Assembly and measurements of the Electromagnetic Calorimeter components for "WASA at COSY" setup

Benedykt Jany

Master Thesis prepared at the Nuclear Physics Department Supervisor: Dr. hab. Zbigniew Rudy

 $\mathbf{Cracow} \ 2006$

"Quod scimus, gutta est, ignoramus mare."

Abstract

This work describes the tests of the scintillator electromagnetic calorimeter of the WASA detector setup after transferring it from the CELSIUS storage ring at The Svedberg Laboratory(Uppsala, Sweden) to the Cooler Synchrotron COSY at the Institut für Kernphysik (IKP) of Forschungszentrum Jülich, Germany. The tests were performed using gammas of 4.4MeV energy from an AmBe source. The status of the CsI(Na) crystals was determined and the indication of gain factor for the energy calibration was extracted.

Streszczenie

Ta praca magisterska opisuje testy kalorymetru elektromagnetycznego detektora WASA po jego transferze z akceleratora CELSIUS The Svedberg Laboratory(Uppsala, Szwecja) do Forschungszentrum Jülich Institut für Kernphysik (IKP) Niemcy (akcelerator COSY). Testy zostały przeprowadzone przy użyciu źródła Amerykowo-Berylowego emitującego promienie gamma o energii 4.4 MeV. Kryształy CsI(Na) zostały sprawdzone oraz stałe kalibracyjne zostały wyliczone.

1 Introduction

This work was performed during my stay from November 2005 to April 2006 in the Institut für Kernphysik (IKP) of Forschungszentrum Jülich, Germany as a diploma student of the Jagiellonian University Cracow. It was motivated by the transfer of the WASA[6] detector setup from the CELSIUS storage ring at TSL(Uppsala, Sweden) to the Cooler Synchrotron COSY at IKP [1]. This latter results in an unique scientific opportunities for hadron physics with hadronic probes: COSY with its phase-space cooled proton and deuteron beams covering an energy region up to the ϕ -meson sector is combined with WASA, a close to 4π detector for photons and charged particles. After the transfer to Jülich and prior to installation in the COSY ring - which is scheduled for summer 2006 - all detectors needed to be tested and to be tuned. This thesis deals with the electromagnetic calorimeter of WASA, probably the most important and most crucial part of the whole setup.

The thesis is divided into three main parts. Section 2 describes the advantages of the transfer WASA to Jülich[2], and gives an overview over the WASA detector including the pellet target system. Special attention was put to the central part and particularly to the electromagnetic calorimeter.

Section 3 reveals the physics of electromagnetic interactions of photons and electrons with matter. Basic issues of calorimeter physics are given.

Section 4 describes the performed measurements on the calorimeter. Section 4.1 shows how the data were taken and a description of electronics is presented. The general analysis of the data is introduced in section 4.2. Finally section 4.3 is dealing with the main goal of this thesis, the test of the CsI(Na) calorimeter crystals with 4.4 MeV gamma source. Section 4.4 provides a comparison with energy deposits by cosmic muons in the calorimeter medium, using a Monte-Carlo simulation of the full WASA setup.

A Summary with conclusions are given in section 5 – future implications for the WASA calorimeter are considered.

2 The WASA at COSY Project

The WASA detector setup had been operated since 1998. It has been built with the focus on studying the decays of η -mesons in nuclear reactions. However, in 2003 it has been decided to shut down the CELSIUS ring thus, to stop the operation of WASA at CELSIUS. Shortly after that announcement the idea came up to continue the operation of WASA at COSY. The reasons are obvious: The combination of WASA and COSY would be of advantages for both communities. COSY offers a higher energy than CELSIUS, allowing the extension of the studies into the η' sector. The WASA detector had an electromagnetic calorimeter as a central component and, thus, the ability to detect neutral decay modes involving photons – such a device is missing at COSY. The proposal [2] for moving WASA to COSY was accepted by the COSY PAC in 2004. The WASA detector was dismounted during summer 2005 and shipped to Jülich. The final installation is scheduled for summer 2006.

2.1 Cooler Synchrotron COSY

Figure 1: View at the Cooler Synchrotron COSY.

The Cooler Synchrotron COSY Fig. 1 is located in the IKP of the Forschungszentrum Jülich Germany. It delivers phase-space cooled polarized or unpolarized protons (deuterons) of momentum from p = 300 MeV/c up to p =3700 MeV/c. The ring has a circumference of 184m and can be filled with up to 10^{11} particles. When using the internal cluster target the luminosity of value 10^{31} cm⁻²s⁻¹ can be reached. Two cooling methods are applied during accumulation of the beam to reduce the phase-space volume, electron cooling at injection energies and stochastic cooling. In the electron cooling method an electron beam, moving with the same average velocity as proton beam, absorbs the kinetic energy of protons, whereas stochastic cooling is the process in which the deviations of nominal energy or position of particles in a beam are measured and corrected. The electron cooling system in COSY is applied at injection momentum p = 300 MeV/c and reaches up to p = 600 MeV/c, and the stochastic cooling from p = 1500 MeV/c to 3700 MeV/c. Both, proton and deuteron beams, can be provided unpolarized as well as polarized. At COSY internal and external target positions are in operation Fig. 2. For further details see [8].

