#### Abstract

We present a fibre-optical quantum key distribution system. It works at 1550nm and is based on the plug&play setup. We tested the stability under field conditions using aerial and terrestrial cables and performed a key exchange over 67 km between Geneva and Lausanne.

### I Introduction

Quantum cryptography or, more exactly, quantum key distribution (QKD) is the most advanced subject in the field of quantum information technologies. Since the introduction of the BB84 protocol by Bennett and Brassard in 1984 [1] and their first implementation in 1992[2], many experiments have been performed by numerous groups (see e.g. [3] for a review). However, to our knowledge, all experiments to date were performed in laboratories or used laboratory equipment (e.g. liquid nitrogen cooled the detectors) or needed frequent alignments (e.g. control of polarisation or phase). In this paper, we present a turn-key, fibre-optic QKD-prototype that fits into two 19" boxes, one for Alice and one for Bob (see Fig.1). We tested the stability of the auto-compensating plug&play system [4] over installed terrestrial and aerial cables. Keys were exchanged over a distance of 67 km.

We start with a short introduction to the plug&play auto-compensating setup, before describing the features of the prototype. We then recall the relevant parameters of a QKD system and shortly discuss some security issues. Finally the results of the field tests are presented.

# II Plug&Play Prototype

Let's recall the principle of the so called plug&play auto-compensating setup [4, 5, 6, 7, 8], where the key is encoded in the phase between two pulses travelling from Bob to Alice and back (see Fig. 2). A strong laser pulse (@1550 nm) emitted at Bob is separated at a first 50/50 beamsplitter (BS). The two pulses impinge on the input ports of a polarisation beamsplitter (PBS), after having travelled through a short arm and a long arm, including a phase modulator (PM<sub>B</sub>) and a 50 ns delay line (DL), respectively. All fibres and optical elements at Bob are polarisation maintaining. The linear polarisation is turned by 90 degrees in the short arm, therefore the two pulses exit Bob's setup by the same port of the PBS. The pulses travel down to Alice, are reflected on a Faraday-mirror, attenuated and come back orthogonally polarized. In turn, both pulses now take the other path at Bob and arrive at the same time at the BS where they interfere. Then, they are detected either in D<sub>1</sub>, or after passing through the circulator (C) in D<sub>2</sub>. Since the two pulses take the same path, inside Bob in reversed order, this interferometer is auto-compensated. To implement the BB84 protocol, Alice applies a phase shift of 0 or  $\pi$  and  $\frac{\pi}{2}$  or  $\frac{3\pi}{2}$  on the second pulse with PM<sub>A</sub>. Bob chooses the measurement basis by applying a 0 or  $\frac{\pi}{2}$  shift on the first pulse on its way back.

The prototype is easy to use. The two boxes just have to be connected via an optical fibre. They are exclusively driven by two computers via the USB port. The two computers communicate via a ethernet/internet link. The system monitors on-line the temperature of the detectors, radiators and cases. The photon counters are Peltier-cooled, actively gated, InGaAs/InP APD's [9]. The darkcount noise of the detectors is measured during the initialization (the darkcount probability  $p_{dark}$  is  $\approx 10^{-5}$  per gate). Although the setup needs no optical alignment, the phases and the detection gates must be applied at the right time. Therefore, the system measures in a next step the length of the link (the operator has only to estimate the line's length at more or less 5 km). The variable attenuator (VA) at Alice is set to a low level and bright laser pulses are emitted by Bob. The time delay between the triggering of the laser and a train of gates of the detectors is scanned until the reflected pulses are detected. The delays for the two 2.5 ns detection gates are adjusted, as well as the timing for the 50 ns pulse applied on the phasemodulator PM<sub>B</sub>. In the plug&play scheme, where pulses travel back and forth, (Rayleigh) backscattered light can considerably increase the noise. Therefore, the laser is not continuously pulsed, but trains of pulses are sent, the length of these trains corresponding to the length of the storage-line introduced for this purpose behind the attenuator at Alice's [5]. Consequently, the backward propagating pulses do no longer cross bright pulses in the fibre. For a storage line measuring approximately 10 km, a pulse train contains 480 pulses at a frequency of 5 MHz. A 90% coupler (BS<sub>10/90</sub>) directs most of the incoming light pulses to a APD-detector module  $(D_A)$ . It generates the trigger signal used to synchronise Alice's 20 Mhz clock with the one of Bob. This synchronized clock allows Alice to apply a 50 ns pulse at the phasemodulator  $PM_A$  exactly when the second, weaker pulse passes. Only this second pulse contains phase information and must be attenuated below the one-photon-per-pulse level. Measuring the height of the incoming pulses with  $D_A$  would allow to adjust the attenuator in order to obtain the right average number of photons per outgoing pulse. For this purpose, the attenuator and the detector must be calibrated beforehand. In practice, we measure the incoming power with a power-metre. Random numbers are generated on both sides with a quantum random number generator [10]. At Bob, clicks from each of the photon counters are written together with the index of the pulse into a buffer and transferred to the computer.

