A method of synthesizing localized optical fields with zeroes on a periodic lattice is analyzed. The applicability to addressing atoms trapped in optical lattices with low crosstalk is discussed.

There is much current interest in using atoms trapped in optical lattices for quantum logic devices[1, 2]. One of the challenges in implementing this scheme is posed by the need to address individual atoms with near resonant light. Current estimates of error limits for scalable quantum computing require primitive logic operations with errors as low as[3, 4] $O(10^{-5} - 10^{-6})$. The corresponding limitation on optical crosstalk when addressing one atom in a lattice can only be quantified in the context of a particular choice of quantum gate. In atomic schemes error rates for operations that are dependent on single photon processes tend to scale with the intensity. This implies that the intensity leakage of a logical control or state readout beam at a site adjacent to a site being addressed should not exceed $O(10^{-5})$. In this letter I describe a novel approach to image formation that allows sites in an optical lattice to be addressed with minimal crosstalk.

In order to emphasize the difficulty of achieving low crosstalk in optical lattices consider the following simple scaling relationships. We have a 1- or 2-D lattice lying in the $x - y$ plane that is defined by counterpropagating beams at wavelength λ_f . Individual atoms are separated by a minimum distance of $d = \lambda_f/2$ and we wish to address them with near-resonant light of wavelength λ . The most obvious approach to doing so involves focusing a beam propagating perpendicular to the plane of the lattice (along \hat{z}) to a small spot. Assuming a Gaussian beam profile the intensity distribution is $I(\rho, z) = I_0 \exp(-2\rho^2/w^2)$ where $\rho^2 = x^2 + y^2$, $w^2(z) = w_0^2(1 + z^2/z_R^2)$, w_0 is the beam waist at $z = 0$, and $z_R = \pi w_0^2/\lambda$. Expressing the ratio of the intensity at a neighboring site to the on-site intensity as ϵ implies a beam waist $w_0 = \sqrt{-1/(2 \ln \epsilon)} \lambda_f$. For $\epsilon = 10^{-5}$ this evaluates to $\tilde{w}_0 = w_0/\lambda_f = 0.21$.

We can quantify the corresponding requirement on the ratio of trapping and addressing beam wavelengths in terms of the performance of high numerical aperture lenses. We assume a lens system with aperture diameter D is used to focus the addressing light. If the ratio of the lens aperture to the Gaussian waist at the aperture is given by $p = D/w(z_{\text{lens}})$ then a focal plane waist of w_0 implies $D \simeq p w_0 z_{\text{lens}}/z_R$.

FIG. 1: Lens numerical aperture needed to focus a Gaussian beam to a waist \tilde{w}_0 for $\lambda_f/\lambda = 1, 2$, and 10.

A reasonable minimum requirement on p to avoid rings surrounding the focal plane image is that the fraction of the optical power blocked by the aperture should not exceed the desired intensity ratio ϵ by more than a few times. Using an optimistic value of $p = 3$ gives approximately 1% transmission loss at the lens and a numerical aperture of

$$NA = \frac{\left(\frac{3}{2\pi\tilde{w}_0} \frac{\lambda}{\lambda_f}\right)}{\left[1 + \left(\frac{3}{2\pi\tilde{w}_0} \frac{\lambda}{\lambda_f}\right)^2\right]^{1/2}}. \quad (1)$$

The variation of the lens NA with \tilde{w}_0 is shown in Fig. 1. Available microscope objectives, as well as high resolution optical lithography lens systems, tend to have numerical apertures not more than ~ 0.8 unless oil immersion is used which is not compatible with atomic imaging inside vacuum chambers. This implies that the lattice light wavelength λ_f must be several times longer than the addressing wavelength λ in order to address single atoms with negligible leakage to neighboring sites. Thus a lattice of Rb atoms which can be manipulated with light near resonant with the D2 line at $\lambda = 0.78 \mu\text{m}$ will not be individually resolvable in the context of scalable quantum logic unless $\lambda_f \gtrsim 1.5 \mu\text{m}$.