Figure 2: The accelerator complex with the cyclotron, the COSY ring and the experimental installations. The place of WASA is within one of the straight sections of COSY. For more details please visit http://www.fz-juelich.de/ikp/cosy.

2.2 The WASA detector

Figure 3: Cross section of the WASA detector as being used at CELSIUS. Beam comes from the left. The Central Detector (CD) build around the interaction point (at the left). The layers of the Forward Detector (FD) are shown on the right. Other symbols (MDC, PSB, FPC, ...) will be explained in text of the thesis.

As mentioned before the **WASA** detector – *Wide Angle Shower Apparatus* Fig. 3, was designed to study various decay modes of the η -meson. This is reflected in the detector setup. The η -mesons are produced in reactions of the type $pp \longrightarrow pp\eta$. Due to the kinematics boost, the two protons are going into the forward direction, while the light decay products of the η are distributed into 4π .

In order to detect the protons, a ϕ -symmetric forward detector for $\theta \leq 18^{\circ}$ is installed. The particles are identified and reconstructed by means of dE measurement and track reconstruction using drift chambers. A trigger, which is set only on the forward detector, can be used to select events independently on the decay mode of the η -meson.

Figure 4: 3D View of the WASA detector[2].

Particles coming from meson decays are e^{\pm} , μ^{\pm} , π^{\pm} and γ , are detected in the central part of WASA ($\theta \geq 20^{\circ}$). Momentum reconstruction is done by tracking in a magnetic field and the energy of the particles is measured using an electromagnetic calorimeter. By including the central detector in the trigger also very rare decay modes can be studied while using a very high luminosity of up to 10^{32} cm⁻²s⁻¹. A 3D view of the detector setup is presented in Fig. 4.

2.2.1 The Pellet Target

The pellet target system Fig. 5 was a special development for WASA. The "pellets" are frozen droplets of hydrogen or deuterium with a diameter between 25μ m and 35μ m. The advantages of using pellet target compared with a standard internal gas target are the following:

- high target density, allows high luminosities necessary for studying rare decays
- thin tube delivery through the detector, 4π detection possible
- very good localized target, small probability of secondary interactions inside the target

The central part of the system is the pellet generator where a stream of liquid gas (hydrogen or deuterium) is broken into droplets by a vibrating

nozzle. The droplets freeze by evaporation into a first vacuum chamber forming a pellet beam. The beam enters a vacuum-injection capillary where it is collimated and is fed through a 2m long pipe into the scattering chamber Fig. 6. An effective beam thickness for hydrogen of 3×10^{15} atoms/cm² has been achieved with a beam diameter 2–4mm, a frequency of pellets 5–10kHz, and an average distance between the pellets of 9 - 20mm.

Figure 5: The Pellet Target system [2].

Figure 6: Photo of generated pellets [7].

2.2.2 The Forward Detector

The Forward Detector (FD) Fig. 3 tags meson production by measuring the energies (dE-E) and angles of forward scattered projectiles and charged recoil particles like protons and deuterons, also neutrons and charged pions. The produced mesons are then reconstructed using the missing mass technique. It covers angles from 3° to 18° . It consists of several layers of detectors described below:

• **FWC** The Forward Window Counters

The FWC is the first detector in the Forward Detector. It consists of 12 plastic scintillators of 5mm thickness. It is used to reduce the background from scattered particles originally from the beam pipe or the exit flange.

• **FPC** The Forward Proportional Chambers The next detector is the FPC. It consists of 4 modules each containing 122 straw tubes detectors. The modules are rotated relatively to each other by 45°. The FPC is used as a precise tracking device.

• **FTH** The Forward Trigger Hodoscope

Close to FPC the FTH ("Jülich Quirl") is installed. It consists of 3 layers of plastic scintillators, one with straight modules, two with bended ones. Each layer has a thickness of 5mm. It is used for a rough determination of the hit position on the higher level and as a starting value for the FPC analysis.

• **FRH** The Forward Range Hodoscope

The kinetic energy of the particles is measured by the FRH. It consists of 4 layers of cake-piece shaped plastic scintillators of 11cm thickness. There are 24 scintillators pro layer. It is also used for particle identification by the dE-E technique.