As a measure of security, the number of coincident clicks at both detectors is registered, which is important to limit beamsplitting attacks (see below). Morover, the incoming power at Alice is continuously measured with  $D_A$ , in order to detect so called Trojan horse attacks.

## III Key parameters in QKD

#### III.1 Key and error rates

The first important parameter is the raw key rate  $R_{raw}$  between Alice, the transmitter, and Bob, the receiver:

$$R_{raw} = q\nu\mu t_{AB}t_{B}\eta_{B} \tag{1}$$

where q depends on the implementation ( $\frac{1}{2}$  for BB84 protocol, because half the time Alice and Bob bases are not compatible),  $\nu$  is the repetition frequency,  $\mu$  is the average number of photons per pulse,  $t_{AB}$  is the transmission on the line Alice-Bob,  $t_B$  is Bob's internal transmission ( $t_B \approx 0.6$ ) and  $\eta_B$  is Bob's detection efficiency ( $\eta_B \approx 0.1$ ).

After  $R_{raw}$  the second most important parameter is the quantum bit error rate (QBER) which consists of four major contributions:

$$QBER = \frac{false\ counts}{total\ counts} = QBER_{opt} + QBER_{dark} + QBER_{after} + QBER_{stray}$$
 (2)

 $QBER_{opt}$  is simply the probability for a photon to hit the false detector. It can be measured with strong pulses, by always applying the same phases and measuring the ratio of the count rates at the two detectors. This is a measure of the quality of the optical alignment of the polarisation maintaining components and the stability of the fibre link. In the ideal case,  $QBER_{opt}$  is independent of the fibre length.  $QBER_{dark}$ 

and  $QBER_{after}$ , the errors due to darkcounts and afterpulses, depend on the characteristics of the photon counters[9].  $QBER_{dark}$  is the most important, it is the probability to have a darkcount per gate  $p_{dark}$ , divided by the probability to have a click  $p_{det}$ .

$$QBER_{dark} \cong \frac{p_{dark}}{\mu t_{AB} t_{B} \eta_{B}}$$

 $QBER_{dark}$  increases with the distance and consequently limits the range of QKD.  $QBER_{after}$  is the probability to have an after pulse  $p_{after}(t)$  summed over all gates between to detections:

$$QBER_{after} \cong \sum_{n=0}^{n=\frac{1}{p_{det}}} p_{after} \left(\tau + n\frac{1}{\nu}\right)$$
 (3)

