Abstract

The opportunities of the application of the recently proposed approach in optical emission spectroscopy of non-equilibrium plasmas have been studied. The approach consists of several methods of the determination of *absolute* particle densities of atoms from measured *relative* intensities within resonance multiplets distorted by self-absorption. All available spectroscopic data concerning resonance spectral lines of atoms having multiplet ground states from boron up to gallium were analyzed. It is found that in the case of C, O, F, S and Cl atoms an application of the methods needs VUV technique, while densities of B, Al, Si, Sc, Ti, V, Co, Ni, Ga atoms may be obtained by means of the intensity measurements in UV and visible parts of emission spectra suitable for ordinary spectrometers used for optical diagnostics and monitoring of non-equilibrium plasmas including industrial plasma technologies.

The opportunities of the application of the recently proposed approach [1—3] in optical emission spectroscopy of non-equilibrium plasmas have been studied. The approach consists of several methods of the determination of absolute particle densities of atoms from measured relative intensities within resonance multiplets distorted by self-absorption. The main idea of the approach is that in the case of sufficient self-absorption for a pair of resonance lines having common upper level the ratio of intensities doesn't depend on the population density of upper level, but depends on the length of homogeneous plasma column along optical axis L , the gas temperature T , and populations of the sublevels of multiplet structure of the ground state. In the case of Boltzmann distribution over the sublevels with the temperature T , the intensity ratio depends on the temperature T and the product NL , where N is the total population of the ground state, usually close to the atomic particle density.

All available spectroscopic data concerning resonance spectral lines of atoms having multiplet ground states from Boron up to Gallium were analyzed (see Table 1). It is found that in the case of the C, O, F, S and Cl atoms an application of the methods needs VUV technique, while densities of the B, Al, Si, Sc, Ti, V, Co, Ni and Ga atoms may be obtained by means of the intensity measurements in UV and visible parts of emission spectrum suitable for ordinary middle class spectrometers used for optical diagnostics and monitoring of non-equilibrium plasmas including industrial plasma technologies. All spectroscopic data needed for experimental determination of particle density of the B, Al, Si, Sc, Ti, V, Co, Ni and Ga atoms in ionized gases and plasma are presented in the Table 2, where the λ_{ik} – is the wavelength of a spectral line in Angstroms, the ν_{ki} – its wavenumber in cm^{-1} , the E_i is energy of lower level of the line in cm^{-1} , the g_k and g_i are degeneracies of upper and lower levels, and the A_{ki} is spontaneous emission transition probability (Einstein coefficient) in 10^6s^{-1} .

The data collected in the Table 2 may be also used for computer modelling calculations of the intensity ratios as functions of the optical thickness NL and the gas temperature T (determining line broadening) under certain assumptions on the population density distribution over ground state sublevels. In the case of Boltzmann distribution corresponding to the gas temperature such calculations give the opportunity to obtain certain three dimensional nomogramms (the intensity ratio against NL and T) useful for *a priori* analysis of an applicability of the method in certain experimental conditions like in [3], as well as for simple, graphical determination of the atomic densities from measured relative line intensities like in [1].
