediary structure resulting from partial shadowing and multiple interactions. Below these three peaks, lower energy gamma rays from 241 Am (maximally shadowed) merge to form the rest of the low energy spectrum.

The upper 60 keV line results from events occuring less than 3 mm from the 241 Am source, with most interactions occuring at a distance of 1 mm. These scintillation signals with no applied electric field, give a measured yield of 3 photoelectrons per keV. These interactions occur in the most efficient light collection region in the chamber, with the rest of the chamber being a factor 2.3 ± 0.3 less efficient. The spectra were energy calibrated assuming 1.5 photoelectrons per keV.

Figure 5 is a spectrum from an external ⁶⁰Co source after subtraction of the background spectrum from the internal source (Figure 3). Due to the amount of liquid xenon surrounding the sensitive region, the spectrum displays only

Fig. 3. Pulse Height spectrum of internal 241 Am source (upper plot) and GEANT 4 simulated spectrum (lower plot). The alpha distribution is broad and peaks at \sim 1900 photoelectrons. The 60 keV gamma peak is found at \sim 180 photoelectrons.

one clear feature: a broad peak from gamma rays scattering at large angles in the external xenon volume and depositing ~ 212 keV in the internal xenon volume. This feature was replicated in the simulation (lower plot).

4 Pulse Height Spectra Analysis

For each applied potential difference, pulse height spectra were recorded, both with and without the 60 Co source. The background spectra (without the 60 Co source) is predominantly from the internal 214 Am souce, see Figure 3. The background spectra were subtracted from the source spectra to give the 60 Co spectra. The position of the peak in each 60 Co spectrum was determined. With the application of an electric field, the position of the peak moved to lower channels as a result of the scintillation signal area decreasing. Figure 6 shows the fraction of the scintillation signal removed (S) as a function of the applied electric field (E). A straight line fit to the inverse of this quantity $(\frac{1}{S})$, and the inverse of the electric field $(\frac{1}{E})$ was made, resulting in:

$$\frac{1}{S} = (0.8 \pm 0.1) \frac{1}{E} + (1.56 \pm 0.06). \tag{2}$$

For an infinite electric field the percentage of signal removed by the electric field is equal to the inverse of the intercept, 64 ± 2 %. Work by Kubota, with 207 Bi conversion electrons of energies 0.976 and 1.05 MeV, found a reduction

Fig. 4. Pulse Height spectrum of internal 241 Am source (upper plot) and GEANT 4 simulation spectrum (lower plot). The 60 keV gamma rays from the 241 Am source result in 3 peaks. The uppermost peak is from gamma rays penetrating the sides of the source holder giving direct light to the phototube. The lower peak (at ~ 20 photoelectrons) is from 60 keV gammas maximally shadowed by the source. The intermediary structure is from partial shadowing of the direct light and multiple interactions.

Fig. 5. Pulse Height spectrum of external 60 Co source (background subtracted). The lower plot is a GEANT 4 simulated spectrum. The broad peak at ~ 200 keV is from gamma rays scattered at large angles into the sensitive xenon volume, and comprises ~ 300 photoelectrons.

Fig. 6. Fraction of the gamma ray scintillation signal removed as a function of the electric field. The dashed line is a line of best fit (Equation 2 rearranged).

Fig. 7. Fraction of charge extracted as a function of applied electric field. The inner error bar represents statistical errors only. The outer error bars represent total errors including systematic errors. The dashed line is the line of best fit to the data (from Equation 2). The dotted lines are from Equation 1, assuming a gamma ray energy of 200 keV (lower curve) and 1 MeV (upper curve).

fraction of 0.74 ± 0.02 [12] at 12.7 kV/cm, significantly greater than found in this work. This suggests a variation in the mean electron creation energy W_e with recoiling electron energy.