 $p_{after}$ , depending on the type of APD and on the temperature, decreases rapidly with time[9]. Nevertheless for high pulse rates ( $\nu = 5$  MHz)  $QBER_{after}$  can become significant. For instance, for  $p_{det} = 0.15\%$  (corresponding to about 7 dB loss with  $\mu = 0.1$ ) we measured a  $QBER_{after}$  of about 4%. By introducing a dead time  $\tau$  of 4  $\mu$ s (during this time, following a detection, no gates are applied),  $QBER_{after}$  can be reduced to 1.5%. The bit rate  $R_{raw}$  on the contrary, is only slightly reduced by a factor  $\eta_{\tau}$ :

$$\eta_{\tau} = \frac{1}{1 + \nu p_{det} \tau} \lessapprox 1 \tag{4}$$

In this example,  $\eta_{\tau}$  becomes 0.97 and 0.92, for 4 and 12  $\mu s$ , respectively. In our prototype the deadtime can be varied between 0 and 12  $\mu s$ . The optimum deadtime varies as a function of distance, in our measurements, however, we applied a constant deadtime of 4  $\mu s$ . Finally,  $QBER_{stray}$ , the errors induced by stray-light, essentially Rayleigh back-scattered light, is a problem proper to the plug&play setup. It can be almost completely removed with the help of Alice's storage line and by sending trains of pulses as mentioned above. However, we have to introduce another factor  $\eta_{duty}$  that reduces our bit rate. It gives the duty cycle of the emitted pulse-trains and depends on the length of Alice's delay line  $l_D$  and the length of the fibre link  $l_{AB}$ :

$$\eta_{duty} = \frac{l_D}{l_{AB} + l_D} \tag{5}$$

Hence with our prototype we can expect a raw rate of  $R_{raw}$  of about:

$$R_{raw} = q\nu\mu t_{AB}t_{B}\eta_{B}\eta_{duty}\eta_{\tau} \approx 140kHz\left(\mu t_{AB}\frac{l_{D}}{l_{AB} + l_{D}}\right)$$

$$\tag{6}$$

#### III.2 Error correction, privacy amplification and eavesdropping

The net secret key rate is further reduced during the error correction and privacy amplification process by a factor of  $\eta_{dist}$ . We didn't implement error correction and privacy amplification for our field tests, but we would like to estimate roughly the net key rate that could be obtained with our system. In theory,  $\eta_{dist}$  is simply given as the difference between the mutal information of Alice and Bob,  $I_{AB}$ , and Alice and Eve,  $I_{AE}[3]$ :

$$\eta_{dist} = I_{AB}(D) - I_{AE} \tag{7}$$

Due to the errors,  $I_{AB}$  is smaller than 1. It is a function of the disturbance D, which is equal to the total QBER:

$$I_{AB} = 1 + Dlog_2D + (1 - D)log_2(1 - D)$$
(8)

In the following we estimate the information of Eve,  $I_{AE}$ . In the line of Felix et.al. [11] we make the following assumptions:

- The measured QBER should, within the statistical limits, be equal to what is estimated according eq.2. If this is not the case, a real user won't proceed and blindly apply privacy amplification, he will stop

the key exchange and look for the problem. If the QBER is within these limits, we attribute to Eve the  $QBER_{opt}$  ( $\lesssim 0.5\%$ ) plus the error ( $2\sigma$ ) of the error estimation ( $\lesssim 0.5\%$  for reasonably long keys), say 1% in total. In the case of perfect equipment of the eavesdropper and true single photon source this error corresponds to an information of  $\frac{2}{\ln 2}1\% \cong 3\%[13]$ .

- In the case of faint laser pulses and especially in the presence of high fibre losses, Eve can take advantage of multi-photon pulses and gain information while creating less or no errors[11]. In this case, it is important to measure the length of the line and to register coincident clicks at Bob's two detectors in order to limit Eve's possibilities. We assume that Eve possesses perfect technology, but cannot efficiently measure the number of photons without disturbing them and cannot store them. Further, she disposes of fibers with losses as low as  $0.15 \, \mathrm{dB/km}$ . Under these assumptions one can calculate Eve's information per bit due to multi-photon pulses  $I_{2\nu}$  and obtains about 0.06, 0.14 and 0.40 for, 5, 10 and 20 dB loss, respectively (for  $\mu = 0.2$ ,  $0.25 \, \mathrm{dB/km}$  fiber loss and  $10^8$  pulses sent). Consequently, we obtain