Various solutions to the addressability problem are under study. The most direct solution is to make $\lambda_f \gg \lambda$. Arrays of widely spaced traps that use many diffractively generated beams[5] instead of lattices also fall into this category of solu-

tion. Unfortunately this is not compatible with loading from a Bose Einstein condensate via the Mott transition[6], although other loading schemes may still be used[7, 8]. Another possibility is to keep $\lambda \sim \lambda_f$ but load the lattice so that only every few lattice sites are occupied, or change the angle between the lattice beams after loading so that a longer periodicity is obtained[9, 10].

Here we analyze an alternative approach to single atom addressing in optical lattices with $\lambda \sim \lambda_f$. The idea is to accept the fact that the light cannot be localized sufficiently well, but tailor the beam profile so that the field has zeroes at neighboring lattice sites. The basic geometry is sketched in Fig. 2. N beams, each with a phase controlled by a spatial light modulator pixel, propagate in the xy plane and are aligned to converge on the origin at $x = y = 0$. The beams necessary for creating the optical lattice can in principle be combined with the imaging beams using dichroic mirrors. Each converging plane wave is polarized along \hat{z} with amplitude $A_j \exp[i(-\mathbf{k}_j \cdot \boldsymbol{\rho} - \omega t + \chi_j)] + c.c.$, where $\mathbf{k}_j = k(\cos \phi_j \hat{x} + \sin \phi_j \hat{y})$, $k = 2\pi/\lambda$, ϕ_j is the azimuthal angle of wave j , and A_j , χ_j are adjustable amplitudes and phases. As shown in the figure this can be achieved using a single one-dimensional modulator with N pixels and a system of mirrors and lenses. In the limit when $N \rightarrow \infty$ and the beam amplitudes and phases are all equal the field amplitude generated on axis is just the zero order Bessel beam $J_0(k\rho)$.

When the field is synthesized from a finite number N of plane waves it is quasiperiodic in space, and rings of secondary interference maxima occur as can be seen in Fig. 2. The diameter of the secondary rings can be estimated from $\Delta k d_{\text{ring}} \simeq 2\pi$. Using $\Delta k = 2k/(N/2)$ gives $d_{\text{ring}} \simeq N\lambda/4$, while the actual diameter found numerically is some 25% larger. Recalling the shift theorem of Fourier analysis it is straightforward to scan the spot location over a distance of up to d_{ring} by adding appropriate phase offsets to the incident beams, as is shown in Fig. 2. It is possible in this way to address hundreds of atoms using a multipixel modulator, without mechanical motion of the optical system. This approach to synthesis and scanning of localized optical fields also finds application in atomic lithography[11].

A Bessel beam written in this way with $\lambda = 0.78 \mu\text{m}$ has a central lobe with $1/e^2$ intensity radius of $0.22 \mu\text{m}$. However the closely spaced secondary maxima of the Bessel function give crosstalk on nearby lattice sites. We describe now a method of synthesizing a beam with zeroes at regularly spaced

sites of a one-dimensional lattice. An arbitrary solution of the two-dimensional Helmholtz equation can

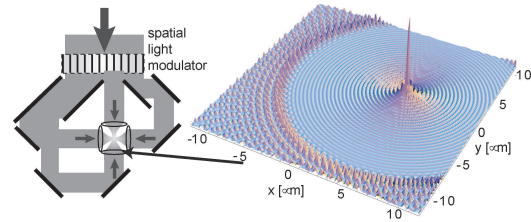

FIG. 2: Optical layout for writing a Bessel beam. The intensity distribution was calculated with $N = 100$ and $\lambda = 0.78 \mu\text{m}$. The central lobe was translated by $\Delta x = 4 \mu\text{m}$ and $\Delta y = 2 \mu\text{m}$ by adding phase offsets, see the text for details.