• **FRI** The Forward Range Interleaving Hodoscope

Between third and forth layer of FRH two layers of plastic scintillators are installed (FRI). Each layer is made of 32 strips of 5.2mm thickness. The FRI is used to determine the scattering angles of neutrons.

• **FVH** The Forward Veto Hodoscope The last layer of FD is FVH. It consists of 12 horizontally oriented scintillator strips with photomultipliers on both sides. The hit position is determined from the time differences of the signals. It is used to identify particles which are not stopped in the FRH.

2.2.3 The Central Detector

The Central Detector (CD) surrounds the interaction point and is constructed to identify energies and angles of the decay products of π^0 and η mesons, with close-to 4π acceptance. It consists of:

• SCS The Superconducting Solenoid

The SCS produces an axial magnetic field necessary for momentum reconstruction using the inner drift chambers. As superconductor NbTi/Cu is used cooled down by liquid He at 4.5K. The maximal central magnetic field is 1.3T. The return path for the field is done by a yoke made of 5 tons of pure iron with low carbon content.

• **MDC** The Mini Drift Chamber

The MDC is build around the beam pipe and it is used for momentum and vertex determination Fig. 7. It consists of 17 layers with in total 1738 straw tubes detectors. It covers scattering angles from 24° to 159° [3]. For the resolution refer to Tab. 1.

particle	$p \; [{\rm MeV/c}]$	resolution $\triangle p/p$
electrons	20 - 600	< 1%
pions, muons	100 - 600	< 4%
protons	200 - 800	< 5%

Table 1:	MDC	resolution
----------	-----	------------

• **PSB** The Plastic Scintillator Barrel

The PSB surrounds the MDC inside the SCS. It consists of 146 8mm thick strips that form a barrel like shape. It is used together with MDC and SEC, and acts as a dE-E and dE-momentum detector and as well as a veto for photons.

• **SEC** The Scintillator Electromagnetic Calorimeter

The SEC is the heart of the WASA detector and maybe the most important part.At CELSIUS it has been used to measure electrons and photons up to 800 MeV. However, using a different setting the energy range can be extended taking into account the higher energy available at COSY. It consists of 1012 CsI(Na) crystals shaped like a truncated pyramids Fig. 8. It covers angles from 20° to 169° and the crystals are placed in 24 layers along the beam Fig. 9. The lengths of the crystals vary from 30cm (central part), 25cm (forward part), 20cm (backward part). The forward part consists of 4 layers each 36 crystals,

Figure 7: MDC and Be pipe. The fully assembled MDC inside Al-Be cylinder (upper left)[3].

covering the range of $20^{\circ} - 36^{\circ}$. The central part consists of 17 layers with 48 elements each, covering the range between $36^{\circ} - 150^{\circ}$, and the backward part with 3 layers, two with 24 crystals and one with 12. The geometrical distribution of the crystals can be seen in Fig. 10 and Fig. 11.

The calorimeter is composed of sodium doped CsI crystals. They are painted with transparent varnish for moisture protection and wrapped in 150μ m teflon and 25μ m aluminized mylar foil [5]. For more information refer to Tab. 2.

The advantages of using this type of material instead of CsI(Tl) are the following:

- emission peak at 420nm (CsI(Tl): 550nm) matches very well the spectral efficiency of the most commonly used PMT's
- the scintillation time is short
- much less afterglow
- much more radiation durability

Figure 8: CsI(Na) crystal fully equipped with light guide, PM tube and housing [5].

2.3 Physics at WASA

The physics program at WASA will investigate symmetries and symmetry breaking as well as hadron structure and interactions. The planned experiments address the following topics: mixing of the scalar mesons $a_0/f_0(980)$, study of hyperon resonances, a_0^+ production, pentaquarks, isospin violation in $\overrightarrow{d} d \longrightarrow \alpha \pi^0$ so it is permeated with newness.

However the most promising and intriguing problems, that maybe at WASA will be clarified, of the whole physics program are **rare and very** rare decays of η and η' mesons. Below I will try to outline the physics behind them.

The η and η' belong to the SU(3) lightest nonet Fig. 12 of the pseudoscalar mesons (0^{-}) [18].

Figure 12: SU(3) nonet of pseudoscalar mesons.