$$I_{AE} \cong 0.03 + I_{2\nu} \tag{9}$$

With equations 7,8 and 9 we can caluclate a theoretical value of  $\eta_{dist}$ . In practice,  $\eta_{dist}$  will be smaller due to the limitations of the used algorithm. Privacy amplification can be performed without additional bit loss in contrary to error correction. For our estimation, we use the results of Tancewsky et al [12] for  $I'_{AB}$  after error correction

$$I'_{AB} = 1 + Dlog_2 D - \frac{7}{2}D \tag{10}$$

which is in fact considerably smaller than  $I_{AB}$ . The information of Eve  $I_{AE}$  is reduced by the same factor  $\frac{I'_{AB}}{I_{AB}}$ , too. Finally, we obtain the following estimation of  $R_{net}$ :

$$R_{net} = \eta_{dist} R_{raw} \cong (I_{AB} - I_{AE}) \frac{I'_{AB}}{I_{AB}} R_{raw}$$

$$\tag{11}$$

$$\approx \left[1 + Dlog_2D - \frac{7}{2}D - (0.03 + I_{2\nu})(1 - (1 - D)log_2(1 - D) - \frac{7}{2}D)\right]R_{raw}$$
 (12)

### IV Field measurements

#### IV.1 Visibilities

In principle the prototype can be tested in the lab by performing key exchange with different fibre losses and compare the measured QBER and bit rates with the estimated values according to the simple formulas developed above. There are two motivations for field tests on installed cables. The first reason is to check, if the auto-compensating setup is robust in many different situations. Several effects could reduce the visibility of the interference. First, we have previously shown that Faraday rotation due to the earth magnetic field cannot considerably decrease the visibility [14]. Second, the time delay between the two pulses, travelling back and forth between Alice and Bob, could change due to a temperature drift. Let's assume that the temperature of the fiber increases with a rate  $\theta\left[\frac{K}{h}\right]$ . The time delay  $\Delta t$  between the two pulses is 54ns. If  $\theta$  is constant for the whole trip of the pulses, the second pulse will see a fibre that is longer by  $\Delta l$ :

$$\frac{\Delta l}{l} = \alpha \Delta T \tag{13}$$

$$\Delta l = \alpha 2 l_{AB} \Delta T = \alpha 2 l_{AB} \theta \Delta t \tag{14}$$

With  $\alpha = 10^{-5} \left[ \frac{1}{K} \right]$ ,  $l_{AB} = 50 km$ ,  $\theta = 10 \left[ \frac{K}{h} \right]$  we obtain  $150 pm \ll \lambda$ . Hence this effect should be negligable especially since installed fibres have slow temperature drifts. On the contrary, slow temperature induced length drifts can be large enough that frequent readjustment of Bob's delay become necessary. In fact, we noticed that during the heating up of Alice's box within the first hour of operation, the changes in the delay line require a recalibration every 10 minutes or so. However, a bad synchronisation of the

detection window does not affect  $QBER_{opt}$ . Finally, mechanical stress could change the fiber length and/or birefringence. If the birefringence changes rapidly, the pulses are no longer orthogonally polarized at the input of Bob, despite the Faraday mirror. In this case the two pulses might suffer different losses at Bob's polarizing beamsplitter and the interference will no longer be perfect. Rapid changes in stress are unlikely in installed cables, a couple of meters below the surface. For this reason we tested the prototype also over an aerial cable. We had at our disposition two fibres of 4.35 km length, whereof 2.5 km in an aerial cable. In order to amplify a hypothetical effect we put Alice and Bob side by side and passed twice through the cable (config. A). In configuration B we inserted 1 spool of about 15 km at the other end of the cable. Hence, the pulses made the following trip: Bob, the aerial cable, 15 km spool, the aerial cable, 15 km Alice with her 10 km storage line and back.