The corresponding fraction of charge extracted as a function of the electric field is shown in Figure 7. Also shown are two trends from Equation 2. The lower dotted curve is for a gamma ray energy of 200 keV, and the upper curve is for an energy of 1 MeV. The line of best fit to the data lies at slightly higher energies than the 200 keV trend. The energies deposited by the large angle scatters peak at 212 keV, resulting in a faster increase in charge removal with increasing electric field strength. For energy deposits greater than 1 MeV, the trends are far less dependent on the energy deposit and all gamma rays behave in a similar manner; this is the maximal charge removal trend.

5 Scintillation Traces

Scintillation traces were recorded at each applied electric field strength. The photomultiplier voltage output was digitised by a Lecroy 7200 oscilloscope of 1 Gs/s at 500 MHz bandwidth, and recorded by computer with Labview DAQ software. A leading edge trigger provided the lower amplitude threshold of 0.1 V. The upper amplitude threshold was set to 0.9 V through DAQ software selection. As alpha and gamma ray signals have different pulse shapes the amplitude threshold settings select different energy ranges for alphas than for gamma rays. For gamma rays, the recorded event energies were between approximately 100 keV and 1 MeV with no applied electric field. Alpha events from the internal ²⁴¹Am source have visible energies of between 50 keV and 400 keV. These alpha events are the lower energy tail of the alpha source energy distribution and the threshold settings used do not include the peak of the spectrum (see Figure 3). The recorded traces were analysed through software, returning maximum amplitudes (pulse amplitudes in V) and pulse areas (in nVs). A characteristic time parameter, known as the time-constant, was defined as the ratio of the pulse area to amplitude (units of ns). Figure 8 shows this quantity for the condition of no applied electric field (solid) and 0.05 kV/cm (dashed).

The data are clearly divided into alpha and gamma ray populations, based upon the measured area to amplitude ratios. Events with time-constants less than 22 ns were deemed alphas, events with ratios greater than this were identified as gamma rays. Figure 8 illustrates the effect of the electric field on the gamma ray scintillation pulse shape, reducing the time-constant. At each electric field value the mean time-constant was determined for alpha particles and gamma rays, see Figure 9.

A Monte Carlo simulation was used to investigate the behaviour of measured time-constant with number of photoelectrons detected. A parent exponential time-constant was chosen to mimic the behaviour of gamma rays under no electric field (47 ns), for alphas a shorter time-constant was chosen (15 ns).

Fig. 8. Histograms of the ratio of pulse area to amplitude. The solid line represents the condition of no applied electric field, and the dashed line is for an electric field of 0.05 kV/cm. The alpha signals have a ratio of \sim 15 ns, and display no discernable change with electric field. The gamma ray signals have area to amplitude ratios greater than \sim 22 ns, which reduce with increasing electric field.

Fig. 9. Variation of pulse area to amplitude ratio with applied electric field for source alphas and gammas from an external $^{60}\mathrm{Co}$ source. The alphas (lower points) show no change with increasing electric field. The gamma rays (upper points) decrease rapidly with increasing electric field from 46.1 ± 0.1 ns with no electric field to 22.6 ± 0.1 ns at $3.7~\mathrm{kV/cm}$.

Exponential random deviates were generated, simulating the emission time of scintillation photons. All emitted photons are assumed to strike the photocathode of the photomultiplier tube, and an output voltage trace is produced. The photomultiplier simulation included the quantum efficiency of the tube, single photoelectron temporal profile, and jitter. The dynode resistor chain, and applied voltage were also implemented to give a realistic single photoelectron spectrum. The simulated voltage traces were analysed, returning pulse areas and amplitudes. The data were binned by pulse area and for each bin the mean and standard deviation of the pulse area to amplitude ratios was found. The simulated data were then compared to experimental data, as shown in Figure 10. The simulations can be made to match the experimental data well by adjusting the the parent exponential time-constant. In this figure the simulations are slightly offset from the experimental data. Simulations were also made to represent gamma rays under various electric fields by changing the parent time-constant.