We can write the pure SU(3) states as:

$$\eta_8 = \frac{1}{\sqrt{3}} (u\bar{u} + d\bar{d} + s\bar{s})$$

$$\eta_1 = \frac{1}{\sqrt{6}} (u\bar{u} + d\bar{d} - 2s\bar{s})$$

$$I = 0$$

$$\tilde{\pi}^0 = \frac{1}{\sqrt{2}} (d\bar{d} - u\bar{u})$$

$$I = 1$$

🕱 Jagiellonian University

States with the same quantum numbers can mix so $\tilde{\eta}$ and $\tilde{\eta}'$ are not pure SU(3) states only mixes of the singlet and octet states [10]:

$$\widetilde{\eta} = \cos(\theta_p)\eta_8 - \sin(\theta_p)\eta_1$$
$$\widetilde{\eta}' = \sin(\theta_p)\eta_8 + \cos(\theta_p)\eta_1$$

The mixing angle is rather small $\theta_p = -11.5^{\circ}$ [13] (different experimental approaches lead to different values between -10° and -20°). Mixing like this is allowed by the charge symmetry. But the situation seems not to be so simple, QCD Hamiltonian

$$H_{QCD} = H_{Color} + H_{Coulomb} + \underbrace{m_u u \bar{u} + m_d d \bar{d} + m_s s \bar{s}}_{H_m}$$

except the Color part H_{Color} contains also the Coulomb part $H_{Coulomb}$ and the part with quark masses H_m which mainly leads to non zero probability of transition between two different isospin states, so the transitions between the $\tilde{\eta}, \tilde{\eta}', \tilde{\pi}^0$ are possible. The physical mesons η, η', π^0 are not pure isospin states but only mixtures. Because of the high mass difference between the η and η' the strongest mixing effect would be observed for the pair $\pi^0 - \eta$. Lets now write the real meson states π^0, η :

$$\pi^{0} = \cos(\theta_{\pi\eta})\widetilde{\pi}^{0} - \sin(\theta_{\pi\eta})\widetilde{\eta}$$
$$\eta = \sin(\theta_{\pi\eta})\widetilde{\pi}^{0} + \cos(\theta_{\pi\eta})\widetilde{\eta}$$

where $\theta_{\pi\eta}$ is the mixing angle between $\pi^0 - \eta$. The easiest way to determine the $\theta_{\pi\eta}$ is to measure the ratio of the widths between two decay modes of the η' meson $\Gamma(\eta' \longrightarrow 3\pi)$ (not allowed by isospin symmetry) to $\Gamma(\eta' \longrightarrow \eta 2\pi)$ (allowed by isospin symmetry) Tab. 5:

$$R_1 = \frac{\Gamma(\eta' \longrightarrow \pi^0 \pi^0 \pi^0)}{\Gamma(\eta' \longrightarrow \eta \pi^0 \pi^0)}$$
$$R_2 = \frac{\Gamma(\eta' \longrightarrow \pi^0 \pi^+ \pi^-)}{\Gamma(\eta' \longrightarrow \eta \pi^+ \pi^-)}$$

and then the $\theta_{\pi\eta}$ can be expressed [11]:

$$R_i = P_i \sin^2(\theta_{\pi\eta})$$
$$\sin(\theta_{\pi\eta}) = \frac{\sqrt{3} \triangle m}{4(m_s - \hat{m})}$$

where P_i is the phase-space factor, $\Delta m = m_d - m_u$, $\hat{m} = (m_d + m_u)/2$.

🕅 Jagiellonian University

Not only these four decay modes will be investigated, thanks to the high production rate Tab. 4, WASA opens possibility to study really **very rare** processes Tab. 5. Lots of these reaction will be measured first time in the world. For more details look at [2].

3 Physics of Calorimetry

Calorimeters are devices used to measure energy of electrons, photons and hadrons. In order to do this they are usually build as a block of instrumented material in which the particles are fully absorbed and their energy is transformed to the measureable quantity. The calorimeters could be divided in general into hadronic and electromagnetic calorimeters. Hadronic calorimeters are used to measure hadrons through their strong and electromagnetic interactions. Due to involvement of nucleon (hadronic) interactions the energy deposit is widely spread and the resolution is quite bad (typically 30-50%). Electromagnetic calorimeters are used to measure neergy and position of electrons(positrons) and photons by means of their electromagnetic interactions (bremsstrahlung, pair production) with matter. I will concentrate on the latter ones i.e. the electromagnetic calorimeters. To understand how they work first the electromagnetic interactions will be investigate.

3.1 Some definitions

Figure 13: Energy loss of electrons per radiation length in Pb as a function of energy [13].

Electrons and photons interact with matter over today good understood QED processes, so the description of them is possible using simple empirical approach. There are two main regimes that govern their interactions Fig. 13 shows the fractional energy loss of electrons in lead and Fig. 14 shows photon interaction cross section. As can be seen for energies larger than $\sim 10 \text{MeV}$

Figure 14: Photon interaction cross section in Pb as a function of energy [14].

photons mainly interact by pair production, while electrons lose their energy mostly by bremsstrahlung. For energies > 1GeV these processes become energy independent. In the lower energy regime, for photons compton and photo-electric effect dominate, for electrons however ionization rises, traversing electron or positron in matter undergoes collisions with molecules and atoms. It is considered as a ionization when energy loss per collision is below 0.255MeV. Although other processes also contribute: Bhabha scattering and annihilation of positrons and Möller scattering for electrons. The consequence of this behaviour is that the sufficiently high energetic photons or electrons interact with material producing secondary electrons by pair production and photons by bremsstrahlung. These secondary particles produce again further particles giving rise for an *electromagnetic shower* Fig. 15. This process continues as long as the energy is high enough to produce other particles. The limit is indicated by so called *critical energy* E_c (to be defined later).