be written as a Fourier-Bessel series

$$A(\rho, \theta) = J_0(k\rho) + \sum_{n=1}^{\infty} a_n J_n(k\rho) \exp[in\theta] \quad (2)$$

with the a_n complex coefficients to be determined. We have set the zero order coefficient to unity corresponding to a normalized field with unit amplitude at the origin. Any field of the form (2) can be synthesized with an amplitude and phase modulator in the geometry of Fig. 2. To make this explicit we note that the Fourier transform of (2) is

$$\begin{aligned} \tilde{A}(q, \phi) &= \int_0^{\infty} d\rho \rho \int_0^{2\pi} d\theta A(\rho, \theta) \exp[i\rho q \cos(\theta - \phi)] \\ &= \frac{2\pi}{k} \delta(q - k) \left(1 + \sum_{n=1}^{\infty} a_n i^n \exp[in\phi] \right). \end{aligned} \quad (3)$$

Thus a ring of converging plane waves with wavenumber k and complex amplitudes given by the term in parentheses in (3) provides the desired field. The role of the lenses shown in Fig. 2 is to tilt the wave passing through each spatial light modulator pixel towards the center of the image region, but the lenses do not tightly focus each wave. Outside of the central spot destructive interference leads to a low background light level. From the point of view of Fourier optics focusing of a beam results from interference of the constituent plane wave components, taking into account relative phase shifts due to propagation. The usefulness of the approach to image synthesis presented here is that we can directly control the amplitudes and phases of each of the plane wave components.

$M =$	1	2	3	4	5	6

$\max A ^2$	3.0×10^{-3}	6.1×10^{-4}	1.9×10^{-4}	7.1×10^{-5}	3.6×10^{-5}	3.3×10^{-5}
m_{\max}	4	8	11	14	19	28
14 bit $ A ^2$	2.9×10^{-3}	6.1×10^{-4}	2.0×10^{-4}	9.3×10^{-5}	7.9×10^{-5}	7.7×10^{-5}

TABLE I: Bessel coefficients and resulting maximum crosstalk which occurs at site m_{\max} away from the origin for $\lambda = 0.78 \mu\text{m}$ and $\lambda_f = 0.8 \mu\text{m}$. The last row shows the maximum error in the first 50 neighboring sites using expansion (3) with $N = 256$.

A field consisting of a finite number of terms in (2) that is useful for addressing a one-dimensional lattice along \hat{x} will have $A(\rho, 0) = A(\rho, \pi)$ which implies that $a_n = 0$ for n odd. Requiring that A vanish at the M lattice points specified by $\rho_m = m\lambda_f/2$, $\theta_m = 0$, for $m = 1 \dots M$ and limiting the sum in (2) to M terms gives M linearly independent equations $J_0(k\rho_m) + \sum_{n=1}^M a_{2n} J_{2n}(k\rho_m) = 0$. These equations are easily solved for the coefficients a_{2n} . The coefficients decrease rapidly with Bessel order provided λ_f is not too much less than λ . The series coefficients, and maximum intensity crosstalk at any site not being addressed are listed in Table I. We see that $M = 6$ is sufficient to ensure a crosstalk of a few times 10^{-5} . In an actual implementation there are several limiting factors to consider including the number of spatial light modulator pixels, and the amplitude and phase resolution of each one. The last row in Table I shows the crosstalk is up to sev-

eral times higher than the theoretical value if we assume the field is synthesized from 256 beams equally spaced azimuthally, with 14 bit resolution in amplitude and phase modulation for each beam. Additional calculations with $\lambda_f = 1.0 \mu\text{m}$ give crosstalk levels roughly 10 times lower than the example in Table I.

In summary we have described a novel method of addressing atoms in periodic 1-D lattices with low crosstalk. The extension of this approach to a 2-D lattice is complicated by the fact that a 2-D lattice has angle dependent interatomic spacings. The Fourier-Bessel expansion (2) can still be used, but the coefficients tend to grow rapidly with n . Generalizations that are suitable for a 2-D geometry are currently under investigation.