To measure the visibilities we send relatively strong pulses (a couple of photons per pulse) with always the same, compatible phase values and look at the counts on the two detectors,  $R_{right}$  and  $R_{wrong}$  (substracting the counts due to detector noise). We obtain then the fringe visibility according to the standard definition:

$$V = \frac{R_{right} - R_{wrong}}{R_{right} + R_{wrong}} \tag{15}$$

and the corresponding  $QBER_{opt}$ :

$$QBER_{opt} = \frac{1 - V}{2} \tag{16}$$

Table 1 summerises the result of visibility measurements over different cables. The indicated visibilities are the mean values over all four possible compatible phase settings. There was no considerable decrease of the visibility in any fibre, hence the auto-compensating interferometers worked well under all tested conditions.

fibre	length [km]	loss [dB]	Visibility [%]
Geneva-Nyon (under lake)	22.0	4.8	$99.70 \pm 0.03$
Geneva-Nyon (terrestrial)	22.6	7.4	$99.81 \pm 0.03$
Nyon-Lausanne (terrestrial)	37.8	10.6	$99.63 \pm 0.05$
Geneva-Lausanne (under lake) A	67.1	14.4	$99.62 \pm 0.06$
Geneva-Lausanne (under lake) B	67.1	14.3	$99.66 \pm 0.05$
Ste Croix (aerial) A	8.7	3.8	$99.70 \pm 0.01$
Ste Croix (aerial) B	23.7	7.2	$99.71 \pm 0.01$

Table 1: Visibility measurements on different fibres

We tried to simulate an extremely unstable fibre link in the lab. For this purpose, we put a fibre-optical polarisation scrambler (GAP-optique) at the output of Bob followed by 25 km of fibre. We measured the visibility as function of the scrambler frequency. This frequency is defined as the number of complete circles that the vector of polarisation would describe per second on the Poincaré sphere, if the birefringence changed uniformly. The visibility drops from 99.7% to 99.5% and 98% at frequencies of 40 Hz and 100 Hz respectively. This shows that the visibilities can decrease under rapid perturbations, however, it's unlikely to find such conditions using installed fibres.

#### IV.2 Key exchange

We performed key exchange over different installed cables, the longest connecting the cities of Lausanne and Geneva (see Fig.3). We used always the same file of random numbers, in a way that Bob could make the sifting and calculation of error rate without communication. We estimated the net key rate using equation (11). Table 2 gives an overview of the exchanged keys with  $\mu = 0.2$ .

fibre	length [km]	Key [kbit]	$R_{raw}[kHz]$	QBER [%]	$R_{net}[kHz]$
Geneva-Nyon (under lake)	22.0	27.9	2.06	$2.0\pm0.1$	1.51
Geneva-Nyon (terrestrial)	22.6	27.5	2.02	$2.1 \pm 0.1$	1.39
Nyon-Lausanne (terrestrial)	37.8	25.1	0.50	$3.9 \pm 0.2$	0.26
Geneva-Lausanne (under lake) A	67.1	12.9	0.15	$6.1 \pm 0.4$	0.044
Geneva-Lausanne (under lake) B	67.1	12.9	0.16	$5.6 \pm 0.3$	0.051
Ste Croix (aerial) A	8.7	63.8	6.29	$3.0 \pm 0.1$	4.34
Ste Croix (aerial) B	23.7	117.6	2.32	$3.0\pm0.1$	1.57

Table 2: Overview of exchanged keys over different fibres ( $\mu = 0.2$ ).

We notice that secure key exchange is possible over more than 60 km with about 50 Hz of net key rate.

## Conclusion

We presented a QKD prototype, which can be simply plugged into the wall, connected to a standard optical fibre and a computer via the USB port. It allows key exchange over more than 60 km, with a net key rate of about 60 bits per second. The system is commercially available [15].