The propper scale for the shower process (expansion description) is the radiation length X_0 , usually given in gcm⁻²[13]. That is defined as:

• mean distance over which the electron will lose 1/e of its initial energy by bremsstrahlung

$$\langle E(x) \rangle = E_0 \exp\left[-x/X_0\right],\tag{1}$$

• 7/9 of the mean distance over which the photon beam will lose 1/e of its intensity

$$\langle I(x) \rangle = I_0 \exp\left[-x7/(9X_0)\right].$$
 (2)

Figure 15: Possible shower development induced by few MeV gamma, the energies of e^{\pm} , γ are given in keV. Following processes are indicated: A - conversion to e^+e^- pair, B - annihilation of e^+ into two gammas, C, D, F - Compton scattering, E, G - photoelectric effect [17].

The radiation length depends on the type of material, and can be expressed as [13]:

$$X_0 = \frac{716.4 \,\mathrm{gcm}^{-2} A}{Z(Z+1) \ln(287/\sqrt{Z})},\tag{3}$$

where Z - atomic number of the material, A - weight number of the material.

In case of compound material it can be approximated by:

$$1/X_0 = \sum w_j / X_j,\tag{4}$$

where w_j – fraction by weight of the j-th element, X_j – radiation length of the j-th element.

The critical energy E_c mentioned above is not so clear-cut defined. There are two definitions used Fig. 16:

• *critical energy* is the energy at which ionization energy loss of electron is equal energy loss by bremsstrahlung

$$\left. \frac{dE}{dx} \right|_{brems} = \left. \frac{dE}{dx} \right|_{ioniz} \tag{5}$$

Figure 16: Two definitions of the critical energy E_c [13].

• critical energy is the energy at which ionization energy loss equals electron energy E divided by radiation length X_0

$$\left. \frac{dE}{dx} \right|_{ioniz} = \frac{E}{X_0},\tag{6}$$

this is the same as the first definition Eq. 5 with approximation

$$\left. \frac{dE}{dx} \right|_{brems} \approx \frac{E}{X_0}.$$
(7)

As shown in Eq. 1 and Eq. 2 the scale for electromagnetic cascade developed by incident photon or electron is the same and is expressed by radiation length X_0 . So now we can describe in proper way the dimensions of the cascade.

The *mean longitudinal shower profiles* of energy deposits Fig. 17 are well described by a gamma distribution:

$$\frac{dE}{dt} = E_0 \frac{b^a t^{a-1} e^{-bt}}{\Gamma(a)},\tag{8}$$

where E_0 is the incident particle energy, a, b are parameters depending on the type of incident particle (e^{\pm}, γ) and t is depth in the material in terms

Figure 17: Longitudinal shower profiles simulated in PbWO₃ in dependence of the material thickness in radiation length, for e^- energy 1GeV, 10GeV, 100GeV, 1TeV from left to right [14].

of radiation length. The maximum of this distribution is located at $t_{max} = (a-1)/b$ which is usually estimated as:

$$t_{max} = \ln\left(\frac{E_0}{E_c}\right) + t_0,\tag{9}$$

where t_0 depends on type of the particle and is -0.5(0.5) for an electron(photon) induced cascade.(E_c is critical energy defined earlier.)

It can be seen in Eq. 9 that the expansion of the electromagnetic cascades is logarithmic and in consequence the detector thickness needed to absorb the energy scales the same way. The thickness that contains the 95% of the shower energy, for material with atomic number Z, can be derived as:

$$t_{95\%} = t_{max} + 0.08Z + 9.6. \tag{10}$$

The transverse development of the shower is mainly caused by multiple scattering of e^{\pm} away from the shower axis. Bremsstrahlung photons of these e^{\pm} also contribute to the cascade spread. The *transverse profile of the shower* is usually characterised by *the Moliére radius* R_M . Transverse size integrated over full shower depth, representing the mean lateral deflection of electrons after traversing one radiation length and it is expressed as:

$$R_M = E_s \frac{X_0}{E_c},\tag{11}$$

with E_s scale energy $\sqrt{4\pi/\alpha}m_ec^2 \approx 21$ MeV (here α Fine structure constant) and E_c critical energy from Eq. 6. On the average in a cylinder of $\sim 1R_M$ radius 90% of shower energy is contained. The transverse size of the electromagnetic shower is energy independent as can be seen on the Fig. 18.