Fig. 10. Comparison between the simulated dataset (denoted by crosses) and binned experimental data (points with error bars). On the left the mean area to amplitude ratio is shown. On the right the standard deviation of the area to amplitude ratio is plotted. The dashed lines represent the effect of lower amplitude threshold on the experimental dataset, pulses with amplitudes smaller than this threshold are not recorded.

The affect of the 22 ns time-constant cut applied to the real datasets was explored by applying the same cut on the simulated dataset. The probability of correctly identifying alphas (with time-constants less than 22 ns) and gamma rays (with time-constants greater than 22 ns) can be assessed. Figure 11 shows the identification probabilities determined by simulation as a function of number of photoelectrons, for the case of greatest applied electric field. The alpha

Fig. 11. The probability of correctly identifying populations using a 22 ns time-constant cut on simulated datasets.

particles are well identified with this cut for all photoelectrons. The alpha identification probability falls with decreasing number of photoelectrons as the standard deviation of the time-constant distribution increases (see right-hand plot, Figure 10). Below a hundred photoelectrons, the probability increases as the mean of the time-constant distribution falls (see left-hand plot, Figure 10) overriding the effect of the increasing standard deviation. For gamma rays, the identification probability falls with number of photoelectrons, due to both the mean and standard deviation of the time-constant distribution falling and rising respectively. For a gamma ray signal comprising 1000 photoelectrons the probability of correctly identifying the signal is 0.96 ± 0.01 . Equivalently for an alpha signal the probability is greater than 0.999. For the experimental datasets (with large numbers of photoelectrons) this time-constant cut was good and should not have biassed the results, even under high electric field strengths. However, using this cut on signals with low numbers of photoelectrons would have resulted in misidentifying many gamma rays as alpha particles. To achieve the most success in separating gamma rays from alpha particles, the time-constant cut should vary with number of photoelectrons and be set according to one of three conditions; to either accept fewer alphas (and reject gammas with high efficiency), to accept fewer gammas (and reject alphas with high efficiency), or to some intermediary state in which the majority of one population are accepted but with a significant contamination of the other population. As an example, with 100 photoelectors and a 22 ns cut

the probability of identifying a gamma ray has a low efficiency (~ 0.5) but the probability of an alpha particle contaminating the sample is unlikely (less than 0.02). In this case, the gamma rays are identified with a low efficiency but alpha particles are highly discriminated.

6 Conclusion

Pulse height spectra produced by an external ⁶⁰Co source and the internal ²⁴¹Am source were compared to GEANT 4 [19] simulations. The features of both spectra are well reproduced. For the majority of this sensitive volume the yield is estimated to be 1.5 photoelectrons per keV (under the condition of no applied electric field).

The variation of scintillation pulse area from $^{60}\mathrm{Co}$ gamma rays was investigated as a function of electric field, using the large-angle scatter peak. The scintillation pulse areas decrease as the applied electric field increases. For a 212 keV gamma ray, 64 ± 2 % of the scintillation is found to be produced via recombination.

The temporal profile of the scintillation signal was investigated for incident alpha particles and gamma rays with increasing electric field. No significant change with electric field was observed for alpha particles. Gamma ray signals, however, become faster with low electric field strengths from 46.1 ± 0.1 ns with no electric field to 25.2 ± 0.1 ns at 0.5 kV/cm. Increasing the electric field strength further reduces the time-constant to 22.6 ± 0.1 ns at 3.7 kV/cm. The behaviour of the derived time-constant with numbers of photoelectrons detected was investigated with simulation and compared to experimental data. The behaviour of measured time-constants from alphas and gammas (at all fields) can be reproduced using only one parameter, the parent time-constant.

From this work, the scintillation signal (both in size and shape) produced by any energy deposit from an alpha particle or gamma ray in liquid xenon can be predicted. The number of electrons extracted from a gamma ray interaction under any strength electric field can also be predicted, aiding simulations of the response of two-phase xenon detectors to gamma ray interactions.