3.2 The electromagnetic calorimeter itself

The principle of energy measurement with an electromagnetic calorimeter is that the energy deposited in calorimeter medium by charged particle of the cascade is proportional to the energy of the incident particle. Therefore the total track length of the cascade T_0 (sum of all ionization tracks in cascade) is proportional to

$$T_0 \sim X_0 \frac{E_0}{E_c},\tag{12}$$

where E_0/E_c – number of particles in the cascade. So the measurement of the signal produced by particles in the shower gives estimation of the incident particle energy.

🕅 Jagiellonian University

Figure 18: Transverse shower profiles simulated in PbWO₃ in dependence of the transverse distance from the shower axis in radiation length's for $e^$ energy 1 GeV(closed circles) and 1 TeV(open circles) [15].

As an example of the calorimeter let us consider the electromagnetic calorimeter of the WASA detector setup(section 2.2.3 on page 14). It is a scintillation calorimeter with inorganic CsI(Na) crystals. The mechanism of scintillation is related to the crystalic structure of the material. Charged particles are producing electron-hole pairs in the conduction and valence bands of the medium. When electrons return to the valence band the photons are emitted. The responce time and the wave length of the photons depends on the gap between the valence and conduction band and on the electron transport in the lattice structure. To increase the light yield and the response time crystals are usually doped with some amounts of inpurities, in our example Na, that create additional activation sites in gap between the bands thus increasing the probability of light emission.

So in this case the amount of light, emitted by scintillation process, induced by electromagnetic shower and collected by photomultiplier is proportional to the energy of incident particle.

The *energy resolution* of ideal calorimeter (infinite size, homogeneous response) is govern mainly by track length fluctuations. The shower development, as known, is a stochastic process, thus the energy resolution:

$$\sigma(E) \sim \sqrt{T_0},\tag{13}$$

using Eq. 12 we can derive:

$$\frac{\sigma(E)}{E} \sim \frac{1}{\sqrt{T_0}} \sim \frac{1}{\sqrt{E_0}}.$$
(14)

The energy resolution of a realistic calorimeter is not so simple defined. Usually it is written the following way:

$$\frac{\sigma(E)}{E} = \frac{a}{\sqrt{E}} \oplus \frac{b}{E} \oplus c, \qquad (15)$$

where \oplus – addition in quadrature.

The three terms in Eq. 15 contribute into resolution:

• the stochastic term a/\sqrt{E}

This term comes from the internal fluctuations of shower development, as described above. Typical values for this contribution are on the level of few percents.

• the noise term b/E

This term comes from electronic noise of readout chain and depends on features of the circuit. This contribution to energy resolution increase with decreasing energy and may be dominant for energies below few GeV.

🗴 Jagiellonian University
• the constant term c

This term includes effects that do not depend on the incident energy of the particle, such as instrumental effects like imperfection of mechanical structure, temperature gradients, detector aging, radiation damage etc. All these effects cause nonconformities of the response signal, thus smearing measured energy. Usually this term should be kept in orders of 1%.

Sample energy resolution curves fitted by Eq. 15 are presented in Fig. 19 for three different scintillator crystals. The parameters of fit are for CeF₃ a = 2.17%, c = 2.7%; for PbWO₄ a = 1.41%, c = 0.9% and for BaF₂ TAPS spectrometer a = 0.59%, c = 1.9%.

Figure 19: Energy resolution of CeF_3 and $PbWO_4$ crystals in comparison with BaF_2 scintillators of the TAPS spectrometer [16].

4 Measurements of the WASA calorimeter

The aim of these measurements was to check the Electromagnetic Calorimeter of WASA after the transport to IKP and to find broken elements as well as those with bad performance. In addition the test results will be used for the relative energy calibration of the CsI(Na) crystals. All channels were checked using source providing 4.4MeV photons (section 4.3). The results were then compared to cosmics measurements which have been performed for few channels (section 4.4).

4.1 Electronics setup

The electronics and readout system used for the test measurements is shown in Fig. 21. In all measurements only one crystal was readout at once. The signals from the crystal Fig. 22 were then amplified by a factor of 100 [ps 776] and split into two branches. One branch was used to construct the trigger: the signal was connected to the discriminator [LeCroy 821] in order to adjust the minimum signal level at which the signal should be sampled. The (logical) output of the discriminator was used to create a 12.2μ s long gate [dual timer C.A.E.N. N93B], which defines the time window, in which FlashADC samples the input signal. The second line from the amplifier was delayed by 600ns (in order to compensate the time for trigger generation and to start sampling well ahead of the signal). The used Flash ADC [SIS 3300] had a frequency of 100 MHz. After digitization the data were sent via crate controller to the computer by a special PCI card and read using data aquisition delivered by $ZEL^{1}(EMS \text{ system})$. The data were written to disk. During the measurements the spectra were monitored on-line using the RootSorter[20] analysis software.

4.2 General Analysis

4

The data were analysed event-by-event. For each sampled pulse Fig. 22 the zero level was computed as a mean value of first 30 channels and subtracted from the original signal. The integration gate was selected by comparing different spectra using various integration gates Fig. 23. The signal to back-ground ratio was taken into account as well as the resolution and the optimal gate was selected. The further analysis was then based on the calculation of the normalized integral within this gate (channel 30 to 200).

Figure 22: Sample CsI signal with subtracted ground level. The finally selected integration gate marked channel (30 - 200).

4.3 Source measurements

Figure 24: Gamma ray spectra of ²³⁹PuBe source (upper spectrum) and ²⁴¹AmBe source (lower spectrum) measured using Na(Tl) scintillator [9].

The measurements of individual crystals were done with ²⁴¹AmBe radioactive source, see Fig. 24, which emits 4.4MeV photons. The experimental setup is shown in Fig. 25 and Fig. 26. The source was pushed as close as possible to the surface of the CsI crystals. The electronics setup was as described in section 4.1. The data first were treated as explained in section 4.2, the spectrum Fig. 27 is a result of it. The analysis using ROOT[19] was performed, by fitting two functions to the spectra, one describing the background(as exponential) and one describing the signal(as a Gauss function). The exponential background is probably a consequence of electronic noise. Using this technique the peak position and the width of the signal was extracted from the data for each tested module. A typical spectrum with fitted background and signal function is shown in Fig. 28.

The peak position of the signal was plotted versus photomultiplier high voltage Fig. 29 to check working conditions. Corrections were applied to high voltage setting of the modules to adjust the gain to the same working level. In total around 100 channels were corrected, the resulting distribution is shown in Fig. 30. The full results from performed tests, for each channel, can be find in the Appendix A on page 59.

Figure 25: Setup for source measurements.

39

Figure 28: One fitted ADC spectrum.

Figure 29: Measured peak position of the crystals versus high voltage.

Figure 30: Measured peak position of the crystals versus high voltage after high voltage adjustment.

The peak width $\frac{\sigma}{mean} *100\%$ for measured crystals was also calculated and is presented in Fig. 31 as a histogram. The histogram is centered around the value of 15%. The peak width is a convolution of the experimental resolution as well the gamma spectrum distribution from used source Fig. 24. The extraction of real crystal resolution is hard to estimate, but the calculated value is quite satisfactory.

Figure 31: Histogram of measured width (in terms of σ) for different crystals.

4.4 Cosmics measurements

The source tests were supplemented by measuring the response for cosmic muons for a few modules. The electronics setup was the same as described in section 4.1. Five modules at diffrent azimuthal angles $(0^{\circ}, 45^{\circ}, 90^{\circ}, 135^{\circ}, 180^{\circ})$ have been selected Fig. 32. The data were analysed as described in section 4.2.

The GEANT3 based Wasa Monte-Carlo program was used to simulate the shape and the peak position of the energy deposits. Consequently, different geometries and sizes of the crystals were taken into account [21]. The muons were generated accordingly with a zenith angular distribution of $\cos^2(\phi)$ for $\phi = 0^{\circ} - 80^{\circ}$.

Figure 32: The positions of the tested crystals in the calorimeter.

The simulated spectra for the five different crystals are presented in Fig. 33. The change of the slopes of tails of distributions is expected and can be reproduced by the simulation. This effect is due to the angular orientation of the measured crystal: most of the cosmics are coming from $\phi = 0^{\circ}$, so for different orientations they penetrate different amount of material. The

Figure 33: Simulated Monte-Carlo spectra for cosmic muons in five different crystals.

Figure 34: Simulated Monte-Carlo spectra: upper picture shows crystals at angles of 0 and 180, the lower picture at angles of 45 and 135.

symmetry of the distributions should be visible between the crystals oriented opposite the 90° direction. The Fig. 34 shows simulated spectra for crystals oriented opposite to the 90° axis.

The comparison was done to check to what extent the source measurements can be used for calibrating the calorimeter. The measured spectra were calibrated using the peak position from source measurements (section 4.3) and compared to the simulated ones Fig. 35. As one can see, the peak position of the distributions differs: the calibration performed in such a way has a precision of about $\sim 10\%$. The explanation of this effect is as follows: The shower induced by 4.4MeV gammas has its maximum in the crystal at depth of ~ 3 cm. The crystals are ~ 30 cm long, so the scintillation light has to pass most of the crystal lenght, reflecting from the aluminized mylar foil wrapping and atenuating. In case of cosmic muons, the crystal is iluminated from all directions with different intensities, the cosmics are minimum ionizing particles. They penetrate the crystal loosing small amount of their energy. This is the reason of diffrences in peak positions. The precision of arrangement of the source in front of the crystal is also important.

The next step was to check the consistency of the data, to see the expected changes of the slope of the tails. The measured spectra were thus re-calibrated using the peak position from the Monte-Carlo simulation and compared accordingly Fig. 36. In order to see also the symmetry effect between the spectra for crystals oriented opposite the 90° direction, Fig. 37 was plotted. The distributions agree quite well.

To validate also the accuracy of the Monte-Carlo simulation predictions with the performed experiment, the data calibrated using simulation were plotted together with calculated Monte-Carlo spectra for five different crystals respectively Fig. 38, the normalization for peak position was applied for each. One can see the spectra are matching very good each other, the shape is described quite satisfactory, from the peak position up to the tails. The conclusion is that the performed Monte-Carlo simulation for the cosmic muons reproduces well the energy deposits in the CsI(Na) crystals.

5 Summary and conclusions

The tests of the electromagnetic calorimeter components (CsI(Na) crystals) for the WASA at COSY setup were performed. All available modules were tested to check their properties after transport. Scanning of the modules was performed with a radioactive source providing 4.4 MeV gammas. Some broken channels were found, fixed or replaced. The energy calibration constant was calculated for each crystal and the peak width for this energy was extracted (in average 15%). This width is a consequence of the experimental resolution as well the used gamma source spectrum.

Figure 39: Comparison between peak the positions measured in Uppsala and in Fz-Jülich.

Similar measurements with a source of the same type were done earlier at TSL in Uppsala before moving WASA to IKP at Fz-Jülich [22]. The comparison between the measured peak positions is presented in Fig. 39. In general, strong correlation between these two measurements is observed, but however, in few cases a discrepancy can be seen. The latter may be the result of changed optical contacts between the light guide and the photomultiplier as an effect of the transport. The data are consistent among the measurements, which proofs the same unchanged good quality of the components after the transfer from the CELSIUS ring to the new site.

In addition the task of investigating the energy calibration was done using cosmic muons (see section 4.4). The measured cosmic spectra were compared with the Monte-Carlo simulation. The experimental bias for calibration was determined from this comparison and estimated on the level of ~ 10%. The WASA calorimeter is in satisfactory condition, as it was in the TLS, and it is ready for mounting at the COSY ring and for commissioning in August. Fig. 40 shows the invariant mass of two gammas reconstructed in the electromagnetic calorimeter versus the missing mass of two protons extracted from the forward detector. As seen on the right, peaks of π and η mesons are identified with good energy resolution, which confirms the detection capabilities of WASA. The performed tests of calorimeter prove the feasibility of experiments planned for WASA at COSY starting at the beginning of 2007.

Figure 40: Left picture: Invariant mass of two gammas reconstructed in the calorimeter versus the missing mass of two protons extracted from the forward detector. Right picture: Invariant mass of two gammas with a cut on missing mass; pion end eta peaks are clearly separated [4].

Acknowledgements

Here I would like to thank all people that helped me to create this thesis and without whom it wouldn't have been possible. I am not able to express my gratitude with my English, I will try my best.

First of all I would like to thank my supervisor Dr. hab. Zbigniew Rudy for introducing me the secrets of data analysis and for time spent on discussions, his guidance was always present.

I am also gratefully to Dr. Volker Hejny, my tutor during the stay in Jülich, for showing me interesting aspects of calorimeter physics and for our fruitfull discussions and, of course, for new definition of common words. I would like to thank Volker as well for being the indispensable source of information concerning experimental physics. Thank You for patience!

I would like also to thank Prof. Hans Ströher for possibility of stay in Forschungszentrum-Jülich and for giving me the opportunity to work with WASA at COSY collaboration.

I am also very grateful to Prof. Reinhard Kulessa for allowing me to prepare this thesis in the Nuclear Physics Department of the Jagiellonian University.

I want to express my appreciation to Prof. Lucjan Jarczyk, Prof. Bogusław Kamys and Prof. Ewa Gudowska-Nowak for their support of my stay in Forschungszentrum.

I also thank all colleagues from WASA at COSY collaboration. It was a pleasure for me to work with You.

I thank my colleagues in IKP: Alexey Dzyuba, Dieter Oellers for the joy of daily work.

I thank also Pawel Podkopal and Michał Janusz for a great time outside the institute.

I also want to express my gratitude to my mother Aniela and father Gerard and brother Michał(Leniwiec) and the rest of my Family, especially granny Rozalia and aunt Bożena for their great love, delicious meals and support through five years of studies in Cracow. Thank You!
